DNA sequences displaying apparent curvature have been found at both the site of integration[1] and the origin of replication[4] of bacteriophage λ as well as in regions of conserved sequence in trypanosomatid kinetoplast DNA[7]. Disruption of a region of curvature upstream from the histidine transfer RNA gene in *Salmonella* appears to be associated with down-regulation of $tRNA^{His}$ transcription[3]. However, the functional significance of curvature *per se* remains obscure, as does its molecular origin.

Marini *et al.*[12] invoked the notion of non-coplanarity of APA/TpT dinucleotide pairs, proposed earlier by Trifonov and Sussman[11], as a possible basis for the observed curvature. Other workers[4,13,14] have attempted to provide a quantitative relationship between the hypothetical ApA wedge angle and the overall curvature of the helix axis. We have therefore attempted to test the hypothesis that an inherent non-coplanarity of ApA/TpT dinucleotide residues determines the contour of the helix axis in solution. In testing this hypothesis, one can invoke the following simple symmetry argument: for curvature arising solely from ApA wedges, the angle-of-transit of the helix axis through the sequence $5'\text{-}A_nT_n\text{-}3'$ (one strand shown) will be equivalent to the corresponding angle-of-transit through $5'\text{-}T_nA_n\text{-}3'$. Should the angles-of-transit through these two sequences prove to be different, one cannot relate apparent curvatures (for example based on gel mobilities) to ApA dinucleotide non-coplanarity. We have shown recently[10] that certain DNA oligomeric

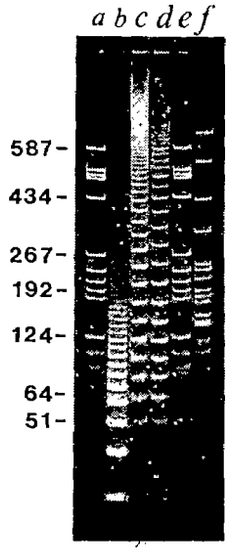

Fig. 1 Demonstration of the anomalous electrophoretic behaviour of certain repeating-block copolymers of DNA. Lane *b* contains polymers of the form $[G_3TCGAC_3]_N$ where $2 < N < 25$. The electrophoretic mobilities of all members of this set are normal *c*, $[G_2A_3T_3C_2]_N$; *d*, $[GA_4T_4C]_N$. The members of the latter two series show distinctly abnormal electrophoretic mobilities for $N > 5$. Lanes *a* and *e* contain DNA molecules derived from pBR322 by *Hae*III digestion; *f*, *Hpa*II digest of pBR322.

Methods. Representative fragment sizes are specified to the left of the gel. All gels used for this study were 12% polyacrylamide (37:1 monomer/bis) and were run at 24±2 °C (running buffer: 40 mM Tris-acetate, 20 mM sodium acetate, 1 mM Na-EDTA, *p*H 7.9). Polymers of varying *N* were constructed from synthetic decamers by phosphorylation and subsequent ligation (with T_4 DNA ligase in 0.5 mM ATP, 50 mM Tris-HCl, 10 mM $MgCl_2$ *p*H 8.0, at 12–15 °C). Ligase concentrations and reaction times were varied in order to produce informative gels; the gel patterns do not represent maximum extents of polymerization. Ligation reactions were stopped by adding Na-EDTA to a final concentration of 20 mM, followed by extraction with phenol/ether. Oligodeoxynucleotides were synthesized manually using the phosphite triester chemistry of Caruthers[15,16]. Oligomer sequences were verified by (1) using the chemical sequencing technique of Maxam and Gilbert[17], with minor modifications for short oligomers, and (2) complete digestion of the polymerized decamers with the appropriate restriction endonucleases.

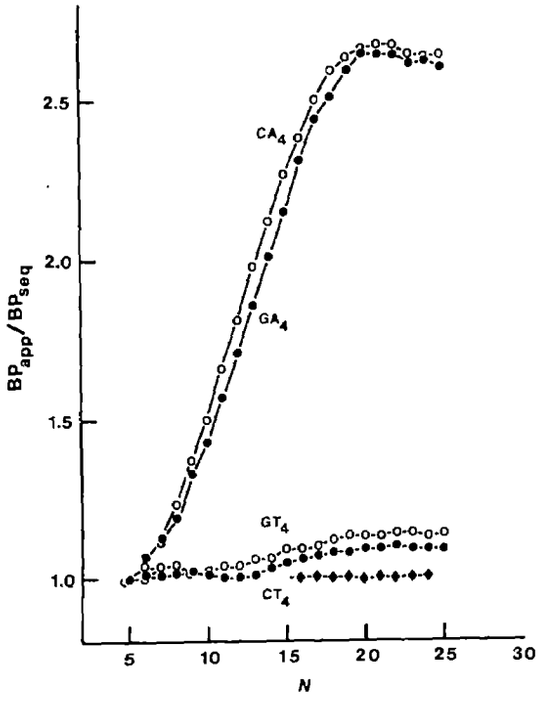

Fig. 2 Gel electrophoretic behaviours of duplex polymers having a repeating decamer motif. CA_4, $[CA_4T_4G]_N$; GA_4, $[GA_4T_4C]_N$; GT_4, $[GT_4A_4C]_N$; CT_4, $[CT_4A_4G]_N$. Mobilities of the various polymers, represented as the ratio of the apparent number of base pairs (BP_{app}) to the true number of base pairs (BP_{seq}), are plotted as a function of the degree of polymerization, *N*. The two curves plotted with solid circles represent sequence inversions of one another; the same applies to the two curves with open circles. ◆, $[G_3TCGAC_3]_N$ (lane *b* of Fig. 1, displaying a normal electrophoretic pattern for a decamer-based series).

sequences, when propagated approximately in-phase with the helix repeat, give rise to significant macroscopic curvature of the helix axis. That study exploited the fact that curved molecules migrate more slowly through polyacrylamide gels than do their linear counterparts (Fig. 1). Figure 2 compares the behaviour of the polymer series 5′-$[GA_4T_4C]_N$-3′ with its counterpart 5′-$[GT_4A_4C]_N$-3′. As the only difference between these polymers is the polarity of the A-T block, they would have to display identical electrophoretic behaviour if ApA/TpT dinucleotide wedges were determining the contour of the helix axis; clearly, this is not the case, as the 5′-T_4A_4-3′-containing polymers display nearly normal electrophoretic behaviour, in stark contrast to the 5′-A_4T_4-3′-containing species. This analysis does not rule out any participation of wedge-like deformations in generating curvature; however, such wedges, if present, do not determine curvature. Hence, it is incorrect to relate macroscopic curvature to an apparent ApA wedge angle. Note that the G and C residues flanking the A–T runs do not appear to influence the degree of curvature, since interchange of these residues (Fig. 2) has essentially no effect on the relative electrophoretic mobilities.

This research was supported by NIH grant GM28293.

CONVENIENT-INFORMATIVE-TIMELY-PROVOCATIVE

FOUR DYNAMITE REASONS WHY YOU SHOULD SUBSCRIBE TO BIO/TECHNOLOGY NOW . . .

1 ■ You'll save time. Because you don't have time to read every journal in the field, BIO/TECHNOLOGY is written and edited to give you all the information you need in ONE convenient source. BIO/TECHNOLOGY is the only journal to give you news. Features. Original research. Product evaluations. Industrial applications. Job openings. Book and product reviews. And more. If it's important to your work, you'll find it between the covers of BIO/TECHNOLOGY.

2 ■ You'll learn new ways to improve your on-the-job skills and run a more successful operation. Each month BIO/TECHNOLOGY gives you the scoop on invaluable start-up information . . . the latest instrumentation . . . marketing breakthroughs . . . funding sources . . . new technologies . . . patents and licences . . . profiles on how others are avoiding the pitfalls and reaping the rewards. In fact, just one practical tip from BIO/TECHNOLOGY can be worth many times the cost of your subscription.

3 ■ You'll be up-to-date on all major industry developments. With correspondents all over the world, BIO/TECHNOLOGY delivers the inside story on who's doing what, where. You'll get the latest word on changing government regulations and tax law, and how they affect your work.

Plus you'll read original research papers by bench scientists, engineers, and biologists that will help keep you in the forefront of every new discovery worth knowing about.

4 ■ You'll get new ideas you can put to use immediately. BIO/TECHNOLOGY lets you rub elbows with eminent scientists, tour new facilities and learn how new processes work in every field from genetic engineering to molecular biology. Each month, BIO/TECHNOLOGY helps spark ideas for your own research, for new industrial applications and for getting along in the increasingly competitive financial arena.

If you're not already subscribing to BIO/TECHNOLOGY, don't delay the moment any longer - return the coupon below and we will send you twelve issues. You risk nothing. If for any reason BIO/TECHNOLOGY doesn't live up to your highest expectations, just let us know and you'll receive a full refund on all unmailed copies. Remember too, that your subscription may be tax deductible

TO START RECEIVING YOUR SUBSCRIPTION, FILL OUT THE COUPON BELOW AND RETURN WITH PAYMENT TO:

The Division of Cancer Etiology

National Cancer Institute

Announces To The Scientific Community The Availability of the Following Resources/Services For Cancer Related Research As Noted Below:

Biological Resources

Avian Myeloblastosis Virus Reverse Transcriptase—2,000 Unit Minimum Order

Contact: Dr. G.E. Houts
Molecular Genetic Resources
6201 Johns Road, Suite 8
Tampa, Florida 33614
(813) 886-5338

Citing Contract #N01-CP-51007

Cost: $0.05/Unit
(Plus Shipping Outside Contiguous United States)

Goat Antisera Against: Avian, Bovine, Feline, Murine, and Primate Intact Viruses and Viral Proteins; Antibodies to Immunoglobulins for a number of species. Preimmune Sera available for some Virus Antisera.

Contact: Ms. P. Massagee
BCB Repository
Microbiological Associates, Inc.
5221 River Road
Bethesda, MD 20816
(301) 657-8169

Citing Contract #N01-CP-11000

Cost: $50.00/5 ml.
25.00/5 ml. (Preimmune Sera)
Plus Shipping
(Frozen Material)

Human Tissues: Carcinomas, Sarcomas, Lymphomas, Leukemias, Benign Tumors, and other Non-Malignant Disorders.

Human sera from donors with: Carcinomas, Sarcomas, Melanomas, Lymphomas, Leukemias, Benign Tumors, Normal Individuals, Family Members of Leukemics, Hematological Diseases, and other Non-Malignant Disorders.

Contact: Coordinator for Research Resources
Biological Carcinogenesis
Branch, DCE, NCI, NIH
Landow Bldg., Room 9A22
Bethesda, MD 20892
(301) 496-1951

Cost: Shipping Charges Only

Cell Culture Identification Service, Using Isozyme Analysis, Immunofluorescence and Karyotypic Analysis (Chromosome Banding)

Contact: Dr. Ward Peterson
Children's Hospital of Michigan
3901 Beaubien Boulevard
Detroit, MI 48201
(313) 494-5705

Citing Contract #N01-CP-21017

Cost: $200/Analysis

Monoclonal Antibodies are available with specificities for synthetic peptides representing the amino acid sequences of the left end, right end and active site of the oncogene products of avian and mammalian retroviruses. Blocking peptides are also available, as are a limited number of cell lines producing the monoclonal antibodies.

Contact: Ms. P. Massagee
BCB Repository
Microbiological Associates, Inc.
5221 River Road
Bethesda, MD 20816
(301) 657-8169

Citing Contract #N01-CP-11000

Cost: Peptides —$20.00/mg.
Ascites Fluid— 35.00/ml.
Cell Culture — 75.00/culture
(Plus shipping)

Cotton-Top Marmosets *(S. oedipus)* for Use as Models for Carcinogenesis—Holding, Inoculation, Observation, and Pathology Services are Available.

Contact: Dr. Neal Clap
Marmoset Research Program
Oak Ridge Associated Universities
P.O. Box 117
Oak Ridge, TN 37831
(615) 576-4103

Citing Contract #N01-CP-51006

Cost: $10.00 per diem (or higher for procedures involving additional care, etc.) $10.00 per blood sample

Cost: Inquire

Chemical Resources

Analytical resources for the collection, separation, and elucidation of the components of cigarette smoke and cigarette smoke condensates: A contractor with experience in the development of analytical methods for the determination of constituents of cigarette smoke and of specialty instrumentation for inhalation toxicology is available to assist qualified investigators with particular interest in studies on human and animal model exposure to environmental and sidestream smoke. A large inventory of reference experimental cigarettes, Standard Low Yield Reference Cigarettes, and an extensive chemical data base on smoke and smoke condensate components is available.

Contact: Thomas B. Owen, Ph.D.
Chemical and Physical Carcinogenesis Branch, DCE, NCI
Landow Building, Room 9C-18
Bethesda, Maryland 20892
(301) 496-5471

Cost: Inquire

Chemical Carcinogen Reference Standard Repository: Reference quantities of over 700 compounds are available. In addition to the newer Fecapentaenes and food mutagens, numerous representatives of the following classes of compounds are available; polynuclear aromatic hydrocarbons (PAH), PAH metabolites, radiolabeled PAH metabolites, nitrogen heterocycles, nitrosamines/nitrosamides, aromatic amines, aromatic amine metabolites, radiolabeled retinoids, azo/azoxy aromatics, inorganics, nitroaromatics, pesticides, pharmaceuticals, natural products, dyes, dioxins, chlorinated aliphatics and miscellaneous groups. Data sheets provided with the compounds include chemical and physical properties, analytical data, hazards, storage, and handling information. Catalog available upon request.

Cost: Subject to chemical class code and quantity (see catalog) plus handling and shipping charges.

Environmental Cancer

NCI's Chemical Carcinogenesis Research Information System (CCRIS) database will be available online through the National Library of Medicine's new Toxicology Data Network (TOXNET) system beginning January, 1986. Through an interagency agreement between NCI and NLM, the CCRIS database will be built, maintained and updated in TOXNET's sponsored databases in the broad areas of chemistry, toxicology, and hazardous waste information. The CCRIS database contains evaluated data and information on carcinogens, mutagens, tumor promoters, cocarcinogens, metabolites of carcinogens and carcinogen inhibitors derived from published review articles, ongoing current awareness survey of primary literature, NCI/NTP's short- and long-term bioassay studies the IARC Monographs on the Evaluation of Carcinogenic Risk of Chemicals to Man, and special studies and reports

Contact: Dr. Thomas P. Cameron
Office of the Director

Epidemiology Resources

The Immunodeficiency—Cancer Registry (ICR) is a unique registry of cancer cases that occur in patients with naturally occurring immunodeficiencies. Case material collected by ICR comes from case reports appearing in scientific literature and voluntary reporting by physicians. Criteria for inclusion in the registry are clinical or laboratory evidence of a primary immunodeficiency syndrome prior to the onset of malignancy. Data contained in the ICR are available to the extramural research community for the planning, design, and conduct of research efforts. Limited assistance is available to investigators interested in utilizing the registry.

Contact: Dr Alexandra H. Filipovich
Immunodeficiency—Cancer Registry
Box 610 Mayo
University of Minnesota
Minneapolis, MN 55455
(612) 376-2174

Citing Contract #N01-CP-31011

The Tumor Virus Epidemiology Repository (TVER) contains sera and other biological samples from more than 13,000 patients and controls obtained in 12 different countries. The TVER was established primarily to support collaborative research on the role of Epstein-Barr virus (EBV) in Burkitt's lymphoma, nasopharyngeal carcinoma, and related diseases. Part of the collection includes sera that were obtained from nonhuman primates inoculated with EBV.

The TVER is able to adjust its collection to facilitate the development of new collaborative studies. In addition, some samples are available for reagents and independent research. The most extensive collections are serum samples from patients with Burkitt's lymphoma (sera from more than 1,000 patients).

Contact: Dr. Paul H. Levine

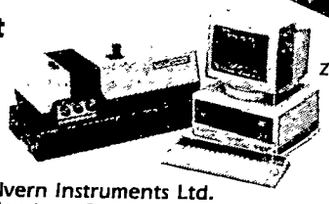
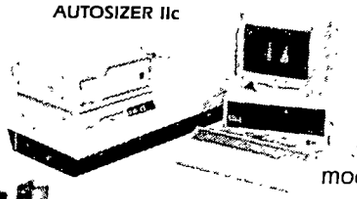
The New Dimension in Particle Technology...

Droplet and Particle Size Analysers 0.5-1800 microns



Fast, easy to use instruments for plant and laboratory applications. All with new 16-bit computer/processor giving full graphical and tabular results in 32 size classes. Compact and cost-effective **3600Ec** for powders in suspension up to 560 microns.

SERIES 2600c modular systems for pulsed or continuous sprays and suspensions up to 1800 microns and dry powders.



Zeta Potential Measurement

Zetasizer IIc laser based particle electrophoresis system. Automated, rapid, eliminates user fatigue and bias. Also measures submicron particle size.

Submicron Particle Size Analysers

Advanced **SYSTEM 4700c** incorporating Malvern's 8-bit correlator with up to 264 data channels and eight sample times. Measures particle size 0.001-5 microns, molecular weight by PCS or Zimm plot methods, diffusion coefficients etc.

AUTOSIZER IIc also features 8-bit correlator for fast, routine particle sizing 0.003-3 microns, with full mono- or multi-modal size distribution data.

Carbohydrate detection gains potential

from Dennis C. Johnson

Combined with liquid chromatography, pulsed amperometric detection extends the capabilities of carbohydrate analysis. The method allows direct electrochemical detection.

THE promise of analytical organic liquid chromatography (LC), enhanced over the past decade by improvements in hardware and methodology, has stimulated the search for new detection concepts to permit greater exploitation of LC capabilities. Detection based on UV-vis photometry (absorbance and fluorescence) has been most common in organic LC; however, photometric detection yields significant results only with unsaturated and aromatic molecules. For aliphatic analytes, photometric detection suffers from poor sensitivity unless aromatic functional groups are attached to the aliphatic molecules using tedious chemical derivatizations.

	Sugar	ppm

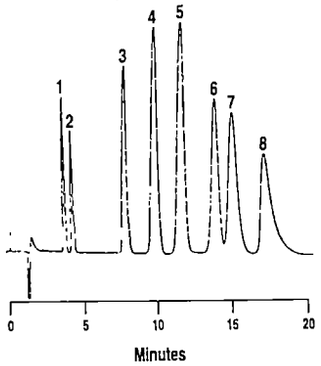
11.	Xylose	100
12.	Fructose	100
13.	Sucrose	300

Fig.2 Separations of carbohydrates using anion-exchange chromatography with electrochemical detection. The column and detection are as in Fig 1, the mobile phase was 8.0 mM $Ba(OH)_2$/0.5 mM acetic acid. (Provided by W.T. Edwards, Dionex Corp.)

EC detection



Oxidative electrochemical (EC) detection has also proved useful for aromatic organic molecules such as phenols and biogenic amines and metabolites[1,2]. In contrast, direct anodic detection of underivatized aliphatic organic molecules under constant (d.c.) applied electrode potentials is essentially unknown. Thermodynamic data predict oxidations in aqueous and mixed solvents. Hence, the apparent electroinactivity of aliphatic molecules at constant potential originates from kinetics problems, for instance the lack of resonance-stabilized free-radical reaction products.

Aliphatic molecules frequently generate transient anodic signals at noble metal electrodes, with the magnitude of the temporary signal and speed of its attenuation being a function of the electrode material. Because the electrode surface appears to interact with analyte molecules and/or reaction products, the reaction mechanisms are characterized as electrocatalytic[3-5].

The example of aliphatic molecule electrochemistry that is best understood is the oxidation of simple alcohols at noble-metal electrodes[3-5]. The standard potential (E^0) for the conversion of methanol to CO_2 in aqueous solutions is predicted to be 0.0V versus NHE (normal hydrogen electrode). Electrode potentials many hundreds of millivolts more positive than this E^0 can be applied at common anode materials without causing decomposition of the aqueous solvent. It follows that all alcohols should be easily detected by electrochemical oxidation reactions.

However, the oxidations of alcohols are not 100 per cent efficient and free-radical intermediates are adsorbed strongly at the noble-metal anode surfaces, thereby eliminating further activity of those surface sites. Electrode currents for alcohols at noble metal anodes fall to zero within a few seconds in acidic or alkaline media[3-5].

The adsorbed hydrocarbon materials which foul Pt and Au electrode surfaces can be eliminated by oxidative desorption when a large positive potential pulse is applied[6,7]. A subsequent negative potential pulse cathodically dissolves surface oxides, restoring the full activity of the metal electrode surfaces.

3.	Arabinose	25
4.	Galactose	25
5.	Glucose	25
6.	Xylose	25
7.	Mannose	50
8.	Fructose	50

Fig.1 Separation of common monosaccharides by anion-exchange chromatography with electrochemical detection. A Dionex HPIC AS-6 column with a 1.0 mM $Ba(OH)_2$/0.125 mM acetic acid mobile phase was used, followed by detection with a Dionex pulsed amperometric detector. (Provided by W.T. Edwards, Dionex Corp.)

Cleaning pulses for analytical anodic potential are under the control of multistep potential waveforms[8]. Each application of the detection potential, with measurement of electrode current, is followed by the positive and negative pulses for surface reactivation. Typically, the waveform is applied with a cycle frequency of about 1 Hz (1 cycle per second). The analytical technique has become known as pulsed amperometric detection (PAD).

PAD and chromatography

Response to PAD has been verified for all carbohydrates tested at Pt[6,7] and Au[8] electrodes: sugar alcohols (such as sorbitol), aldoses (glucose), ketoses (fructose), polysaccharides (sucrose) and aminosaccharides.

Because of the electrocatalytic basis of PAD for carbohydrates, the potential dependence of the anodic response is virtually independent of the identity of the molecule. The technique cannot distinguish between different types of carbohydrate in a mixture. Therefore PAD is applied as a general electrochemical detector for carbohydrates in the chromatographic effluent stream.

Among the possible designs for LC electrochemical flow-through detectors[9,10] the most popular is the thin-layer cell. In this design, the fluid stream is confined to a narrow channel cut into a thin Teflon sheet (< 0.2 mm) separating two flat plastic plates (Kel-F). For PAD of carbohydrates, the indicating electrode (Au) and counter electrode (Au, Pt or carbon) are the flat end surfaces of rods (about 1 to 2 mm diameter) pressed into holes drilled

in one plastic plate. The Ag–AgCl reference electrode, mounted in the opposite plate, is separated from the fluid stream by a cation-exchange membrane.

Any chromatographic system designed for carbohydrate LC-PAD must recognize the requirement for a supporting electrolyte and the desirability of maintaining a high *p*H to maximize sensitivity. It is preferable that the buffered supporting electrolyte serve as the chromatographic mobile phase. Low-capacity anion exchange columns, such as those used in ion chromatography[15–17], have been successful in this application[11,12,18]. Cation exchange columns in the Ca^{2+}-form are also effective where pure H_2O is the mobile phase, provided an appropriate electrolyte/buffer solution is mixed with the column effluent stream prior to detection[9].

Separation of a mixture of common monosaccharides is shown in Fig. 1; Fig. 2 shows the separation of a more complex mixture of carbohydrates. The retention mechanism apparently operates by ion exchange of the weakly ionized alcoholic groups under the conditions of moderately high *p*H. Sugar alcohols have low retention under these chromatographic conditions, and oligosaccharides are retained more strongly than the monosaccharides. Detection limits are approximately at the part-per-million (p.p.m.) level.

Analysis by LC-PAD has already been applied to fruit juices and alcoholic beverages[9,18] and other food products[15]. In the future, clinical laboratories may use LC-PAD to obtain carbohydrate profiles of physiological specimens. Ultimately the analytical potential of LC-PAD may reveal the physiologial function of many carbohydrates. □

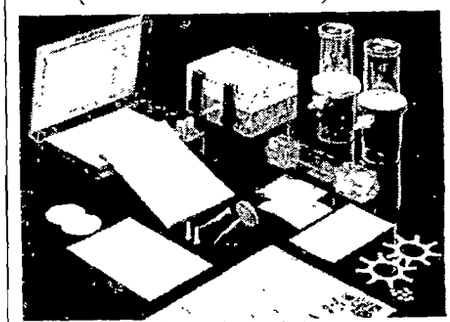
Analytica instrumentation

Munich comes alive this June with chemical technology to count, size and analyse.

HYBRITECH's new fully **automated immunoassay analyser** will be on display at Analytica. The Photon-Era can perform most of the manual laboratory procedures associated with Tandem-E immunoenzymetric assays, including precisely-timed pipetting, aspirating, washing and quenching (Reader Service No. 100). The machine measures samples by way of a fixed- or discrete-wavelength spectrophotometer. Equipped with an IBM-PC XT system, Photo-Era's processing unit is comprised of two independent sections: the sample processor and the reaction processor. Together, these components can



Hybritech puts immunoassays on their own.

process up to 100 samples per hour, and can serve as general automated pipettor/diluters or spectrophotometer/spectroflourometers as well.

A **bench-top liquid scintillation counter** for bioresearch, biotechnology and clinical laboratories fills out Beckman's LS 5801 series. Beckman has designed the LS 1701 for quick and simple routine analyses (Reader Service No. 101). The standard instrument features three independently programmable user files, with preset isotope settings for tritium, carbon-14, phosphorous-32, sulphur-35 and iodine-125, as well as automatic isotope endpoint determination so that the system can adjust itself to any isotope selected. Beckman's machine can provide accurate d.p.m. data regardless of the scintillation cocktail or counting vials being used, and it retains its accuracy throughout changes in volume, quench types or isotope pairs and ratios.

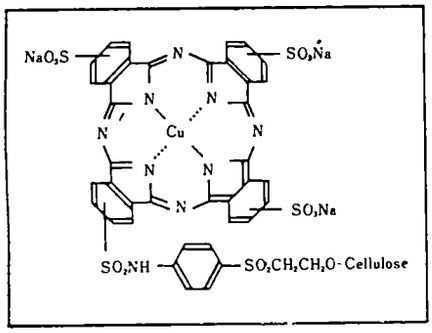
Using protein pigments that occur naturally in algae and cyanobacteria, Biomeda Corp. has developed **immunofluorescent probes** that exhibit 10 to 30 times the fluorescent intensity of conventional fluorescein conjugates. Bound covalently to specific antibodies, these phycobiliproteins can combine recognition with fluorescence emission that is uniform over a wide *p*H range, and in the presence of most biological compounds (Reader Service No. 102). Biomeda's latest addition to their offerings, Phycoprobe-PE (for phycoerythrin) antibodies, can be excited at the same wavelength as fluorescein-labelled compounds, although the Phycoprobe's maxima is at 575 nm. The higher wavelength transmission can translate into a clearer signal, because it creates a larger Stoke's shift.

Schleicher and Schuell, showing in hall 3 at stand B4, plan to present several new products at Analytica including an **electroelution system** for the purification and concentration of electrically-charged biopolymers. Underlying the Biotrap's efficacy is a novel membrane which, when subjected to an electrical field, retains only charged molecules of molecular weights ≥ 5,000 — without adsorbing them (Reader Service No. 103). With Bio-

Schleicher and Schuell's Analytica array.

trap, DNA/RNA and protein samples can be eluted from gels, concentrated by dialysis and separated by isoelectric methods. Disposable filter units, DNA purification chromatography columns and transfer media will also adorn Schleicher and Schuell's exhibit area.

Filter and ferment



The star of Elga's show in hall 14 stand B16 is the Elgastat UHQ laboratory **water purification unit.** Incorporating five different purification techniques, the Elgastat unit yields high quality water for use in HPLC, fluorescence analysis, atomic absorption and ion chromatography (Reader Service No. 104). Water processed through Elga's system conforms to the following specifications: inorganics, 18 MΩ cm^{-1} at 25°C; organics, 0.0001 absorbance at 254 nm; TOC, 20 parts per 10^9; bacteria, 1 CFU ml^{-1} and particles, 0.2 μm absolute filtration.

In hall 2 stand B14/D, a variety of **fume filtration cupboards** from ASTEC Environmental Systems Ltd will grab the spotlight. All ASTEC's cupboards can be installed without ducting or building work, or mounted on trolleys for the

greatest flexibility (Reader Service No. 105). And 13 types of filters are available to combat the effects of solvents, acids, alkalies, ammonia, H_2S, SO_2, formaldehyde, resins and so on. ASTEC's latest cupboard series, called Condor, has powder handling and cytotoxic drug preparation facilities and can be used as a glove box as well. It features high- and low-level extraction vents, a floor-level filtration system and a 1,200 mm × 600 mm epoxy resin dished work surface. Also exhibited in ASTEC's stand are the Astecair filtration fume cupboards and Mystaire scrubber.

A fermenter family from Infors AG will be making its world premier at Analytica this year, in hall 11 stand B15. Infors says it set out to build fermenters that were easier to handle, maintenance-free, more versatile and safer to operate (Reader Service No. 106). How well they have achieved their purposes can be judged first-hand. Compact ISF-fermenters can use top or bottom drive, selected at sight without tools or service engineers. The bottom valve, with high current flow, is combined with a sampling port which allows the extraction of very small probes. Infors guarantees sterilization *in situ*; when the sterilization procedure is initiated, the air inlet and outlet lines automatically separate from the vessel and can then be sterilized apart from the vessel. Peripheral measurement, together with control and regulation modules, complete Infors's ISF-fermenter package.

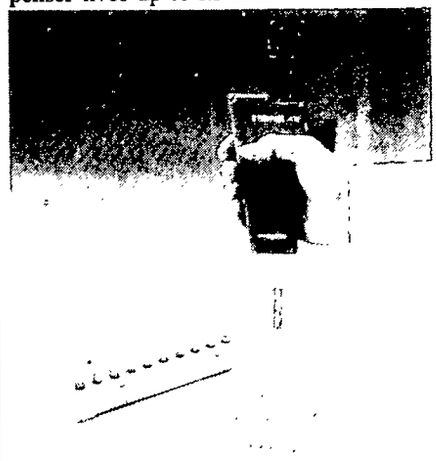
Aqueous and organic solutions can be **cleansed of mutagens in minutes** with a new adsorbent from Pierce, hall 14 stand

Mutasorb's formula for nabbing mutagens.

E17. Called Mutasorb, Pierce's agent consists of adsorbent cotton bearing covalently linked trisulpho-copper-phthalocyanine residues (Reader Service No. 107). This ligand enables Mutasorb to adsorb mutagens containing more than three fused aromatic rings, such as mutagenic polycyclic aromatic hydrocarbons, mutagenic heterocyclic amines, polycyclic antibiotics and dyes such as ethidium bromide and crystal violet. One gram of the adsorbent contains approximately 10 μM of copper phthalocyanine; about 5 mg of Mutasorb per ml of solution can remove 1 μM of ethidium bromide. Pierce's product can be added directly to aqueous solutions, whilst solid materials have to be extracted with water or organic solvents.

Next on the bench

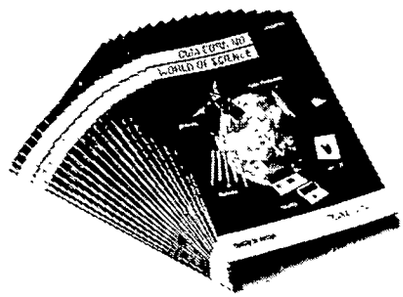
Earlier this year, Sartorious brought a new line of **analytical balances** to the market with capacities up to 12,000 g, readabilities from 0.00001 g to 0.1 g and full-range electronic taring. Now at Analytica, Sartorious will show most of these balan-



The A200S balance has clear advantages.

ces; and of these, the Analytic balance A200S may capture the most attention (Reader Service No. 108). Sartorius's top-loading A200S, with a 200 g capacity, features a weighing chamber housed in glass all around for 'five-sided' viewing. All balance functions can be controlled with up-front, one-finger formatting. One touch calibrates the balance, which then automatically returns to the weighing mode and displays sample weight. The Sartorious A200S has a 0.1-second update speed and an RS232C data output option that permits interfacing with printers, computers and Sartorious keyboards.

Carl Zeiss's **research microscopes** have just emerged from a design overhaul, and the results will be exhibited at Analytica. The Axioplan and Axiophot microscopes incorporate two design changes that should make switching between microscopic techniques more convenient (Reader Service No. 109). What Zeiss calls infinity colour-correlated system optics, or ICS optics, gives all objectives an infinite image distance so that a range of techniques including brightfield, darkfield, phase contrast, qualitative polarized light, differential interface contrast and fluorescence can be accommodated without additional lenses or loss of image quality. ICS optics also maintains a large consistent field of 25 mm and a contrast magnification factor, regardless of the method employed. System-integrated, or SI, design enables permanent or modular optical components to be integrated into the microscope housing without impairing image quality or field of view. Components for either reflected or transmitted light microscopy fit the system equally well.

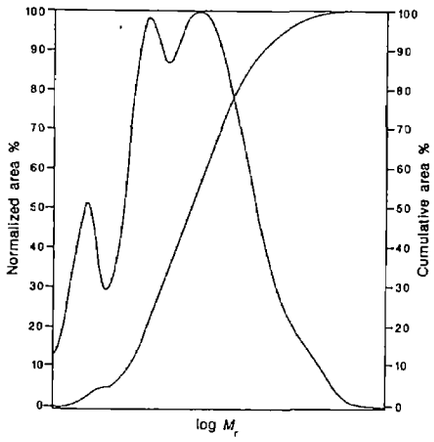


The **adjustable volume repetitive dispenser** lives up to its name: with this de-

Wheaton's dispenser: a cure for the common aliquot.

vice, up to 74 repetitive deliveries of preset microlitre volumes can be made without refilling the syringe. The dispenser is the brainchild of Wheaton Instruments (Reader Service No. 110). Filling the dispenser involves inserting a disposable syringe into the device's housing and raising the piston. A volume knob indicator can be rotated to the desired setting. Three sizes of disposable syringes effect total deliveries from 10 μl to 5,000 μl, with an accuracy of ± 1 per cent above 20 μl, ± 1.5 per cent at 20 μl and less.

As a primer for Ciba-Corning's Analytica exhibit, their 1986 laboratory instruments catalogue *World of Science* describes in full their Delta *p*H meters and ion analysers, their 410 digital flame photometers, carbon dioxide analysers, chloride analysers and colorimeters. The 20-page colour brochure gives individual specifications and information on accessories for Ciba's instruments (Reader Service No. 111). The catalogue also has lists of charts and brochures available on speci-



Essentials and accessories in Ciba-Corning's catalogue.

fic application methods should the reader wish to pursue a particular application in further detail.

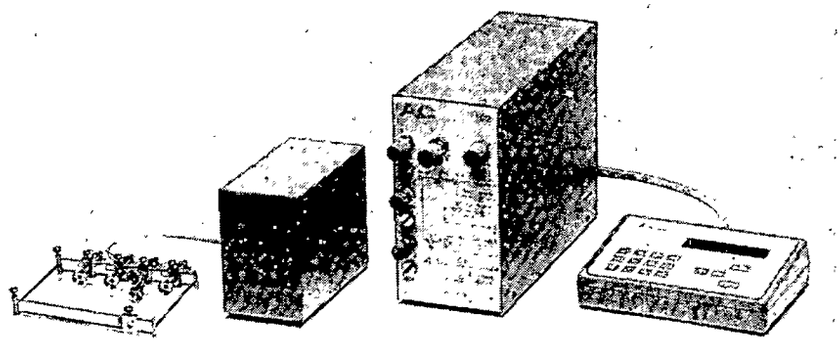
Perkin-Elmer, in cooperation with the biotechnology company Cetus, have produced a **computerized pipetting system** specifically intended for biological procedures in microtitration assays. The Pro/Pette automated liquid handling instrument can be programmed, using a hand-held controller, in 1-μl increments throughout a 1- too 200-μl range (Reader Service No. 112). With interchangeable pipette heads, Perkin-Elmer's device can perform serial dilutions, plate-to-plate transfers of samples, aspiration, filling and mixing of well contents. The ability to alternate between single- or multi-channel pipetting is another aspect of the Pro/Pette's flexibility. Perkin-Elmer plan to display their product in hall 5, stands A6/B3.

Software schemes

In conjunction with Heyden & Son's Chromatochart software, their new **gel permeation chromatography (GPC) software** for Apple II microcomputers can perform molecular weight distribution calculations. Consisting of two modules, calibration and analysis, GPC enhancement software is linked to Chromatochart's menu structure (Reader Service No. 113). The Software combines information from its parent's method, baseline and data files with calibration coefficients created by the calibration module. The GPC analysis module ties coefficient calculations together with Chromatochart's capabilities to correct for baseline drift and to define peak start and stop positions. Molecular weight distributions for the sample as a whole, or for individual peaks in a sample, can be obtained from Heyden's software package. Heyden can provide additional information on GPC software at their Analytica stand.

Heyden MW distribution straight from the chart.

Two-dimensional gas chromatography, which can be built into any capillary GC system, just got its own microprocessing controller from Chrompack. At Analytica Chrompack will demonstrate the advantage of MUSIC, or multiple switching intelligent controller (Reader Service No. 114). MUSIC analysis begins by using a short 0.53 mm fused silica column to effect pre-separation of chromatography samples. Then, eluting peaks are trapped on a CO_2-cooled cold trap and injected into a narrow-bore fused silica column with a different polarity, to achieve further separation. MUSIC's microprocessor allows fully automated operation and controls all flows, pressures, oven and trap temperatures.

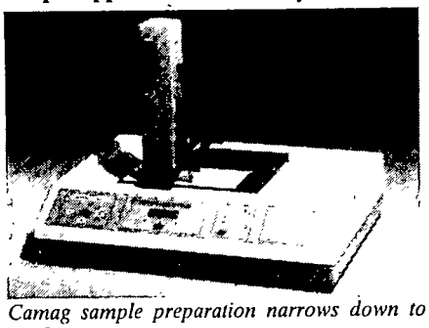


Membranes, media and midgets

As an alternative to conventional cellulose dialysis sacs, Millipore is now offering V series membranes which can prepare microvolumes of proteins or nucleic acids for analysis via the **drop dialysis technique**. With this method, the V series membrane is floated on a Petri dish filled with dialysate, and the sample added to the membrane with a micropipette (Reader Service No. 115). The 0.05- or 0.025-μm pore structure of Millipore's membranes accelerates salt diffusion, and sample additions of 5 μl to 100 μl are probably less time-consuming than procedures used with cellulose bags. At Analytica Millipore can answer questions on their dialysis procedure. The company cites recovery rates in excess of 98 per cent with the drop dialysis technique.

Dialysis with a difference from Millipore

Gold Label **dehydrated culture media** from BBL Microbiology Systems are the result of improved formulations that BBL says will provide superior test results. Currently BBL sell five varieties of the media (Reader Service No. 116). TSA II is BBL's improved general-purpose bacterial culture medium base for preparation with 5 per cent sheep blood. The critical components in another medium, Mueller Hinton II, are controlled to give consistent results in lot-to-lot susceptibility tests. BBL's third Gold Medal culture, MacConkey II, improves the inhibition of *Proteus* swarming so as to give other Gram-negative pathogens room to breath. GC II agar was developed in combination with BBL's IsoVitaleX enrichment and haemoglobin to facilitate the growth of *Neisseria gonorrhoeae* and other fastidious microorganisms. Finally, BBL has a grade A agar that, used as an ingredient, may improve growth and test reaction results.

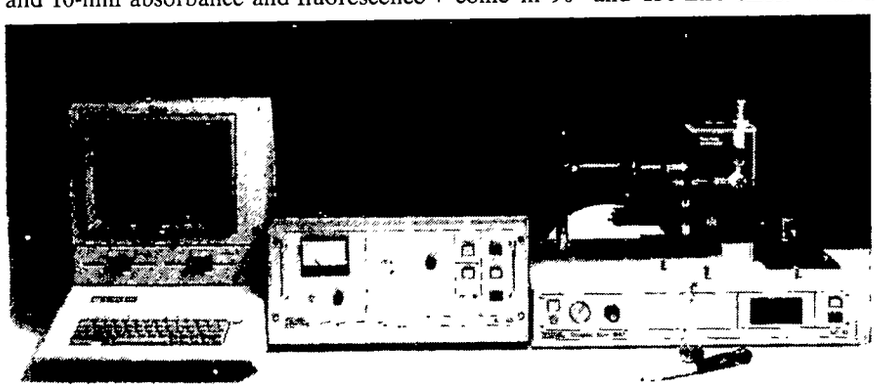


Chrompack will bring MUSIC to chromatography at this year's exhibit.

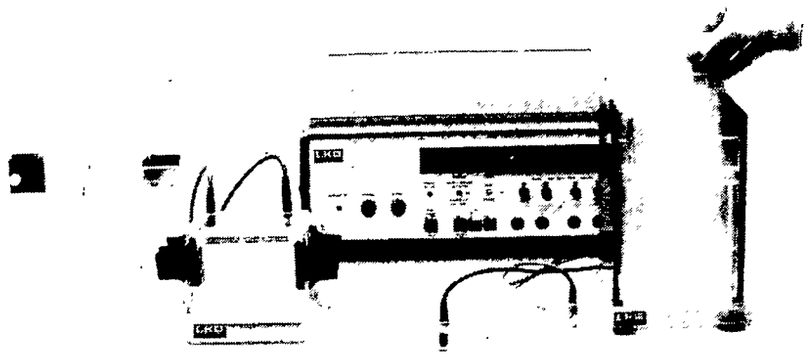
In the race to catch up with Pharmacia's Phastsystem, LKB has introduced a **miniature electrophoresis system** that completes an analysis from gel-casting to scanning in under two hours. On display at Analytica, LKB's 2050 Midget system can perform screening of small samples by high-resolution techniques such as zone, disc, gradient, SDS and 2D electrophoresis (Reader Service No. 117). The complete Midget package includes multiple gel casting units, an electrophoresis tank, an electrophoretic transfer unit, a laser densitometer, digital power supply and accessories. The system can cast up to 14 gels at one time and run two gels with 5, 10 or 15 samples each in less than 45 minutes;

LKB claims the time savings can cut running costs by 90 per cent.

Newcomers in instruments...



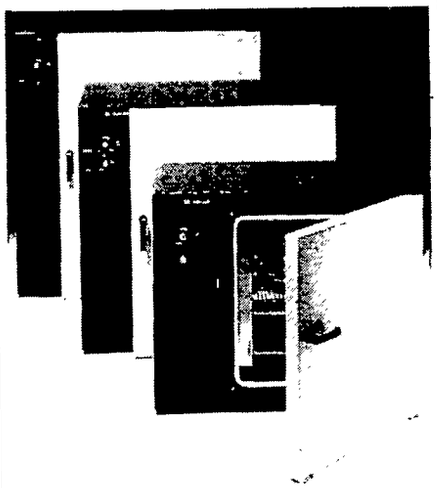
Automation has won over Camag's Linomat spray-on techniques for **narrow-band sample application** in thin-layer chroma-



Camag sample preparation narrows down to TLC

tography. The Linomat IV is a microprocessor-controlled, programmable instrument with keyboard parameter entry that automates the same spray-on technique, using nitrogen as the carrier gas, that previously bore the Linomat title (Reader Service No. 118). Camag's latest version, exhibited in stand C8/D7, hall 2, computes the number of available tracks from information on band length, distance between samples, edge space and plate width. Linomat IV then indicates the tracks by means of light-emitting diodes, and sample deliveries from the syringe proceed automatically.

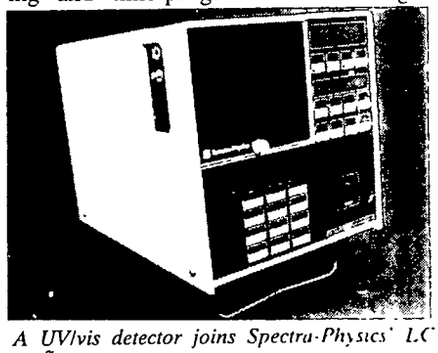
A **stopped-flow spectrophotometer** from Hi-Tech Scientific can generate five runs from 500 µl of each reagent. Hi-Tech intended their instrument for work with precious biological materials, and minimized the quantities required to fill the flow circuit, which is totally thermostatted, chemically inert and readily aerobicized (Reader Service No. 119). Their spectrophotometer features a two-tier design consisting of an upper sample handling platform and lower optical platform. The optical cell itself uses an integral ball-mixer and has four optical windows for 2- and 10-mm absorbance and fluorescence



A stopped-flow spectrophotometer from Hi-Tech gets the most out of small samples.

LKB's Midget runs high-resolution separations in less than an hour.

work. At Analytica, Hi-Tech will be located in stand B14, hall 7.



The display at Gallenkamp's stand B3 hall 9 will reveal a rounded-out collection

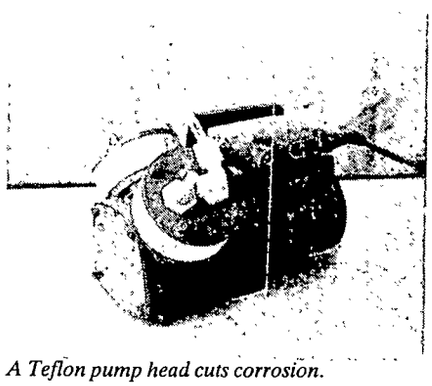
Gallenkamp ovens in all shapes and sizes.

of **laboratory and light industrial ovens**, from standard 23-litre units to large 586-litre units, and from vacuum to humidity oven environments. Gallenkamp's most recent arrivals are the standard ovens sized up to 200 litres, in gravity-convected and fan-circulated versions (Reader Service No. 120). General-purpose ovens, which specialize in temperature control, come in 90- and 150-litre sizes. With a temperature range of 40°C to 240°C, Gallenkamp's large-capacity ovens (340 and 586 litres) were designed for large loads or awkwardly-shaped items. And two large-capacity vacuum ovens in 90- and 260-litre volumes have joined Gallenkamp's 30-litre vacuum variety. The company will also have their incubator line, including the Gallenkamp Orbital models, at Analytica this week.

Bent on expanding the possible system configurations of their LC instruments, Spectra-Physics has added a **scanning UV-vis detector** to its product list. The SP8480XR connects with the Spectra-Physics computing integrators, SP4270 or SP4290, via a plug-in PROM chip installed by the user (Reader Service No. 121). The SCAN chip enables the integrator to perform automatic stop-flow peak scanning with background subtraction, peak ratioing and time-programmed wavelength

A UV/vis detector joins Spectra-Physics' LC outfit.

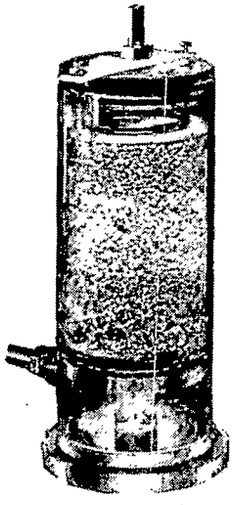
changes for selected peaks within a chromatogram. The detector itself has a drift measured at less the 1/10,000th of an absorbance unit per hour. Baseline zeroing can be carried out manually or automatically. Spectra-Physics will have the scanning detector on display at their Analytica stand.



...and accessories

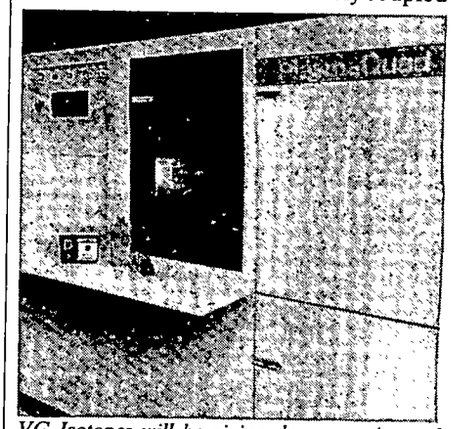
A **wideline solids accessory** (WSA) for use in biophysical research can expand the capabilities of Varian's VXR series of NMR spectrometers to include the examination of samples in solid states. With

Varian's new solids NMR instrumentation, researchers can obtain detailed structural and dynamic information about molecules and investigate molecular motion (Reader Service No. 122). WSA has a 1 kW high-power pulse amplifier that generates the short radio-frequency pulses needed to cover the wide spectral widths associated with solid protein NMR spectra. Likewise, the WSA receiver bandwidth has been increased to 2 MHz. Varian can also demonstrate the software included in WSA that performs specific wideline NMR experiments on Varian's spectrometers.



A **sealed rotor** for middle-capacity benchtop and under-bench refrigerated centrifuges helps contain blood samples and other infectious materials during centrifugation. Heraeus Separationstechnik has engineered the 3360 rotor with a stainless steel shield and transparent polycarbonate lid to replace their 3350 rotor (Reader Service No. 123). The tightly-closing lid keeps infectious agents from getting into the centrifuge or surrounding areas in the event of aerosol formation or glass breakage, and breakage can be identified immediately because the lid is clear. Heraeus Separationstechnik's rotor also uses a racking system which caters to tubes of capacities from 7 to 100 ml, and has decanting and incubation facilities. More information will be available at Analytica from Heraeus Separationstechnik.

KNF Neuberger have machined a **vacuum pump head** from solid Teflon, resulting in a pump with strong chemical resistance to corrosive vapours. The inlet and outlet valves in KNF's pump are also made from Teflon, and the diaphragm is produced from rubber laminated to a thick layer of Teflon (Reader Service No. 124). Teflon protection means that the pumps can be used with all kinds of chemical vapours without inevitable pump failure. KNF's series of corrosion-resistant pumps spans flow rates from 18 to 32 litres per minute, with vacuum levels down to 10 mbar.



A Teflon pump head cuts corrosion.

Savant Instruments, in stand D4, hall 7, take another approach to vapour corrosion in vacuum pumps. Their **chemical trap**, the model SCT120, removes acidic, alkali, organic and inorganic vapours that can condense in the pump system and wreak corrosive havoc (Reader Service No. 125). Savant's plexiglass cylinder measures 5 inches in diameter by 11 inches in height, with a removeable top for cleaning and re-charging. In operation, the SCT120 should be placed between the concentrator/evaporator and the vacuum pump; standard ½-inch tubing will make adequate connections. □

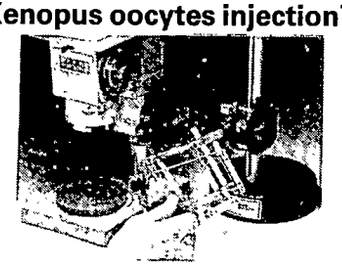
Savant traps vapours before damage begins.

A computer-assisted **data acquisition and analysis** system for VG Isotope's VG 9000 glow discharge mass spectrometer (GDMS) will make its debut at VG Isotopes' stand A10, hall 11 at Analytica (Reader Service No. 126). The system offers multipaging of screen memory for access to menu-driven utilities such as current status readouts, real-time data acquisition displays, peak information and graphic analysis of old or current data. Graph scaling, peak identification and selection, baseline setting and other parameters are controlled from soft keys. VG Isotopes claim this package enhances the performance and convenenience of their VG 9000, a GDMS instrument which has achieved detection limits below 10 parts per 10^9. Also at the company's Analytica stand, VG Isotopes scientists will be operating the PlasmaQuad inductively coupled mass spectrometry system (ICP-MS), a machine that gives detection limits better than 0.1 parts per 10^9 for most elements.

VG Isotopes will be giving demonstrations of their ICP-MS at Analytica.

Baird & Tatlock's motorless stirring technique has some new followers. The Flatspin 2 range of **stirrers**, on view in Analytica at stand B3 hall 9, has a 'spin-off' feature that provides a warning if the magnetic follower loses capture while stirring (Reader Service No.127). Baird & Tatlock have developed two types of Flatspin 2 products; the new immersion stirrer and a hotplate stirrer. The immersion stirrer has an encapsulated head that can withstand temperatures up to 100°C; the hotplate stirrer now includes an external probe for monitoring temperature suspended in solution. □

These notes are compiled by Karen Wright from information provided by the manufacturers. To obtain further details about these products, use the reader service card bound inside the journal.



Erratum: VCA/AIDS ELISA test kit

THE product review for Cellular Products' Retro-Tek AIDS test, published in the 10 April 1986 issue of *Nature*, incorrectly stated that "direct absorbance readings [generated by the test kit]... indicate the progress of the disease". In fact, these readings can only be used to monitor the concentration of the AIDS viral antigens in tissue culture samples or the presence of AIDS antigens in isolation and purification schemes. □

NATURE VOL. 321 29 MAY 1986

The changing of the old guard

The British government seems to have sensed that its policy on education could be an electoral liability, which is correct. But throwing printed money at the problem will not help.

MR Kenneth Baker, the new Secretary of State for Education and Science in the British government, has with enthusiasm taken on an impossible task. After two years of bruising labour troubles in the schools, he has implicitly undertaken to restore the morale of the dwindling band of able teachers, to modernize the school curriculum and to produce results (better examination results). He has to do the same in higher education, somehow persuading academics and their institutions that the government's reduction of their budgets by more than 20 per cent in five years is in reality a measure of its high esteem for them. Harder still, he must persuade researchers (for the government has not taken this golden chance to split off the administration of research) that his predecessors have caused institutes to close, and cohorts of bright young people to find posts elsewhere, so that the remainder will have better pearls to look for. All this has to be done in less than eighteen months.

Mr Baker's enthusiasm is his strongest suit. It won him notable success when, as minister of information technology five years ago, he persuaded the British government and many of its electors that the time had come to "cable Britain", putting umpteen channels of cable television into every home. He had fortunately been promoted from that post by the time it became apparent that he had not persuaded that section of the community with funds sufficient to launch commercial cable that there could be no better place for their money. It would nevertheless be a great misfortune if the transformation now planned for British education follows the pattern of the cable revolution that never happened. Education is too important.

The most chilling sentence in last week's letter from the University Grants Committee to its constituents is the statement that there is now no prospect of being able to increase the proportion of university students following courses in the government's special engineering and technology programme by more than 14 per cent over 1984–85 by the end of the decade because of "early specialization and staffing" in the schools. Similar constraints apply elsewhere across the educational spectrum, and governments are not entirely to blame. British universities have been chiefly influential in requiring that school-leavers should have so thoroughly rehearsed at school what they will learn at university that students are at once bored (because they know it all already) and ill-educated (because they know nothing else). The universities have now changed their tune.

So how should Mr Baker best blend his endearing personal enthusiasm with the long-term character of the problem of education and research? Here are a few maxims he might follow. Most parts of his new intellectual empire have been through a long period of change, which has accelerated in the past few years. The schools had hardly survived the intense curriculum development of the 1960s when they were required to change again, for largely social reasons. Higher education began that period by being expected to grow quickly and was then asked to stand still until the time came to contract. The same has happened in research. People are sick and tired of it. A moratorium on organizational revolution would be a blessing.

An end to upheaval does not however require stagnation. Mr Baker would do himself and his constituents a power of good if he allowed that, within a framework of stability, it would be in the public interest if people or institutions who wish to change were allowed to do so. There would be some schools keen on taking up new bits and pieces of curriculum, even some universities anxious to break out in new directions, not to mention a small army of academic researchers who would eagerly do new things. Inspection might even discover that the Royal Greenwich Observatory, about to be moved for largely administrative reasons, might usefully be left where it is on the understanding that its professional astronomers should compete for research grants with their colleagues in the universities.

To whom should even an enthusiastic new minister turn for advice on matters like these? The trouble with the British enterprise in education and science is that its managers have been tainted by the failures of the past. All honourable men and women, they are the same who have failed to defend their institutions from internal weaknesses and from the malevolence of Mr Baker's predecessors. They have lost the allegiance of their younger and more creative colleagues. Mr Baker, if his intentions are serious, had better get out and about, off the beaten tracks of the corridors of administrative tidiness. While on his journeys, he might make the speech or two suggesting that he is someone who knows what the enterprise is for. □

What yellow peril?

The British government has said it has not found mycotoxins in samples of yellow rain.

THE notion that the people of Laos and Cambodia were attacked by their Vietnamese neighbours by means of a chemical toxin sprayed from aircraft had become a bit of a joke even before Dr Matthew Meselson turned it into pastiche by remarking that most of what appears to be yellow rain consists of the excrement of bees. The allegation was first made by Mr Alexander Haig during his brief spell as US Secretary of State, but on the flimsiest of evidence. Trichothecene toxins, produced naturally by *Fusarium* fungi, are undeniably lethal in appropriate circumstances, but less quickly so than cheaper modern chemical warfare agents.

As time has passed, the case has been less easy to sustain. People's capacity to analyse for trichothecenes is one of the marvels of mass-spectrographic assay. The fact that Britain's Porton laboratory has looked for trichothecenes in yellow rain and failed to find them does not imply that all samples of yellow rain are free from mycotoxins, or that no yellow rain has ever been so contaminated deliberately. But it does give the lie to the notion that all yellow rain is lethal, which is not surprising since most of it is known and admitted to be the excrement of bees. So now there are two choices; either the State Department must acknowledge that the Vietnamese were even more devilishly clever than had been supposed in concealing their use of an improbable chemical weapon behind the cloak of a previously ill-recognized biological phenomenon, or the State Department should allow that it may have been mistaken □

Genetic regulations

US to settle dispute over agency jurisdiction

Washington

AFTER months of inter-agency wrangling, the new federal government policy statement on biotechnology research is expected to be published in the *Federal Register* by the end of the month. Its supporters believe it will make clear the complex maze of regulatory jurisdictions among federal agencies. But even its authors acknowledge that the new document, which is two-and-a-half inches thick, will be a challenge to general understanding.

The framework is the next step in the process begun in December 1984 to coordinate government policy regulating biotechnology (see *Nature* **313**, 85; 1985). Since last November, when an index of relevant statutes appeared in the *Federal Register,* the Domestic Policy Council (DPC) Working Group on Biotechnology has been conducting an intensive effort to arrive at an inter-agency consensus on how those statutes are to be applied.

"The goal was to get coordination and consistency", says David T. Kingsbury, National Science Foundation (NSF) Assistant Director for Biological, Behavioral and Social Sciences and chairman of the DPC working group. The effort attempts to get away from a process approach to regulation, and move toward a product oriented approach.

The DPC working group felt that placing all products created by recombinant DNA techniques under the same regulatory umbrella was misguided. As an example, the pseudorabies vaccine developed by Saul Kit at Baylor College of Medicine uses a modified virus missing a part of its genome. Because it incorporates no new genetic material, it may reasonably be treated just like any other altered vaccine. The working group takes the approach that it is only when genetic material from organisms of different genera are combined that special attention needs to be paid to the potential hazards of a new organism.

The new document, the Coordinated Framework for Regulation of Biotechnology, contains policy statements by all the major regulatory agencies involved in biotechnology. Because of the "mosaic" of statutes covering biotechnology issues, "the potential for confusion is enormous," says Kingsbury. To ameliorate this problem, the new framework proposes two new definitions as a basis for coordinating new regulations.

The Biotechnology Science Coordinating Committee (BSCC), made up of senior policy officials of agencies involved in biotechnology research and products, took responsibility for coming up with the definitions. An "intergeneric organism (new organism)" is one formed by "deliberate combination of genetic material from sources in different genera". A "pathogen" is defined to include microorganisms that "belong to a pathogenic species or that contain genetic material from source organisms that are pathogenic." Specifically excluded from both these definitions are organisms that are "well characterized and contain only noncoding regulatory regions." BSCC is considering expanding these exemptions, as well as defining more formally an environmental release.

A key accomplishment of the new framework is to sort out the overlapping jurisdications of the various federal agencies involved in biotechnology regulations. The framework attempts where possible to identify the single agency having responsibility for a single product, but where overlapping jurisdictions arise, the lead agency is identified. Kingsbury, as chairman of BSCC and DPC working group, will be the *de facto* arbiter of disputes over jurisdiction.

While sorting out overlapping jurisdictions between agencies was a major accomplishment for the DPC working group, jurisdictional issues also cropped up within the agencies. At the US Department of Agriculture (USDA), disputes arose between the science and education division and the marketing and inspection services over review issues.

One upshot of the disputes was the creation of an Office of Agricultural Biotechnology to keep track of all items either reviewed for licence or proposed as research. In addition, the Agriculture Recombinant DNA Committee (ARC) is being disbanded; an Agricultural Biotechnology Recombinant DNA Advisory Committee will now assume responsibility for review of all research projects.

Although the new framework represents a step forward in coordinating federal policy, some worry that the regulatory system is still chaotic. Quick to acknowledge the magnitude of the task Sue Tolin, co-chair of the USDA ARC, is unconvinced that the new framework will sort out all the regulatory tangles now confronting biotechnology research firms. She points to a discouraging catch-22 situation; to prove organisms are safe, they must be tested, but before they can be tested they have to be proven safe.

Meanwhile, the first attempts at actually field-testing a genetically engineered organism are still running into problems. The Environmental Protection Agency declined to issue an experimental use permit to Monsanto to test two strains of *Pseudomonas fluorescens* containing a gene insertion of a toxic gene from the microbial insecticide *Bacillus thuringiensis*. The agency wants to see additional data on the organisms' environmental impact and short-term pathogenicity.

Joseph Palca

Chernobyl

British embassies turn monitors

AN attempt at comprehensive monitoring of the radioactive fallout from the Soviet nuclear accident at Chernobyl has been carried out by British embassies in European capitals bordering the Soviet Union. A statement put out last week by the National Radiological Protection Board and by the Foreign and Commonwealth Office (FCO) suggests that contamination is greatest in north-east Poland, Czechoslovakia and Hungary.

The FCO statement says, however, that the contamination of local foodstuffs is nowhere high enough to suggest that travellers to those parts of Europe would receive "more than a fraction" of the annual dose limit for members of the general population. The statement adds that travel to Kiev and the western Ukraine, and to Minsk and Byelorussia, should be avoided if possible, but that simple precautions (such as the avoidance of fresh milk and leaf vegetables) would be sufficient elsewhere in the Soviet Union and Eastern Europe.

The use of the network of British embassies as a means of monitoring fallout from Chernobyl was made possible by the supply of simple equipment immediately after the accident. According to figures accompanying the statement, the dose-rate at Kiev, south of Chernobyl, had fallen from 30 to 2 microsieverts an hour between the period immediately after the accident and 14 May. Elsewhere in Eastern Europe, the highest dose rates recorded by British embassies were in north-east Poland (4.5 microsieverts an hour) and Romania (3.6 microsieverts an hour), but these had fallen to 0.8 and 0.9 microsieverts an hour by 14 May.

By comparison, the estimated radiation dose rate due to natural causes (cosmic rays, radon and internalized natural radioactive species) is generally taken to be 2 millisieverts a year at normal altitude and in mid-latitude, roughly the equivalent of 0.5 microsieverts an hour. □

British universities

Further contraction ahead?

BRITISH universities were last week divided in their estimation of what the future holds. The replacement as Secretary of State for Education and Science of Sir Keith Joseph, who has retired from the government, by Mr Kenneth Baker, previously Secretary of State for the Environment, was generally regarded as a sign that the government may change course on the continued contraction of the university system. But the letter to universities from the University Grants Committee (UGC) has confirmed others in the belief that deprivation will continue.

Mr Maurice Shock, chairman of the Committee of Vice-Chancellors and Principals (CVCP) and vice-chancellor of the University of Leicester, in a fierce statement after the publication of the UGC letter, said that the present gap between the universities' needs and the total recurrent grant from UGC amounts to 4 per cent of the total budget, not merely the 2 per cent of annual income estimated by UGC. That estimate, he said, had been made in "far-off, happy, dreaming days". Now, "you can forget about 2 per cent".

The worsening of the immediate financial prospects for the British universities has come about for several reasons, most of them outside the control of the universities themselves. One is the unexpected increase in the amounts universities have to pay as rates (local authority taxes), which have risen for the university system as a whole by 13 per cent as a consequence of government policies on central subventions for local government.

The cost in the present financial year amounts to £15 million for all the universities, roughly 1 per cent of their total cost. Shock said last week that if the British government wished to give an earnest of its intention to deal more generously with the universities (see *Nature* **321**, 370; 1986), as promised by Sir Keith Joseph in his pre-retirement statement to the House of Commons, it should make good this shortfall.

Academic salaries (which account for 70 per cent of academic costs) have become another issue between the universities and the government, chiefly because the university budget for the coming year has been drawn up on the assumption that salaries would increase only in line with inflation, itself supposed to be 4 per cent a year, while the government has just concluded a pay settlement with its civil servants that will give them more than 6 per cent a year.

CVCP's pessimism is borne out by the details given in the UGC letter of subventions for universities in the year 1986-87 (which begins on 1 August). By that time, UGC says, it will have become apparent that the university system will have fallen back during the year, relative to inflation, by about 3.5 per cent and that in future the shortfall will exceed 2 per cent in each year.

This year's letter to universities is of particular interest in that it is the first in which UGC has based its allocations on a deliberate assessment of the quality of individual institutions both in research and in quality of teaching. Over the succeeding three years, the proportion of the total UGC budget (£1,213 million in 1986-87 after deduction of rates and other special amounts) likely to be redistributed between institutions to allow for differences in research output is expected to amount to 15 per cent. But in this first year of the new regime, the consequences of these judgements have been limited to variations of between 1 and 3 per cent in the grant to individual universities.

The result is that it is not possible to tell from the figures published last week which universities are likely to prosper in the coming years and which will be in danger of extinction. Two newer universities (Warwick and Bath) do best out of the allocation, with grant increases between this year and next of 4.0 per cent and 3.6 per cent respectively. Oxbridge marks time (the Cambridge budget goes up by 0.7 per cent between this year and next, that of Oxford is unchanged). Universities such as Essex and Hull, the business schools and the Welsh university colleges will have their budgets cut by 0.5 per cent between this year and next, but a full explanation will be apparent only when individual letters are sent to universities early this week.

The prospects for an improvement of the situation turn entirely on a proposal in Sir Keith Joseph's final statement that there should be talks between the universities and the government on the financial situation, and the promise that extra funds would be made available to universities able to demonstrate that they had met certain objectives, not yet clearly defined. Will Mr Baker be able to put flesh on the bare bones of this promise?

Yellow rain

British analyses find no toxin

THE British government last week disclosed that attempts to find traces of mycotoxins in samples of yellow rain from South-East Asia have yielded negative results. In reply to a question from Mr Leo Abse, Member of Parliament for Pontypool, on 19 May, the Ministry of Defence acknowledged what has been widely rumoured for some time, that the British work so far has failed to confirm reports from US laboratories of the presence of trichothecene mycotoxins collected from Laos and Cambodia.

It is understood that the British investigations have been carried out at the Chemical Defence Research Establishment of the British defence ministry at Porton in Wiltshire. Samples of yellow rain collected from South-East Asia were supplied by the US authorities. The British laboratory was involved in a collaborative study of the composition of yellow rain after the first allegations in 1981 by the US State Department that yellow rain was an agent of chemical warfare were followed by reports of mycotoxins, notably by Dr J. Mirocha of the University of Minnesota.

The British government said last week that the Porton laboratory has analysed a number of "environmental and biomedical samples" from South-East Asia "to see whether trichothecene mycotoxins could be detected". Noting that the absence of positive results is "not necessarily incompatible" with positive findings elsewhere from different samples, the statement nevertheless says that "we are confident" that the techniques used at Porton would have detected mycotoxins had they been present in the "alleged chemical warfare" samples available.

The statement by Mr John Stanley, Minister of State for the Armed Forces at the Ministry of Defence, went on to say that, in spite of the negative findings in the analysis is at Porton, the British government believes that "chemical warfare attacks probably did take place in South-East Asia" on the basis of "epidemiological evidence". He added that the British government is unable to say what agent may have been used in those attacks, or who may have supplied it.

In reply to one of the points raised by Mr Abse, the British government said its investigations "neither support nor contradict" the suggestions made chiefly by Dr Matthew Meselson of Harvard University that drops of yellow rain of the kind reported from South-East Asia are indeed the faeces of bees.

The British government's statement is important because of repeated suggestions from the United States that the British measurements confirm the positive findings in some US laboratories. The "epidemiological evidence" referred to in the government statement presumably refers to reports of mycotoxins in the blood of members of the Hmong population of Laos and Cambodia who have reported being attacked by chemical agents in the form of yellow rain.

US research control

Professional societies still at sea

Washington

DESPITE the attention given in recent years to restrictions imposed by the US Department of Defense (DoD) on foreigners' access to technical meetings, professional societies still differ widely in their policies on the sponsorship of closed or restricted sessions.

According to the committee on scientific freedom and responsibility of the American Association for the Advancement of Science (AAAS), many societies apparently deal with DoD in an *ad hoc* fashion. Fewer than half of 45 technical societies affiliated to AAAS that responded to a questionnaire have adopted policies dealing with the question, but those that have generally favour prohibiting restricted-access sessions.

Government policy on open communication has been subject to several revisions in recent years. Recently, controversy has focused not so much on security classification as on export controls used to prevent access by foreigners to unclassified research results. Last October, the White House issued a security directive stating that the administration intended to use only security classification to control access to fundamental research data, to the general approval of the research community. But the imposition of export controls on meeting sessions for limiting access to applied research remains contentious.

Several important scientific societies, including the Institute of Electrical and Electronic Engineers (IEEE), have said they will not sponsor such sessions under any circumstances. Foreigners sometimes voice the suspicion that such controls are imposed more to give US industries a competitive advantage than to protect national security.

The 45 affiliated societies responding to the questionnaire were selected for their interest in subjects likely to be militarily important. Forty per cent had adopted policies on restricted sessions, almost half of them within the past five years; two-thirds of those with explicit policies restricted or closed meetings. The report concludes that if more societies were to adopt formal policies, these would probably prohibit closed sessions.

A total of four societies had actually experienced "problems" with access by foreign participants in the past three years, one of them more than five times. A separate survey of 24 technical societies not affiliated with AAAS drew only 8 responses; 5 of these societies had experienced problems with access by foreigners to meetings. The AAAS report suggests that the response rate of the non-affiliated societies was poor because the subject is politically sensitive.

DoD's most recent proposal on the subject was in a *Federal Register* notice on 12 February (p.5210). DoD responded to professional societies' concern by undertaking to complete security reviews of the research it sponsored in not more than 30 days, except in "rare and exceptional" cases. DoD also informally undertook in meetings organized by IEEE to ensure that security reviews would be conducted by scientifically qualified personnel, rather than by security inspectors who would "see one key word on a page and classify the whole thing", according to one IEEE negotiator.

The February statement did, however, stir already muddy waters by appearing to contradict the October White House directive on fundamental research, declaring that DoD policy is to allow the publication of unclassified fundamental research only "to the maximum extent possible". But the October security directive definitely still stands, according to Leo Young, director of research and laboratory management in the Pentagon's office of research and advanced technology.

Young said his office had erred in not making this clear in the February statement, but, he said, the great majority of responses from societies to the proposed policy had been favourable. Young said he hoped societies could avoid holding export controlled sessions, but that some, such as the Society of Photo-optical Instrumentation Engineers, were likely always to be in sensitive areas, and that it was up to them whether or not to restrict sessions at their meetings by the use of the export controls. **Tim Beardsley**

Ethiopia

Brief respite from famine

Addis Ababa

IT is now raining in Ethiopia, and much of the country has turned green as a variety of arable crops and pasture have begun to grow again. But this has not chased away the general belief that Africa is a continent in crisis. Dr Mostafa Tolba, executive director of the United Nations Environment Programme (UNEP) based in Nairobi, Kenya, is planning to use the special meeting of the United Nations in New York from 27 to 31 May as a chance to emphasize that the current problems of Africa stem from the underlying deterioration of the African environment.

In Ethiopia, the drought and subsequent famine of 1984–85 has been the focus of attention, but the underlying question is why the ill-effects of the drought were so serious. There were at least eight serious droughts earlier this century, but none of them had such disastrous consequences.

The rapidly expanding population concentrated in the highlands of the east is one of the most conspicuous problems. The traditional pattern of settlement is that of a regular distribution of homesteads across the cultivated areas, but the density is now so high that the marginal land on the steep slopes of the mountains and precipitous river gorges has also been cleared and settled.

One consequence is that the loss of traditionally dense forest to firewood and building lumber has been enormous. In twenty years, the proportion of wooded land has fallen from 16 per cent to about 3 per cent. The result is increased erosion of the soil whose capacity for water retention is itself reduced. At the same time, UNEP officials say, the productivity and drought resistance of the land is falling, which puts pressure on subsistence farming especially when the preferred crop (teff) is lower yielding, less drought-resistant and requires more work than near-equivalents such as millet.

The vulnerability of the land to drought is made worse by poor communications and the preoccupation of the government with rebellions in at least three regions. Referred to as "structural problems" by Commissioner Tadesse of the Government Relief and Rehabilitation Commission, their significance is not underestimated. But the continuing internal conflicts make the outcome for the next drought look bleak.

Similar environmental problems in other African countries led governments to attend the first African Environment Conference, organized by UNEP, the Organization for African Unity and the Economic Commission on Africa, held last December. The outcome has been an increased awareness of the seriousness of environmental deterioration and a strong commitment to cooperation in obtaining the best possible assessment of problems such as desertification and water use to provide a reliable basis for appropriate development.

Although the piles of wheelbarrows now accumulating in the distribution centre of the aid agency, Worldvision, in Wallo region attest to the changing emphasis as the current crisis passes, any major reversal in the trend of environmental deterioration will require an awareness at all levels of the importance of the problems and the enormous collaborative effort required to tackle them. **Nigel Williams**

Japan

Another academic city planned

Tokyo

PLANS are being laid for a large-scale academic city in the Kansai area of Japan. It is hoped that the city will be approved as the region's next giant construction project following the completion of the new international airport at Osaka. Its proponents do not see it as a rival to Tsukuba Science City near Tokyo; it will aim more at basic research and cultural activities than Tsukuba, which is dominated by government research laboratories.

Two thousand five hundred hectares of land have been set aside for the city where the prefectures of Kyoto, Osaka and Nara meet. The location is within 30 km of Kansai's major cities of Kyoto, Osaka and Kobe with their large state universities, and the ancient capital of Nara.

The region also contains the headquarters of a number of Japan's high-technology companies, including several of those involved in research in biotechnology and new materials, and many are proud of being "Kansai" as against "Kanto" (Tokyo zone) companies. Contributions from companies and relocation of their research institutes could very significantly help construction of the new academic city.

The nucleus of the city is at present contained in the "International Institute for Advanced Studies", the only part of the city that has passed from a dream to a reality. The institute was set up, in name at least, in 1984 on the initiative of two former presidents of Kyoto University, Professor Azuma Okuda and Professor Michio Okamoto, a member of the Prime Minister's Council for Science and Technology and head of the Extraordinary Reform Council for Educational Reform.

Since then, the institute has successfully passed through its "phase one": raising a capital of 133 million yen ($830,000), largely from Kyoto-based companies, to establish a foundation and open an administrative office. Now it is well into "stage two" in which 3,000 million yen ($18.7 million) is being raised to endow the foundation and to allow construction work to begin. With luck the institute will be built and running in five years' time. It was conceived after the study of succesful advanced studies institutes elsewhere, notably those at Aspen and Princeton and the Rockefeller Institute, as well as other unique research institutions, including the Research Triangle Park of North Carolina and the Cavendish Laboratory (*Nature*'s issues of 1874 providing a record of its establishment).

As in other advanced studies institutes, the aim will be to invite "the foremost scholars of the world" to come and work there for periods of a few years at a time. Early plans for the institute suggest it will provide an exceedingly pleasant environment: Japanese-style buildings containing guest houses, seminar rooms and dining halls are to be laid out in parkland and connected by the covered corridors found in temples and traditional houses.

The Advanced Studies Institute has in fact already begun activities with the sponsorship of international seminars in Kyoto on artificial intelligence and biosciences. More seminars, centred on scholars invited from abroad, will take place until the institute can assume its full functions.

Several other new facilities may serve as kernels for the academic city. Among them are a new branch of the National Library; a new graduate university, linked to the joint-use university research facilities like those at Okazaki; and a new laboratory for basic research in electrocommunications to be run jointly by the Ministry of Posts and Telecommunications and the newly privatized Nippon Telegraph and Telephone Corporation. These are, at least, possibilities that are being pursued; whether they can be turned into realities remains to be seen.

Those supporting plans for the new academic city believe it will be complete within 15 years. But there remain differences of opinion about its final form. There are some in the universities nearby who see it as a chance to relocate existing departments requiring expansion or renewal, or to bring together related institutes from different universities in the areas.

Others see the creation of a new academic city as a chance to break free from restrictions in the Japanese university system and to create a new style of institute, where deficiencies perceived in Japan's basic research contribution can be rectified.

Alun Anderson

Synchrotron sources

Stanford versus Argonne?

Washington

WITH pressure on the big science budget likely to increase in coming years, gentlemanly competition seems imminent over a proposal by the Stanford Synchrotron Radiation Laboratory (SSRL) to expand material research facilities at one of its electron storage rings. Recent experiments with the ring have been so successful that adding more beam lines might reduce the need for a future 6 GeV synchrotron coveted by Argonne National Laboratory.

The PEP (Positron Electron Project) ring at Stanford, generally agreed to have been something of a disappointment, was originally used for high-energy physics experiments, but with the impending completion of the Stanford Linear Collider (SLC), particle physicists have rather lost interest in it. In its heyday, PEP had five beam ports for high-energy physics experiments, but this figure is now down to one.

PEP might, however, be ideal for materials science measurements with synchrotron radiation if suitable beam ports and insertion devices were installed. For this purpose, the ring has to be run in a low-emittance mode. Although not designed for such a purpose, the machine excelled itself when low trials were conducted in March this year, reaching emittances close to those intended for the planned 6 GeV machine. It can reach energies of up to 8 GeV at low emittance, and if it were turned over exclusively for synchrotron radiation studies, 20 or more beam lines could be installed, according to Arthur Beinenstock, director of SSRL.

The Department of Energy (DoE) is indeed this week reviewing a proposal from SSRL to add three more beam lines to PEP, bringing the total to five. The proposal observes coyly that the existing beam lines have demonstrated "an emittance and dynamic aperture comparable to other potential storage rings presently being evaluated". The ring's long straight sections make it ideal for adding insertion devices such as undulators and wigglers.

The proposal to build a 6 GeV synchrotron radiation facility at Argonne by 1992 at an estimated cost of $300 million has not yet received the offical go-ahead from DoE, although its 1987 federal budget request includes some funds for preconstruction research and development. For the time being, extending the radiation facilities at PEP is being considered just as a means of paving the way for the dedicated 6 GeV machine, according to Lou Ianniello of DoE's office of basic energy sciences.

But Don Stevens, deputy associate director, adds that "it's a valid question" to ask whether an expanded PEP might not now be able to do all that the 6 GeV machine could do and one that "will have to be addressed".

Others are not so impressed. Ken Kliewer, who heads the 6 GeV project at Argonne, says that a dedicated above-ground machine could have up to 60 beam lines, and "Stanford can't match that". Kliewer thinks it unlikely that DoE will approve adding 20 or even 10 beam lines at PEP, in part because of the expense of necessary underground tunnelling.

Tim Beardsley

French reactors

Near-catastrophe at Le Bugey

A FRENCH pressurized water reactor (PWR) at Le Bugey on the Rhône river, not far from Geneva, came very close to a serious nuclear accident in 1984 after the failure of a single electrical component, a rectifier, it was claimed last week in the French satirical weekly, *Le Canard Enchainé*. The French national utility, Electricité de France (EDF), and the atomic energy commission, the Commissariat à l'Energie Atomique (CEA), immediately held press conferences and admitted that the satirists were right.

There had been no cover-up, insisted Pierre Tanguy, head of safety at EDF, in a telephone call from Paris; a press release had been issued at the time, but "there had been no Chernobyl incident" to sensitize the media to nuclear issues.

What took place on the night of 14 April 1984 on the five-reactor site at Le Bugey, however, showed how a "very minimal failure" in a control circuit can give rise to a major incident, said Tanguy.

The event began with the failure of the rectifier supplying electricity to one of the two separate 48-V direct-current control circuits of the 900-MW reactor, which was on full power at the time. Instantly, a battery pack switched in to maintain the 48-V supply, and a warning light began to flash at the operators in the control room.

Unfortunately, the operators ignored the light (if they had not they could simply have switched in an auxiliary rectifier). According to Tanguy, the same light served three warning systems (to save space on the control panel). The installation on one of these other circuits had proved faulty a few days before, and the light had been flashing intermittently. It was marked down for repair, and ignored when it began correctly to signal the rectifier failure.

What then happened was something which had been completely ignored in the engineering risk analysis for the PWR. The emergency battery now operating the control system began to run down. Instead of falling precipitously to zero, as assumed in the "all or nothing" risk analysis, the voltage in the control circuit steadily slipped down from its nominal 48-V to 30-V over a period of three hours. In response, a number of circuit breakers began to trip out in an unpredictable fashion until finally the system, with the reactor still at full power, disconnected itself from the grid.

The reactor was now at full power with no external energy being drawn from the system to cool it. An automatic "scram" system then correctly threw in the control rods, which absorbed neutrons and shut off the nuclear reaction. However a reactor in this condition is still producing a great deal of heat — 300 MW in this case. An emergency system is then supposed to switch in a diesel generator to provide emergency core cooling (otherwise the primary coolant would boil and vent within a few hours). But the first generator failed to switch on because of the loss of the first control circuit. Luckily the only back-up generator in the system then did switch in, averting a serious accident.

A report of the whole sequence of events was distributed through the Organisation for Economic Cooperation and Development (OECD) "incident reporting system", said Tanguy, and PWR constructors and operators got together to consider the implications of the incident. "It drew everyone's attention to the possibility of a complete blackout of a nuclear plant", and was probably "the most significant event in relation to safety in a PWR" that has occurred.

The Three Mile Island incident, where operator error led to the venting of primary coolant and the ultimate collapse of the core of the reactor, realerted utilities to the well-known dangers of "loss of coolant accidents", or LOCAs; and so much attention has been paid to those that the danger is now minimized, according to Tanguy. But the Le Bugey incident shows that a whole new class of possible events had been ignored — those where electrical systems fail gradually. It shows that "risk analysis must not only take into account a yes or no, working or not working, for each item in the reactor, but the possibility of working with a slightly degraded system".

Such analysis, involving continuous in place of discrete variables, is very difficult. The French reaction had been to undertake such studies where possible, but also to introduce voltage monitors on critical circuits, to make sure that electrical values stayed within the ranges assumed in the discrete risk analysis.

Other measures taken since Le Bugey have been to introduce a single gas turbine generator that can be started up "within minutes" on each reactor sites, to maintain power to control and safety circuits, and to lay physical cable connections to allow a rapid emergency interconnection of generators between one reactor and another on each site if this proved essential. The critical "three warning system" lights in the control room have also been separated into multiple lights and circuits.

The occurrence of the unpredicted Le Bugey and Three Mile Island incidents had led to a lower probability of such events occurring again Tanguy's view is that accidents were inevitable, but with experience they become less and less likely. Which is why it is essential to learn every detail about what happened at Chernobyl. **Robert Walgate**

Biotechnology companies

T cells' turn to ride high

Washington

ONE of the more unusual new biotechnology companies, T Cell Sciences of Boston, made its first public stock offering last week, raising $12.6 million to continue its development of diagnostics and therapeutic agents focusing on T-cell receptors, in particular the T-cell antigen receptor. The company, founded two years ago by Dr Patrick Kung, has sewn up collaborative research agreements with many of the most prominent US research groups working on T-cell receptors, a remarkable feat given that basic understanding of the subject has been achieved only in the past two years.

The company, which now has about 30 employees, has centred its efforts on developing monoclonal antibody-based products that exploit the correlation of T-cell receptors and disease states. Its one current product (for research only) is ACT-T-SET, which is intended to distinguish chronic and acute immune disorders by assessing immune system activation through expression of very late antigen and interleukin-2 receptor.

Diseases that might be diagnosed through characterization of T-cell structures include various leukaemias, autoimmune diseases such as rheumatoid arthritis and systemic lupus and, perhaps, some cancers and acquired immune deficiency syndrome. Monitoring of the immune system for transplant rejection is another area where the company hopes to develop products. Later still, therapeutic products may be devised that would activate and control the immune system.

T Cell Sciences has a $4.7 million research contract with Syntex Corp, and has licensing agreements with Ontario Cancer Institute, California Institute of Technology, Dana-Farber Cancer Institute and Stanford University, among others. Jim McCamant, editor of *Medical Technology Stock Letter*, comments that T Cell Sciences seems to be typical of a trend in which biotechnology companies are increasingly basing themselves on more speculative ideas and basic science, as the obvious technologies have already been adopted by the larger companies. Nevertheless, according to McCamant, the degree to which T Cell Sciences has established collaborations with major research groups makes it unusual, and means "you have to take it seriously". **Tim Beardsley**

East European nuclear power

Bloc countries think again

THE Soviet Union's Comecon partners have responded to the Chernobyl disaster, predictably, by endorsing the Soviet line that Western commentators have overdramatized the danger of nuclear power for political motives. While, as a result of the accident, Finland has cancelled its fifth and Yugoslavia its second nuclear power plant, the Comecon allies have spoken up firmly in favour of nuclear power. Czechoslovakia, Cuba and East Germany have been particularly vocal.

Within the bloc, the only indirect official criticism of Soviet and Comecon nuclear policy came from Hungary's chief spokesman on Foreign Affairs, Mr Matyas Szueroes, who publicly urged the "inalienable right" of all people to knowledge in all matters which concern them, and the duty of all concerned with science and technology to respect public fears and concern, whether or not those fears were justified, a statement widely interpreted as a hit at Soviet reticence on the consequences of Chernobyl.

Poland, which caught the first phase of fallout from Chernobyl and which is at present building its first nuclear power station at Zarnowiec, is a special case. Clearly, after implementing a mass distribution of iodine pills to under-16s, ordering cows to be kept indoors and destroying contaminated vegetables, the authorities could hardly proclaim that nuclear power was without any hazard. Official statements have therefore urged that the Chernobyl accident will make the Polish authorities "additionally aware of improvements to all safety measures", and that in any case, the Zarnowiec reactor will be of the pressurized water type, quite different from that at Chernobyl, and will have, unlike reactors in the Soviet Union, a containment building. These assurances have clearly not been sufficient. Three thousand citizens of Bialystok, close to the eastern frontier of Poland, the area most affected by the initial fallout, have signed a petition to the Sejm (parliament) asking for the Zarnowiec plant to be cancelled, and five scientists working in nuclear physics and related fields have sent an open letter to the Minister of Energy, General Czeslaw Piotrowski, calling for more stringent safety tests at Chernobyl. At his regular press conference last week, government press spokesman Jerzy Urban said that he knew nothing of these documents.

Dissident opinion in Eastern Europe has been somewhat divided on the issue of Chernobyl. In Poland, some small anti-nuclear protests took place on 1 May and 3 May (Constitution Day), and underground Solidarity newsletters have attacked the reluctance of the Soviet and Polish governments to publish sufficient details. (The Polish government, in fact, has been fairly open with contamination statistics, at least at the international level.) In Czechoslovakia, the Charter-77 movement likewise put out a statement urging the public's right to be fully informed. But in Hungary, the "green" dissidents of the Danube Circle declined to comment, noting only that the hazard of accidents at nuclear power stations was in their opinion less of a threat to the environment than the Gabcikovo-Nagymaros hydroelectric project which would disrupt the ecological balance even when it was working properly. And in the Soviet Union itself, although there was some attempt to organize an anti-nuclear protest last week in Moscow, no less a person than Academician Andrei Sakharov has backed up the official Soviet line. Sakharov, whose place of enforced residence, Gor'kii, will be the site of the first joint power/district heating nuclear plant in the Soviet Union, said last week, in a message to his relatives in America, that he still viewed nuclear power as inherently the best option. Western reporting in Chernobyl, he said, echoing the official Soviet statements, has been considerably exaggerated. **Vera Rich**

Correction

IN last week's News item about Dr Robert Gale's treatment of patients from the Chernobyl nuclear accident (*Nature* **321**, 369; 1986), the number of patients who received bone marrow or fetal liver transplants was incorrectly given as 35; the figure should have been 19. The estimated average radiation dose of the 35 patients Dr Gale examined is 2 Gy or more; the estimated average dose of the 19 who received transplants was 5 Gy or more. □

Chernobyl

Improvising against radiation

THE Chernobyl clean-up has demanded "non-standard" and "unexpected" solutions, Academician Evgenii Velikhov, Vice-President of the Soviet Academy of Sciences, told the Moscow journal *Ogonek* last week. But what are these solutions? The accounts in the Soviet press, which concentrate more on the heroism involved than the technical details, give the impression of a series of improvisations worked out after the accident.

According to Ivan Silaev, one of the deputy prime ministers of the Soviet Union, the cost of a Swedish decontamination fluid at $18.5 a kilogram was so high that a rush effort by Soviet scientists was necessary. By 14 May, production had reached 30 tonnes a day, allowing 300,000 m^2 of contaminated area a day to be coated with the material. Silaev also said, in an interview in *Izvestia*, that exposed surfaces of buildings were being coated with sodium silicate solution to prevent rainwater carrying contamination into the groundwater and to the river Pripyat.

Operations around the damaged reactor itself have been organized in typical Soviet style, with planned targets and campaigns to beat them. The miners drilling under the reactor have a target of five reinforcement rings installed per shift (giving a nominal rate of progress of 14 to 15 m a day, twice that of normal mining operations). Engineers from the Ministry of Transport are installing a liquid-nitrogen cooling system.

The damaged reactor seems to be cooling very slowly; on 6 May, the Ukrainian Prime Minister Aleksandr Lyashko said that the temperature had fallen to around 300°C, but ten days later, Academician Velikhov cited the same figure. Also, the "sarcophagus" being built around the damaged reactor is not a simple casing, but, according to Silaev, is a "complex engineering structure", which will "fully control the internal heat and release any excess".

Not only the damaged reactor, No.4, will be entombed in this way. According to Prime Minister Lyashko, the unfinished reactor No.5, where shoddy building operations had caused concern before the accident, is also to be buried.

Away from the reactor site, but still within the 30-km evacuation zone, some measures have been implemented to safeguard agriculture. By 13 May, barrages had been built to stop effluent or rainwater reaching the river Pripyat. The main problem is the contaminated soil, which is being dealt with mechanically, by digging it out, and by planting with crops that "neutralize harmful elements in the soil".

To deal with long-term contamination further afield, an aerological monitoring station has been established, some 50 km from Chernobyl, which will make round-the-clock measurements of the radioactive contents of the air, and relay aggregate figures to the International Atomic Energy Agency in Vienna daily.

Little has emerged about radiation levels near the plant. By mid-May, according to transport construction minister Vladimir Brezhnev, radiation was still too high to work more than a four- or at most five-hour shift near the reactor, while the youth Party daily *Komsomolskaya Pravda* spoke of the emergency workers receiving a year's maximum permissible dose in two weeks. **Vera Rich**

SERC failing astronomers?

SIR—As a senior member of the research staff of the Royal Greenwich Observatory (RGO), I found your News article "Observatory move stirs passions" (*Nature* **321**, 4; 1986) most interesting. At RGO I am somewhat of a "dove" about the move because I am concerned that a refusal to accept the decision of the Science and Engineering Research Council (SERC) in this matter, particularly on political grounds, could in the long term be bad for UK science. It may be better to accept a bad decision made by scientists now, in the hope of good decisions by scientists in the future, than to give ourselves over to overtly political decisions for ever.

Why does the decision seem so bad and arouse so much passion? Primarily because the stated reasons make no sense and are widely perceived to be a cover for a cost-cutting exercise. Placing RGO in a more stimulating academic environment is a worthy goal, but it would command more credibility if the actions of SERC over the past few years (an overall rundown at RGO, a further cut of our research in favour of a support role and failure to support efforts to strengthen the existing link with the University of Sussex) were consistent with this objective.

The expectation that the move can be self-financing also seems questionable. How can it be self-financing compared, for example, to the unexplored option of selling the castle and grounds at Herstmonceux while retaining the observatory, which is mostly in a modern office block in one corner of the property?

Thus most people believe that the move is an administrative device to cut costs in optical astronomy to free funds for new activities. They are reinforced in this belief by the rundown of RGO over recent years and the failure of SERC to place any of its New-Blood positions in university departments specializing in optical astronomy (only fifteen went to astronomy as a whole).

Thus, as an optical astronomer who believes in the importance and intellectual validity of my subject, I was opposed to the decision for exactly the same reasons as it seems to be attractive to SERC.

I do not believe that there is any wickedness involved in the decision or the under-appreciation of optical astronomy; simply muddle. Two more examples of SERC's confusion appear in your article. First, the publication of the results of the poll of staff in RGO about the move: the survey was co-sponsored by the RGO staff side who had the privilege of seeing them for the first time in your pages. Second, the gymnastics by Harry Atkinson as portrayed in your final paragraph suggest that political considerations (at least of a regional nature) are indeed part of SERC's desiderata.

I am sorry to say that all this makes my stated support of SERC's decision pretty thin. What is needed to get SERC off the hook is an independent review as sought by the East Sussex County Council and preferably along scientific lines. I propose as chairman of this review the vice-chancellor of the University of Sussex, Sir Denys Wilkinson, who should be joined by a world-renowned foreign optical astronomer and a leading representative of our own (non-political) astronomical community. Such a group might have the moral authority to persuade everybody to accept its decision.

It is clear to me, however, that the organization most in need of serious investigation is the Swindon headquarters of SERC. It has shown itself much more eager to control the minutiae of activities in its laboratories, such as RGO, than to try to bring new resources into (in particular) a pure science like astronomy. From my perspective, they have singularly failed me, and other active scientists whether in universities or in their own laboratories, in this regard.

MICHAEL PENSTON

Rose Lodge,
Magham Down,
Hailsham,
E. Sussex, BN27 1PR, UK

SIR—As representatives of the staff of the Royal Greenwich Observatory (RGO), we read with interest your analysis (*Nature* **321**, 4; 1986) of the current debate on the future location of the Observatory. Even though it is our lives and careers that will be affected by the outcome of this debate, we feel we are but pawns in the Science and Engineering Council (SERC)'s game. For example, SERC has refused to allow the report of the Kingman panel to be circulated among RGO staff, although it is obvious that members of the press and others have had copies. We also learnt of the results of the survey of RGO staff for the first time in your columns, and although this has been traced to an administrative bungle rather than a deliberate act, it demonstrates SERC's scant regard for the people who will be most involved. Staff have been asked to state their preferences, but in view of all that has gone before they wonder how much notice will be given to their opinions.

We have now received the results of the staff survey but interpret the numbers very differently from your informant. In the first place, the questions did not even mention the possibility of remaining at Herstmonceux. Almost all staff are strenuously opposed to *any* move and have said so consistently and vociferously from the outset. Had you been present when the chairman of SERC, Professor E.W.J. Mitchell, met staff at Herstmonceux on 1 May, you too would have been in no doubt of their views. Second, the apparently high percentage who preferred Cambridge accounts for only 40 of the 119 "mobile" staff (out of the present total staff of 190 or so): replies from "mobile" staff who said they would resign rather than move anywhere and from "non-mobile" staff who face redundancy as a result of any move, were excluded. Staff who said they would follow the observatory wherever it went were added to the Cambridge-first-choice group. Fifty-five of the 119 did not reply at all to the questionnaire (many because they were fearful that the results would be misused). What price statistics?

Our strong desire to remain in Sussex is not blindly reactionary. If we could be convinced that there were clear and quantifiable benefits to be gained from moving to a different environment, we would welcome the proposal and consider the arguments on their merits: instead we are offered grounds which the council's officers themselves describe as a "matter of judgement" and "intangible" which to us as scientists is just not good enough. RGO staff wish to participate fully in the bright future for ground-based astronomy which the present facilities offer. A futile move would place this future in jeopardy and we urge our many supporters in the astronomical community to convey their views to SERC before it is too late.

Ageism

SIR—Jürgen Neffe (*Nature* **320**, 295; 1986) writes: "Although now 74, von Weizsäcker's opinion is still influential in West Germany." The probably unintentional pejorative use of "Although now 74...." implies that the influence of an opinion should diminish with advanced age of the opiner.

This is an outdated, incorrect ageist myth. It is out of place in any publication intended to be a modern journal of science. I believe that an apology is due to Professor von Weizsäcker.

Paranormal theories

SIR—While accepting Marks' general remarks about the standing of research into the paranormal (*Nature* **320**, 119; 1986), I should like to comment upon some of his statements.

It is not true that there are "no theories to account for paranormal effects". In Bell's theorem and its refinements, in physics, we are confronted with a universe where local causality might not apply (for an entertaining discussion see Zukav, R. *The Dancing Wu Li Masters;* Fontana, London, 1984). This allows Jung's "synchronicity" and *psi* phenomena to be placed within a theoretical framework, although not suggesting a mechanism.

Theories such as those above are at the same time physical and metaphysical, as they question our basic concept of reality. It is not surprising that "believers" in the paranormal are resistant to change in their core constructs, and it seems trite to add that they have "significantly higher neuroticism scores". What does that prove? Is it Marks' view that these "millions of people throughout the world" are psychologically abnormal? One would assume that the whole review could be rewritten, with relevant changes, to cover "investigating God". Believers would, no doubt, react in a similar way, based on a similar "dearth of hard evidence".

In summary, I agree with Marks' conclusion that there have been no significant discoveries made by parascience, but I think that he need not have looked for psychological reasons for belief in the paranormal. As far as I can see (adjusting one of his phrases), scientific ideas will have little chance of affecting the magical thinking from which science itself evolved, because the fundamental mysteries remain.

M. COUCH
Department of Human Metabolism and Clinical Biochemistry, University of Sheffield Medical School, Sheffield S10 2RX, UK

SIR—In his Commentary, Marks[1] misrepresents the area he purports to review. A large part of the paper refers to religious and neurotic motives as explanation for the belief in the paranormal. However, similar psychiatric explanations are used to account for the need to deny these phenomena[2,3]. *Ad hominem* arguments lead nowhere.

As for Marks' more straightforward claims, they are indirectly based on a sample of works that is by no means representative. He relies on two reviews[4,5] that do not address themselves to the question of repeatability in general, but rather to the specific question of whether parapsychological research involving altered states of consciousness constitutes a repeatable paradigm. Thus, these reviews deal with a narrow group of experiments. For example, Akers[4] excluded all studies of highly selected subjects, thus considerably decreasing the overall significance of the results. Moreover, Hyman's[5] analysis is flawed, as Honorton has demonstrated in a response which followed Hyman's paper[6], and his methods were shown by a statistician to commit the very error that he criticized in the parapsychological studies[7].

Marks is quite right in pointing out that parapsychology has so far failed to produce a repeatable experiment. But it is misleading to use this as an argument against the credibility of parapsychological research. Marks fails to mention highly significant results of experiments that are characterized by extraordinary instrumental sophistication and methodological rigour, as exemplified by the recent work of R.G. Jahn of Princeton University[8], and the Maimonides Hospital dream researches[9–13]. These works, although not yet replicated, pose a serious challenge to the sceptic.

There are four counterhypotheses by which parapsychological findings can be explained away: (1) coincidence; (2) artefact; (3) self-deception; and (4) deliberate fraud. Now, the growing sophistication and rigour of modern psi research[14] is gradually ruling out the first three counterhypotheses. The fraud hypothesis (or, considering the present number of scientists involved in the field, the conspiracy hypothesis) remains as the only resort for the sceptic.

Psi or fraud? This is the real issue. Yet it is seldom presented unambiguously. Recently, Child[15] has thoroughly analysed the ways in which the above parapsychological works have been treated in the sceptical literature. He has shown that they were either ignored or grossly misrepresented, and that the resort to the accusation of fraud was often made implicitly. It is deplorable that Marks' review, written after Child's grave charges have been issued, commits the same errors.

Pesticide dangers

SIR—J. Gordon Edwards (*Nature* **320**, 391; 1986) has misunderstood Lord Ashby's review of *Pesticides and Nature Conservation: The British Experience 1950–1975* by John Sheail (*Nature* **318**, 21; 1985); I cannot believe that he has read the book.

I agree that members of the "loony left" of the conservation movement deserve J. Gordon Edwards' strictures, and I have myself criticized them for the past 30 years. But John Sheail's book describes the way in which scientific work in pesticides in Britain generally resulted in collaboration between industry, government and responsible conservation bodies, to introduce sensible controls of potentially dangerous chemicals. As director of the Nature Conservancy's Monks Wood Experimental Station at the time, I know that my colleagues certainly did not "resort to such unscientific methods as deliberately distorting or omitting all the data that refuted their allegations". The work has, of course, been published in reputable scientific journals.

Lord Ashby in his review implies that Rachel Carson's *Silent Spring* alerted the authorities and the public to the dangers of pesticides. That danger was already fully recognized, at least among scientists. In fact, in Britain the most important controls of pesticides that had been shown to have harmful ecological effects were introduced, with the fullest cooperation of the chemical industry, some months before *Silent Spring* was published.

Monks Wood Experimental Station, Huntingdon PE17 2LS, UK

Ling defended

SIR—The ill-natured and unnecessary sideswipe at Gilbert Ling (*Nature* **320**, 318; 1986) by Peter Newmark needs to be answered. Ling, "a physiologist... who remains a voice in the wilderness", is the man whose pioneer work with Gerard on intracellular potentials initiated just about all the advances in neurophysiology of the past fifty years. Is it possible that Ling knows something about cell interiors that his critics are missing?

As for the sodium pump, Newmark could consult our papers in *Nature*[1] which by some miracle escaped the greater excommunication. To my knowledge, no other papers critical of the peculiar and unlikely hypothesis of active transport "powered" by metabolic pumps have ever been accepted and published by either *Nature* or *Science*. Such unanimity in science is unreal.

Prehistoric ecology from pollen record

SIR—A "settlement gap" implied by the Weser estuary pollen records circa AD 500–700 does not pose "a fresh problem"[1], rather it supports an old conclusion. This is a protohistoric period significantly called the Migration Period (*Völkerwanderungszeit*) and virtually every settlement and cemetery in the western half of the Weser–Elbe "triangle" was abandoned in the first half of the fifth century, while those in the eastern half continued into the sixth century[2]. Mass emigration brought many of these people, who called themselves Saxons, to eastern and southern Britain. The artefacts buried in their new settlement and cemeteries here link directly back to the Weser–Elbe homeland.

There is no need to invoke plagues or other sudden catastrophes, for a steadily rising sea level left the coastal marshland settlements on their *Wurten*, for example Feddersen Wierde[3], without sufficient agricultural land and the inland settlements on the *Geest*, for example Flögeln[4], appear to have reached a point of marginal returns from their over-cultivated soils. The Venerable Bede summarized the historical basis for all this in the eighth century AD in Book I Chapter 15 of his *Ecclesiastical History of the English Peoples* and both archaeology and the environmental sciences appear to confirm his account.

Nuclear risks

SIR—After reading your leading article (*Nature* **320**, 384; 1986), the persecuted employees of the nuclear power business must wonder what they have to do to satisfy journalists and broadcasters. As I understand it, their industrial accident record, both in respect of injuries to their own operators and to the public at large, is among the best in either the fuel industries or the chemical industries, to which their activities have perhaps the closest similarity. What can you mean therefore by your reference to the "poor safety record of Sellafield"?

As to the supposed poor public relations activities, I am not sure that you and the press generally give them much attention. What can your victims do in the face of a persistent campaign based upon the supposed occurrence of dangerous accidents for which there appears to be no evidence, when that same lack of evidence is the basis for claims of secrecy and "cover-ups".

Is it not clear that the employee of the nuclear power business is, while at work, far less liable to accident or death than you are at the wheel of your car? Indeed, are not members of the public more at risk from you at the wheel of your car than they are from the nuclear power business? Drivers kill about 5,000 people each year in the United Kingdom, whereas handling radioactive products for nuclear fuels appears to kill nobody (not even, I believe, the shellfish living comfortably by that waste water outlet from Sellafield into the Irish Sea).

Velikovsky's evidence?

SIR—Your more perceptive readers may have been surprised to read in C. Leroy Ellenberger's letter (*Nature* **318**, 204; 1985) the statement, attributed to me, that "if a formerly very bright comet periodically altered the sky's brightness, then the dates of appearances and disappearances for Venus would be affected". Venus is such a brilliant object that variations in the brightness of the sky would make little difference to its setting and rising dates. "The debris from the disintegration of comet Encke 4700 years ago" might, of course, act indirectly by filling the stratosphere with enough dust to prevent Venus being seen near the horizon line. This would produce longer invisibility periods; but only in one year, or perhaps two separated by an interval corresponding to the period of the comet. It would not explain all the anomalies of the Venus Tablets.

With regard to the Velikovsky theory, archaeological evidence from Babylonian clay tablets has not verified the "Comet Venus" identification; but a large comet other than Venus, as deduced by Clube and Napier in their "Cosmic Serpent", is a possibility.

Plasma — the fourth state of matter?

SIR—J.N. Goldschvartz (*Nature* **320**, 302; 1986) basically asks "what is the fourth state of matter?". There is no debate about the first three phases of matter[1] — solid, liquid and gas. When a solid is heated, a liquid is formed, and when a liquid is heated it is transformed into a gas; a commonplace example is the progression from ice to water to steam.

When a gas is heated, that is, when additional energy is provided to the atoms or molecules, some of the electrically neutral particles can be split into electrons and positive ions. Such an electrically charged gas, a partially ionized gas, which overall is electrically neutral, is termed a plasma if it exhibits "collective" (jelly-like) behaviour[2] due to the long-range (on an atomic scale) electromagnetic forces acting between the charged particles.

Clemmow and Dougherty[3] say on page 1 that "the state in which there is an appreciable degree of ionization has indeed been called the fourth state of matter". Surely plasma should, unequivocally, be termed the fourth state of matter.

South Africa

SIR—In suggesting that South African scientists be required to sign a statement of political beliefs before their articles are considered by international journals or they themselves be allowed to attend overseas conferences (*Nature* **320**, 486; 1986), Masters, Caithness and Rayner respect neither science nor scientists. The quality of a work of science exists entirely within the work. Other requirements for publication or conference-attending are inherently corrupt and corrupting. And a man's political beliefs are nobody else's business unless he is a politician.

Bethesda, Maryland 20814, USA

A child's guide to radiobiology

The view that radiobiology (made fashionable by the accident at Chernobyl) is unknown territory is belied by the vast literature on the subject. But uncertainties persist.

FEW subjects can have been given as much attention in the past thirty years as that of the biological consequences of radiation. The explanation is simply that governments have felt it necessary to make independent assessments of the consequences for their populations of the bulk production of large amounts of artificial radioactivity, which became a live issue in the late 1950s with the testing of nuclear weapons in the atmosphere. The result is that there is no shortage of information. Public reaction outside the Soviet Union to the consequences of the Chernobyl accident has nevertheless provided further proof that to publish is not necessarily to spread understanding.

That radiation may be damaging has been plain for more than half a century, most vividly by the evidence of the damage accidentally done to occupational groups such as the sad cohort of workers in the US watch-making industry employed to paint the luminous dials of watches and who kept their paint-brushes moist by licking them. In the 1920s, the liability to injury of people working with X rays used for medical diagnosis and therapy was recognized by the fixing of a supposed safety limit for exposure, defined as ten per cent of the dose (in roentgens) required to cause a disorder of the blood-forming process in adults.

Now, as the limits have been steadily reduced for the allowable exposure to radiation for occupational and other groups, there is also a reductionist framework to explain the rationale of the dose-fixing regulations. But that does not mean that the uncertainties have been banished.

The agents of the biological damage are, microscopically, a mixed bag, whose effects are best described in language more familiar in high-energy physics. Charged particles such as alpha-particles are stopped in matter of all kinds, living or dead, by the ionization they cause, although there may be occasional nuclear collisions as well. X rays and more energetic gamma rays are also chiefly sources of ionization. Electrically neutral particles, neutrons for example, interact to a comparatively negligible degree with the electrons in the outer shells of the atoms through which they pass, but are capable of colliding with nuclei, which is the simple reason why neutrons are relatively more damaging, by the yardstick of the amount of energy deposited in irradiated material, than most other kinds of radiation.

Inanimate matter is not permanently damaged by radiation except to the extent that ionization of atoms and molecules may catalyse chemical reactions (which is why radiation may cause organic materials to polymerize) or that atoms may be displaced from their required positions by nuclear collisions (which is why irradiated graphite requires annealing).

Living cells are obviously more vulnerable. The mere deposition of external energy in the form of ion-pairs is an assault that may affect essential processes, killing damaged cells or, alternatively, like nuclear collisions at the wrong places in a vital molecule, causing mutations that, in somatic cells, may lead to cancer and, in germline cells, to genetic defects.

By what yardsticks should the potential of radiation for causing damage be assessed? In an ideal world, there would be two quite different bodies of information: first, a set of what physicists would call cross-sections to determine the chance that the passage of a particle (or photon) would set in train each possible biochemical process; and, second, a body of information about the biological consequences. Instead, there are two largely empirical sets of rules of thumb.

The equivalent of the set of cross-sections is the assumption that the damage done to a tissue by irradiation is proportional to the amount of energy deposited within it, whence the unit called the rad. The different components in a mixed source of radiation are weighted according to their "quality factors" to allow for the biological damage they do, by which process rads are translated into rems (for which the unit is the sievert).

Present practice will probably in due course seem crude. Because cross-sections are functions of energy, one would expect the quality factors of the same particles to be functions of energy as well. This point has emerged from analysis during the past few years of the incidence of genetic defects among the children of the survivors of the two bombs at Hiroshima and Nagasaki. Ultimately, no doubt, there will be different quality factors for the causation of genetic defect, cancer and more acute effects, and new units in which to measure them.

The other side of this coin, the numerical relationship of biological damage to its causes, measured as radiation doses, is inevitably more crude. Part of the trouble is simply biological: a genetic defect may show up as a fetus that dies *in utero*, and the biological consequences may be negligible in a population living within its reproductive potential. That is why the working yardstick since the Second World War has been the assumption that, whatever the quantitative relationships may be, the natural dose of radiation to which we are exposed is, by definition, one with which a species must expect to be able to live.

The assumption is natural but its form has changed. Thirty years ago, cosmic rays were supposed to be the chief source of natural radiation; most of the components of cosmic rays, being fast, penetrate the whole body and deliver a reliably calculable dose of radiation, 0.30 millisieverts a year. The effects of naturally occurring radioactive species such as those of potassium-40, have always been recognized as important, but radon-222 now accounts for as great a general radiation dose as the other two put together. On the average, individual exposure to radiation for people living near sea-level is 2 millisieverts a year.

To use natural exposure as a measure of the risks to which people are artificially exposed, it would clearly be necessary that there would be quantities (not necessarily constants of proportionality) relating damage to dose. But it seems unlikely that simple numbers will ever be found. Different kinds of cancer may be induced by radiation with differing efficacy; some genetic defects may be more likely than others.

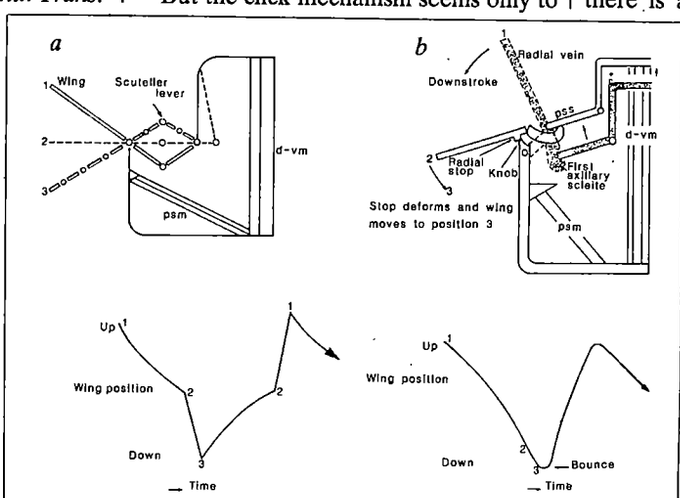
Complications such as these already have a bearing on some practical problems, especially where internally ingested radioactivity is involved. Although claims that the rate of genetic malformation among the children of people living near nuclear test sites in the United States, put forward by Dr David Sternglass of the University of Pittsburgh in the 1960s, have been shown to be statistically invalid, there is always a possibility that certain radionuclides may have biological consequences that are systematically underestimated by the measure in rems of the dose they deliver, perhaps because they concentrate in particular places. The difficulty here is that each investigation is a major undertaking, and that there are simply not enough people to go around.

John Maddox

Biomechanics

The flight of the dipteran fly

from H.C. Bennet-Clark



THE wing-beat frequency of flies in the order Diptera varies from 120 Hz in the larger species to more than 500 Hz in the smallest midges. These frequencies are far faster than can be maintained by conventional muscle, where there is one impulse per contraction. The flight muscles of dipteran insects are not excited synchronously in this way (Pringle, J.W.S. *J. Physiol., Lond.* **108**, 226; 1949) but vibrate at a far higher frequency. Attempts to model the processes in the dipteran thorax that cause flight have been based on a 'click' mechanism which can be elicited in anaesthesized flies. But recent experiments indicate that the click mechanism is an artefact and that the flight of flies *in vivo* involves a quite different mechanism (Miyan, J.A. & Ewing, A.W. *Phil. Trans. R. Soc.* B**311**, 271; 1985).

Early experiments by Pringle and others demonstrated that, when insect flight muscle is activated and subjected to rapid elongation, the subsequent response is a contraction after a brief delay and over a short distance. Thus, these muscles are stretch-activated and must be inserted in a skeletal system of considerable stiffness, with kinematics that provide an appropriate stretch to activate the antagonistic wing levator and depressor muscles at appropriate phases in the wing-beat cycle of the insect.

When flies are anaesthesized with CCl_4 they 'go under' with the wings either abnormally elevated or depressed. In this condition, with the wings in the raised position, the thorax can be squeezed longitudinally between forceps and the wings will then start to depress until, at about mid-position, they suddenly click into the fully depressed position. If the thorax is squeezed dorso-ventrally, the opposite slow movement occurs, followed by the click. This model mechanism (Boettiger, E.G. & Furschpan, E. *Biol. Bull. mar. biol. Lab., Woods Hole* **102**, 200; 1952) has two attractive features; it provides, at approximate phases in the wing stroke, stretch-activation for the major flight muscles; and, because of the geometry of the wing base, it automatically alters the angle of attack of the wing between the downstroke and the upstroke.

One snag with this model is that the wing should behave like a toggle switch (*a* in the figure). In such a switch, force on either upstroke or downstroke opposes movement until approximately mid-stroke and then reverses to act in the same direction as movement, to complete it with a snap. In practice, this is only seen in the CCl_4-anaesthetized flies: in normal flight, the wings of Diptera only decelerate near the top and bottom of the wing beat instead of in the mid-downstroke and again in the mid-upstroke. This simple click model has the deficiency that it does not take account of the force caused by the flight muscles, which tends to be maximal in the part of the stroke where maximal force has to be produced to overcome that resulting from the click mechanism.

But the click mechanism seems only to appear under CCl_4 anaesthesia, according to the recent work of Miyan and Ewing (*J. exp. Biol.* **116**, 313; 1985). In this special circumstance, the muscle that tenses the side of the thoracic box (psm in the figure) goes into such strong tetanus that the normal action of the sclerites of the wing base cannot occur — the click mechanism thus appears to be an abnormal artefact of the anaesthetic.

Wing mechanisms of a fly. The upstroke is provided by contraction of the dorso-ventral muscles (d-vm). *a*, In the classic click mechanism model, the wing is driven like a toggle switch and is stable in positions 1 and 3 and metastable at position 2. The spring force required for the click of the toggle is provided by the pleurosternal muscle (psm) stressing the elastic skeleton of the thorax. The movement expected from this mechanism is shown below: at mid up- and downstroke (2) the wing suddenly accelerates in the direction of movement. *b*, With the new radial wing stop mechanism, in the downstroke (1 to 2) the stop engages near the bottom of the stroke (2), slowing the downward movement and raising the top of the thorax via the first axillary sclerite and the parascutal shelf (pss). The wing then bounces off the elastic stop (3). The movement expected from such a mechanism is a slowing at the bottom of the stroke, with a subsequent rapid reversal of movement: that is what is observed in normal flight (see below).

What then does happen during the normal action of the dipteran thorax? In their new work, Miyan and Ewing studied in detail the thoraces of a dozen dipteran species, many of which were literally frozen in flight by being tipped into liquid nitrogen. They describe a stop under the base of the principal vein, the radius, which can engage on a knob at the crest of the side of the thorax (*b* in the figure). In the downstroke, when the wing stop engages, the inertia of the wing causes the outer part of the wing to bend downwards (seen in high-speed films of flight in many species) and, in addition, through the action of the first axillary sclerite and parascutal shelf in the wing base, causes a sharp lifting of the dorsal part of the thorax (*b* in the figure) which, in turn, stretches the dorso-ventral muscles to activate them for the ensuing upstroke. The wing is accelerated upwards only at the very start of the upstroke, probably because of the elastic recoil off the radial wing stop, and thereafter swings with nearly constant angular velocity, as would be expected if there is a steady torque caused by the flight muscles (but which is against the predictions of the click mechanism) until the wing decelerates at the top of upstroke and then starts the downstroke (*b* in the figure). Vortex shedding at the bottom of the wing stroke will be enhanced by the rapid change of wing direction and angle of attack that the radial wing stop allows, which is compatible with the analysis of the unsteady-state aerodynamics in the flight of small insects made by T. Weis-Fogh (*J. exp. Biol.* **59**, 169; 1973). It is not clear whether there is a special mechanism at the top of the upstroke to snap-stretch and activate the muscles involved in the downstroke.

The older click mechanism model also allows the amplitude and/or frequency of the wing beat to be increased by contraction of the pleurosternal muscle (psm in the figure) increasing the spring force produced between the side of the thorax (at the outer wing hinge) and the inner, complex, wing hinge attached to the dorsal part of the thorax. The prediction from the click mechanism model is that this would act symmetrically on both the upstroke and the downstroke, but what is in fact observed is an asymmetrical effect, mainly affecting the downstroke, which can now be explained partly by the larger size of the dorsal-longitudinal wing depressor muscles compared with that of the dorso-ventral wing depressor muscles.

Miyan and Ewing also address the prob-

lems of control of the plane and form of the wing beat by the various skeletal and muscular elements. Their description of the action of the sclerites in the wing base allows both the continued beating of one wing when the other is folded back, as seen in the rapid turning of bluebottles, and also fine control of wing twisting, neither of which is easy to explain using the old model. These manoeuvres are effected by contraction of various of the 17 distinct, normally activated, non-fibrillar muscles in each side of the thorax. The system is amazingly complex: the wing base is the region at which the stresses are highest but it allows both control of the wing beat and the wing to be folded back, both when the insect is at rest and when the other wing is beating. □

Nuclear magnetic resonance

Protein structure determination

from Wolfgang Kabsch and Paul Rösch

ONE of the most fruitful areas of biophysics is the elucidation of the three-dimensional structures of biologically active molecules such as proteins and nucleic acids in atomic detail. These investigations have brought a wealth of new information on the structural design principles of these molecules and their functions and interactions. Two papers published in the 20 May issue of the *Journal of Molecular Biology*[1,2] report the three-dimensional structure of the 75-amino-acid-long α-amylase inhibitor by two different methods: Pflugrath *et al.*[1] used the classical method of X-ray crystallography, whereas Kline, Braun and Wüthrich[2] derived the three-dimensional structure of the protein entirely from proton nuclear magnetic resonance (^{1}H-NMR) measurements in solution. The overall features of the X-ray structure and the NMR structure seem to be very similar, confirming that NMR gives an accurate measure of protein structure.

Until recently, the only method for determining macromolecular structure at atomic resolution was X-ray crystallography. For this technique to be applicable, single crystals of the molecules have to be grown to linear dimensions of at least 0.2 mm. In addition, to resolve the phase ambiguity of the scattered X-rays, isomorphous heavy-atom derivatives of these crystals are required. For proteins up to a relative molecular mass (M_r) of about 50,000, structure determination is a straightforward application of standard techniques as long as the amino-acid sequence is known. Unfortunately, it turns out that not all biologically interesting molecules can be obtained in crystalline form. Although new methods are constantly being developed, crystallization and selection of suitable heavy-atom derivatives remain an art in themselves.

The paper by Kline *et al.* is a remarkable step forward in the biochemical application of NMR. Since the 1950s, ^{1}H-NMR has delivered structural information of small molecules predominantly by its main parameter, the chemical-shift value. Even in the mid-1970s it was generally thought that structural information on biological macromolecules could be obtained, if at all, only by retrieving the information hidden in the shift values of the proton resonances, as for technical reasons no other parameter seemed directly available from the NMR spectra. An obstacle which had to be surmounted anew for each protein molecule was the assignment of resonances to the chemical groups of the individual amino-acid residues in the protein. This task is formidable, considering that even a small protein of $M_r \sim 10{,}000$ (corresponding to about 90 amino acids) already gives approximately 500 different resonance lines. In addition, most of these lines are split into multiplet structures. Thus it seemed that what was needed for ^{1}H-NMR to become generally useful in structure determinations was first, a method for the sequence-specific assignment of resonances; and second, a method for the retrieval of structural information from chemical-shift information. Ten years ago the possibility of achieving at least the first goal, let alone the second, seemed remote. The gradual improvement in available magnetic field strength brought about no substantial change — nor did anybody seriously expect it to do so.

Thus, an entirely new approach was needed. It originated in 1971, when Jeener[3] supplied a basic idea seemingly remote from practical applications in the general NMR laboratory. In Fourier NMR (today the standard way of obtaining NMR spectra) the decay of nonequilibrium magnetization after application of a high-frequency pulse is observed as a function of time. This function yields, after Fourier transformation, the desired spectrum, that is, the absorbance of the sample as a function of frequency. Jeener's idea was to substitute the single high-frequency pulse with two pulses of variable pulse separation, thus introducing a second time parameter. Two-dimensional Fourier transformation then yields a matrix with two frequency axes. Resonances on the diagonal correspond to the normal one-dimensional spectrum and off-diagonal resonances originate from the mutual interactions of protons; lines parallel to the two frequency axes through an off-diagonal resonance connect the two on-diagonal resonances originating from the two protons whose interactions gave rise to this off-diagonal peak. It was the achievement of Ernst and co-workers[4] to recognize the great practical importance of this technique. His group and that of Freeman, among others, developed a wealth of new experiments based on this basic idea (see, for example, ref. 5).

What change did this bring about for biochemical applications? The advantage of two-dimensional over one-dimensional spectroscopy is twofold: first, the basic two-pulse two-dimensional experiment (later termed COSY, from correlated spectroscopy) allows resolution of connectivities of resonances belonging to groups covalently connected with a spacing of only a few bonds. The off-diagonal peaks are generated by 'through-bond' interaction of two protons — in general, a distance of not more than three bonds between the protons is required. This yields, at least in principle, the assignment of all resonances to types of amino-acid residues with one single experiment, because each amino acid is characterized by a specific fingerprint of proton connectivities. In practice, some additional information from other types of two-dimensional experiments may be required. Second, a three-pulse variant of the basic COSY experiment (termed NOESY, from nuclear Overhauser effect spectroscopy) yields information on spatial distances of groups closer than about 0.5 nm via the dipolar 'through-space' interaction of those groups. Thus, the resonances in a two-dimensional spectrum originating from directly neighbouring NH and $C_\alpha H$ groups and $C_\alpha H$-CO-NH groups in the peptide bond are connected via off-diagonal resonances generated by the through-space interaction of those protons. The backbone resonances may then be traced according to the chain of amino acids in the protein by following the chain of -NH-$C_\alpha H$-CO-NH- backbone proton resonances. The corresponding side groups are then identified in the COSY spectrum or via the NH-$C_\beta H$ dipolar interaction in the NOESY spectrum. In addition, the distances between protons belonging to groups closely spaced in the three-dimensional structure — but not necessarily in the sequence — can be estimated. This yields information in the three-dimensional folding of the protein. Unfortunately, the spread of the correlation times for chemical groups in proteins prevents accurate determination of these distances via the nuclear Overhauser

effect. Thus, in general, only upper bounds on distances may be obtained by this method.

Thus, a set of two-dimensional spectra of a small protein generates a set of distance constraints for neighbouring groups. If a nuclear Overhauser effect is detected, the interproton distance is judged to be closer than, say, 0.4 nm. If no such effect is detected, the interproton distance can have any value. The potential of this method for structure determination of proteins was first realized by Wüthrich and co-workers[8], but the methods for structure calculations from the knowledge of a set of proton–proton distance constraints are by no means trivial, and much work went into setting-up computer programs to this end. Evaluation of NMR data with the aid of programs such as those introduced recently by Havel and Wüthrich[6] and Braun and Go[7] may finally result in the elucidation of a few possible tertiary structures.

Kline, Braun and Wüthrich[2] have now gone one step further in the interpretation of their experimental results by grouping their measured nuclear Overhauser effects into three categories: large, medium and small proton–proton separations. They then assigned numerical values to these categories by comparison with the magnitude of the effects observed for protons with covalently fixed distances. As their result shows, the approach works for the α-amylase inhibitor structure, and will thus probably work for most other protein structures.

In the past five years the secondary structures of several polypeptide strands have been determined by these ^{1}H-NMR methods[9,10]. As an example of a larger unit, secondary structure elements have been determined for the DNA-binding *lac*-repressor headpiece and a low-resolution model of its tertiary structure has been suggested[11]. Of course it helped that the tertiary structures of other DNA-binding proteins, such as the CAP of *Escherichia coli*, were known from the start[12]. The *lac*-repressor headpiece was until now the best example of a protein structure determined at low resolution by NMR methods, although the structural model has so far not been verified directly by X-ray studies. For the *lac*-repressor headpiece, extensive use has been made of molecular dynamic calculations as a further method of secondary structure refinement[13], a method that could also strongly influence protein structure determination by NMR methods in the future.

The paper by Kline *et al.*[2] is a step forward in the application of NMR to three-dimensional protein structure determination, but too much enthusiasm would be premature. The conditions under which NMR studies can reveal secondary structures or complete tertiary structures of proteins are rather restrictive: the protein must be sufficiently small ($M_r < 10{,}000$) to allow assignment of most resonances; soluble to high concentrations (several millimolar) to yield sufficiently good signal-to-noise ratios; available in compa large amounts (tens of milligran stable in solution for several day vated temperature and preferably (less than 6) to allow observatio changeable NH backbone prot present, the determination of structures by X-ray analysis is st more straightforward as long crystals are available. Neverthe expect NMR to become a powerfu the foreseeable future for determi structure of small- to medium-siz tides and hormones, which are in very sensitive to heavy-atom sub and are often not crystallizable at a

Rock mechanics

Luminous phenomena and th relationship to rock fracture

from John S. Derr

INVESTIGATIONS of earthquake lights are moving from the gathering of anecdotal sightings into the laboratory, and in the process gaining a measure of respectability. Most recently, Brady and Rowell report on page 488 of this issue[1] that breaking rocks in the dark produces lights whose spectra are those of the ambient atmosphere. The experimental design is intended to help discriminate among several possible mechanisms for the lights, including frictional heating to incandescence; sparks caused by the piezoelectric effect; or charge separation, plasmas and charged particle bombardment. The authors show, for example, that rock fracturing under water produces spectra of both atomic and molecular hydrogen, and for this and other reasons conclude that earthquake lights are caused by exo-electron excitation of the ambient medium rather than by any of the other suggestions.

One of the early giants of seismology, Perry Byerly, enjoyed telling students that the subject of earthquake lights was the darkest area of seismology. The reason for its neglect was probably that most observations have been highly anecdotal in nature, made by untrained observers and contain little or no 'hard' data. To make matters worse, sightings of clear examples of earthquake lights and ball lighting are generally confused with even more controversial subjects like UFOs. Typical reports of earthquake lights can be found in the 'grey' literature and the popular press — no wonder scientists have been reluctant to touch the subject!

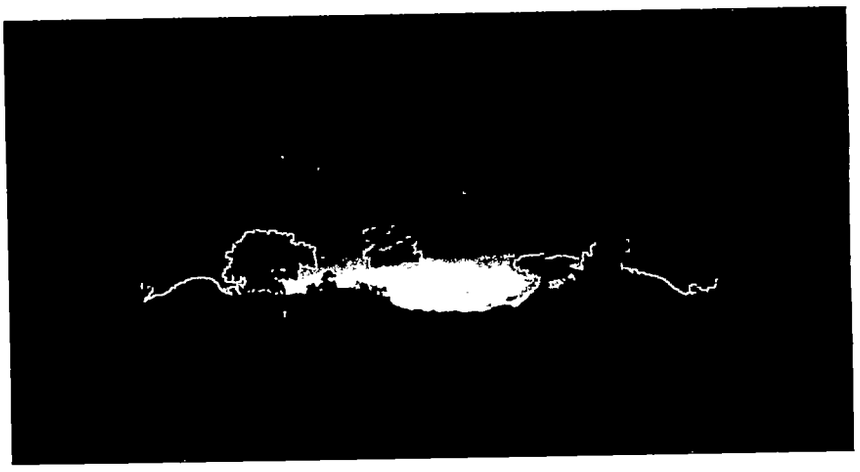
The phenomena have been reported for centuries. George Frederick created an imaginative rewrite of lical passages for his oratorio " Egypt"

> He gave them hailstones
> for rain: fire mingled
> with the hail ran along
> upon the ground.

This is probably a description of l ning, but is typical of common m tions which read religious or interpretations into the sighting examples include a recent sig luminous phenomena along faul the United Kingdom which was ted as "luminous beings"[2]. Tibet have considered regularly mountain-top lights to be a manif of the Bodhisattva[3]. These acco of course, subject to many in tions, but I find them at least c with the hypothesis that these pe astonished at the sight of phenomena and gave the unknov ious interpretation.

There is a very graphic Japan of unknown origin and time:

> The earth speaks softly
> To the mountain
> Which trembles
> And lights the sky



This suggests a general awaren phenomenon which may have Japanese seismologists, Ter Musya, to initiate the modern earthquake lights in the early 19 immediate stimulus was certa ficient: the Idu peninsula earthqu November 1930 was accompa lights brighter than moonlight[4]

descriptions came from the great Tangshan earthquake in China on 27 July 1976: people were woken up, thinking that someone had turned the lights on[5]. Other typical descriptions of earthquake lights include a glow at sea like a ship on fire; small, sequential flashes from different, random places on a hillside; fireballs or meteors; and auronal streamers diverging from a point on the horizon[4].

Probably closely related to the lights are sightings of luminous phenomena which have many of the same characteristics and occur in the same areas as earthquakes, but not at the same time. The best-documented examples come from the Yakima Indian Reservation, Washington[6], where photographs and extensive written records permit statistitical analysis. A typical description compares the luminous phenomena with a bright white light the size of a baseball floating among the tree tops. The results in that study support the hypothesis that the lights are associated with tectonic strain in active seismic areas and tend to accompany increases in earthquakes. Thus, earthquake lights and luminous phenomena may be related phenomena with slightly different time relationships to the associated earthquakes, or else luminous phenomena may, in fact, be earthquake lights for very small, high stress-drop earthquakes that have not been detected because of a lack of instrumentation.

The work of Brady and Rowell is a significant step because it discriminates between several proposed mechanisms and demonstrates that luminosities can be produced by any instrumentally recorded earthquake, even of the lowest magnitude. It strongly suggests that luminous phenomena are indeed earthquake lights produced by microearthquakes. Before this work, it was supposed that rock fracture produced plasmas which would generate easily detected microwave emissions. However, only a low frequency ($\sim 10^3$ Hz) was detected in these experiments[7], a result which agrees with general observations during earthquakes. (Microwave emissions across the fault plane are consistent with this theory, but very little should be observable at the surface.) Also, it was not possible to explain earthquake lights at sea, except by invoking the help of legions of excited, phosphorescent plankton. By actually generating lights underwater, Brady and Rowell have advanced a reasonable mechanism for these sightings. This work is, therefore, the first fully successful laboratory demonstration of a possible mechanism for this phenomenon.

If microwave interference could be detected from an earthquake, a different mechanism involving spark discharge would be required. King and Freund[8] show that nominally anhydrous minerals which dissolve small amounts of OH

Earthquake lights from Matsushiro, Japan, near Mount Kimyo on 26 September 1966 at 0325 JST. The luminosity lasted for 96 s. Direction, due north. Photograph by T. Kuribayashi.

during crystallization eventually develop peroxy anions (O_2^-) and hydrogen molecules (H_2). With heat of decompression, unbound O charge carriers can be generated. Extremely high local electric fields would result, with dielectric breakdown of air and strong microwave emissions if the density of O ions exceeds about 20 parts per million. The dielectric breakdown and exoelectron mechanisms can be differentiated by the presence or absence of significant microwave radio noise, although both mechanisms can produce lights and should generate radiation in the 900- to 5,000-Hz range[7].

Laboratory investigations of earthquake lights are just beginning, and the work of Brady and Rowell suggests many areas for investigation. Both exoelectron and dielectric breakdown mechanisms can explain the lights only if cracks extend to the surface in the area of the actual sightings. If a fault break does not reach ground level, one would require either a continuous series of cracks to provide a path for gas flow; or sufficient secondary fracturing at the surface to generate lights away from the primary fault. There is also a problem of timescale: to date, no experiment has produced any luminosity lasting even as long as one second. All laboratory tests should include broadband electromagnetic spectrum analysers to detect frequencies from ~10 Hz to X ray (10^{17} Hz).

Similarly, field investigations are in their infancy — there are great gaps in our knowledge. No one has tried to obtain pictures of earthquake lights triggered by nearly simultaneous signals from both a seismometer and photometer, or pictures and other measurements of lights in mine tunnels crossing faults. We do not know how exoelectron bombardment could produce a stationary light of relatively constant luminosity for as long as one hour, nor, as observed in the field, can we explain what would cause an image on infrared film that was not visible to the eye when the picture was taken[9]. Further study may reveal luminous phenomena to be a useful geophysical prospecting tool if they are related to mineralized bodies, or for earthquake prediction if we can understand the relationship between the area of sightings and subsequent earthquakes. Very preliminary correlations suggest that stress propagates across a geological terrane, causing luminous phenomena in the strong areas as it moves and earthquakes at the weaker boundaries[10]. In general, however, we remain ignorant of the necessary and sufficient conditions for generation of luminous phenomena and earthquake lights.

Brady and Rowell also suggest that their work has implications for biogenesis. It would be interesting to perform a Miller–Urey experiment using rock fracture as the electrical source to see if amino acids can be generated from primeval components under water or otherwise independent of atmospheric electricity.

Hence, a new, challenging area of geophysics is just opening. Previous studies have been criticized as statistical analyses without contributing towards finding a physical explanation. Brady and Rowell's work is a significant step to finding one such mechanism for the production of geophysical luminosities. But investigations in other areas are still required because we may be looking at several phenomena which sometimes share a common appearance and name. □

Pattern formation

Segmentation genes and the distributions of transcripts

from Douglas Coulter and Eric Wieschaus

RESEARCH on the fruitfly *Drosophila* during the past five years shows that much of the global character of the insect's segmental pattern, as well as its finer details, depends on gene activity in the embryo. One of the attractions of segmentation as a system for studying pattern formation is that most of these zygotically active genes have been identified and their phenotypes characterized in mutant embryos[1]. In the past year several of the genes have been cloned, so it is now possible to compare the actual patterns of gene expression at the blastoderm stage with the altered segmentation observed in mutant embryos. Recent results, reported on page 493 of this issue[2], suggest that mutant phenotypes and transcript distributions do not always match.

The common feature of all the mutations isolated so far is that they cause reductions in the overall pattern. In what is perhaps the most relevant class (the 'pair-rule' mutations) the pattern deletions are about one segment in size and are repeated at double-segment intervals along the length of the animal (see figure). Although each of the nine pair-rule loci is associated with its own precise deletion pattern, the domains affected by different genes overlap. A given element of the final pattern thus requires a defined subset of pair-rule gene activities for its formation. The deletion phenotypes observed in mutant embryos apparently arise because in the absence of any one of these activities, the cells that make those pattern elements die or assume alternate fates.

If wild-type genes for each locus are required only to form specific subsets of the final pattern, one might expect that at the blastoderm stage the respective gene activities would be found only in the precursor cells for those pattern elements. After the first pair-rule gene, *fushi tarazu* (*ftz*), was cloned[3,4], the distribution of transcripts was determined by using *in situ* hybridization to sectioned blastoderm embryos[5]. The transcripts were localized in seven stripes which seemed to correspond to the seven deletions observed at double-segment intervals in mutant embryos (see figure). This very exciting result suggested that the patterning mechanism in *Drosophila* might be decipherable strictly in terms of localized gene activity at the blastoderm stage.

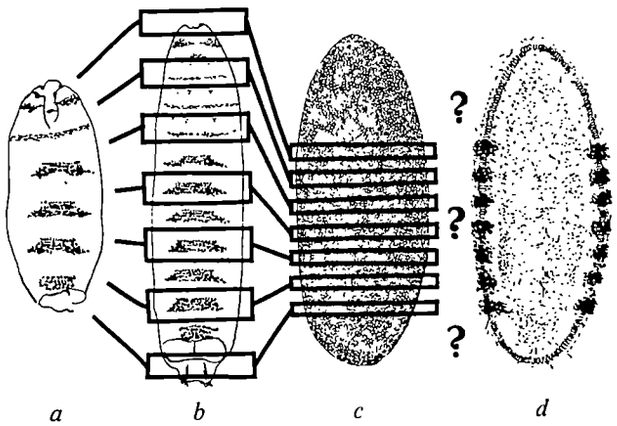
Because each of the nine pair-rule loci produces its own pattern of deletions, it is difficult to argue that any mutant domain defines a unit more fundamental than any other domain. This is contrary to what one would expect if the repeating pattern was established immediately as a series of units or 'compartments'[6], because, if this were true, realms of gene expression would be expected to coincide with compartment boundaries. At first glance, it seems that the range of phenotypes is more compatible with some combinatorial or hierarchical model assigning fates to individual cells[7] rather than to cell groups or polyclones[8]. Compartments could then be established later in response to the identities assumed by individual cells. Inherent to any of these models, however, is the assumption that one can actually extrapolate from the overlapping phenotypes in mutant embryos to actual gene requirements at the blastoderm stage.

This could only be tested when a second pair-rule gene, *hairy*, was cloned. Transcripts from *hairy* were shown to be localized in stripes with a width and periodicity similar to that of *ftz*[9], but the phasing of the stripes was different for the two loci. When embryos were simultaneously hybridized with probes from both genes, four regions could be identified in each double-segment interval: cells which contained either *hairy* or *ftz*; cells which contained neither transcript; and cells which contained both. This overlapping distribution of transcripts appears to be analogous to the overlapping pattern deletions observed in some mutants at each locus[7], suggesting that domains of gene expression at blastoderm correspond to domains of gene requirement in the final pattern.

Because the double segment is at most eight cells wide at the blastoderm stage, all seven of the remaining pair-rule gene products would not be required to specify unique identities to each cell within the double segment. It follows that not all pair-rule genes would play exactly the same part in the process (see below) — yet no one anticipated the surprising result (reported in this issue by Kilchherr *et al.*[2]) obtained when another pair-rule gene, *paired*, was cloned.

This gene is almost the archetypal pair-rule mutation; the deletion patterns in mutant embryos define seven stripes with the standard double-segment spacing. But analysis of the final pattern of transcripts at late blastoderm revealed fourteen stripes rather than the expected seven, indicating a periodicity corresponding to single-segment primordia. Interestingly, this single-segment mode of expression is preceded at a slightly earlier stage by seven broad stripes; it is (presumably) the subsequent 'splitting' of these stripes caused by elimination of transcripts from cells in the middle which gives rise to the final pattern. Although the stripes in this transient double-segment mode are too broad to correspond exactly to the more limited deletions observed in *paired* mutants, it is possible that this earlier pattern is the one most relevant to the establishment of the final pattern. In any event, the exact relationship between the relatively simple deletion pattern observed in mutant embryos and the more complicated pattern of transcription remains a mystery.

As we have described above for the *paired* pattern, a static description of the final or most stable pattern of striped transcripts from a given pair-rule gene is likely to yield an incomplete picture of a complex, dynamic process. An understanding of how segments are established and maintained requires an understanding of how the patterns arise, how these transcript patterns relate to translational expression and, ultimately, determination of the functions of the gene products. Ideally, such analyses will be extended to all the segmentation genes; meanwhile, most work has focused on the pair-rule gene *ftz*, and on another gene, *engrailed*, which is required later during development in the posterior compartment of each segment[10], but also reveals a pair-rule phenotype in mutant embryos and is transiently expressed in a double-segment mode during the blastoderm stage.



The establishment of a periodic, segmental pattern along the length of the embryo is thought to be initiated by the zygote in response to some maternally derived factor(s) present in the egg, but the nature of this global mechanism is not understood. One approach to studying this problem has been careful reconstructions of transcript distributions during the stages when the pattern is being formed. In general, transcripts arise in a defined sequence, with stripes in anterior regions becoming apparent before posterior ones. This sequence provides the first indication that the segmental pattern may be established progressively, possibly analogous to the gradual addition of the more posteriorly situated somites observed during vertebrate development. Furthermore, Weir and Kornberg[11] show that *engrailed* and *ftz* arise with even broader bands of specificity than the double segment. In pre-cellular stages, the transcripts are spaced at four-segment and even broader intervals, suggesting that the final segment pattern arises by progressive subdivision of larger units into smaller ones.

When fluorescently labelled antisera to the ftz and engrailed proteins were obtained, it was shown that in those cells which express either gene, the protein is

ocalized in the nucleus[12,13]. This presumably reflects the postulated DNA-binding activity conferred by the homoeobox domain present in each protein, and is consistent with a postulated regulatory role in programming cells for specific patterns or fates. The use of antisera has also provided more detailed information on the spatial patterns of gene expression and how they are achieved, while confirming most of the general features inferred from transcript distributions. The distribution observed with the ftz antiserum suggests that the final stage of the patterning process involves two clear phases, with the initially broad stripes tightening up into narrower bands as gastrulation begins. This contrasts with the patterning of engrailed stripes, which are generally a single cell wide at the time they arise.

The transition in the blastoderm patterns of *ftz* suggests that establishment of the final pattern of that gene is not a direct response to maternal cytoplasmic cues, but instead involves some kind of fine-tuning among zygotically active loci. This possibility is currently being investigated in several laboratories by analysis of the striping patterns in mutant embryos. Howard and Ingham[14] have recently analysed transcripts of *hairy*, *ftz* and *engrailed* in embryos mutant for either *hairy* or *ftz*. The pattern of *engrailed* expression is altered in either pair-rule mutant, with the usual pattern of fourteen stripes reduced to seven in each case, reflecting the deletion of alternating segmental repeats. These results are gratifying, but not entirely unexpected, because *engrailed* and other genes that are required later in every segment are likely to be regulated in response to the pattern established by the pair-rule genes at the blastoderm stage.

A more surprising result is that the pattern of *ftz* expression is altered by mutations in *hairy*, whereas the *hairy* pattern appears normal in *ftz* blastoderms. Thus, the two pair-rule genes seem to play different parts in the process of segmentation, with hairy somewhow acting to regulate *ftz* (and possibly other pair-rule genes). Because the *ftz* stripes become much broader, apparently extending further into the domain where *hairy* is normally expressed, *hairy* might at first glance seem to be a simple repressor of *ftz* transcription; the existence of overlapping domains of transcription observed in wild-type blastoderms (see above), however, suggests that the nature of the interaction is more complex. Also, it is not clear whether the only role of *hairy* is to regulate some subset of the pair-rule genes, or whether it also acts together with these genes to regulate processes further downstream. An understanding of segmentation will require the elucidation of all such hierarchical regulatory relationships, both within each 'class' and between classes of segmentation genes.

Relationship between segmentation phenotypes and transcription patterns at the blastoderm stage. Embryos homozygous for *ftz* differentiate as larvae with an abnormal segmentation pattern (*a*) in which the odd-numbered denticle bands have been eliminated (*b*). The cells in the wild-type embryo that would normally make those pattern elements are located in the blastoderm stage as seven parallel stripes (*c*), each of which is about four cells wide. When sectioned, blastoderms (*d*) are hybridized with labelled *ftz* DNA to determine the normal location of ftz transcripts, the transcripts also occurring in seven stripes. The positions of the stripes seem to correspond to the locations of those cells which normally make the pattern elements deleted in *ftz* mutant embryos. Recent results suggest that this correspondence is not maintained for other segmentation loci (see text).

An interesting question which arises from the early *ftz* and *engrailed* transcript patterns (see above) is that the deletions in the corresponding mutant embryos give no clear indication of a requirement at any stage earlier than the double segment. The earlier striping patterns, as well as the localization of *paired* transcripts to fourteen rather than seven stripes, argue that the relationship between phenotypes and transcript distributions must be re-examined. How can such discrepancies be resolved? In some cases, it could be argued that the differences observed are artefactual; or that the patterns of transcription at the blastoderm stage can never be described with absolute accuracy within the eight-celled double-segment interval because of the scarcity of gross morphological landmarks at the stage and the scatter of grains in the emulsion above each stripe. Moreover, the exact deletion domain in a given phenotype is difficult to define because the patterns vary slightly from one mutant individual to the next, even when the genotype is kept constant. But all these inaccuracies are relatively small compared with the differences we outlined earlier in this article, and it is unlikely that the discrepancies will be resolved by more detailed examinations of the phenotype or transcript patterns.

A more likely explanation is that the discrepancy reflects some fundamental difference between molecular and genetic approaches. Transcript analysis determines where RNAs accumulate, independent both of their role in development and of whether they are ever translated (although experiments with the appropriate antisera should resolve that point). Mutations, on the other hand, will only detect gene products if they are needed. They provide no direct indication of where in the embryo those products are made. These differences in techniques provide two classes of explanation for the discrepancy between molecular and genetic results. In the genetics version, *ftz* and *engrailed*, for example, may be transcribed in broader patterns during pre-blastoderm stages not because those transcripts are required, but because whatever condition controls their expression at the double-segment stage is already present and distributed with a broader spacing at earlier stages. In this view, the early transcripts provide a valuable assay for understanding how *ftz* or *engrailed* transcription is controlled, although the elimination of those transcripts does not block the segmental pattern in the larger (earlier) modes and the early transcripts have no obvious function. Similarly, one could assume that only every other stripe of transcripts observed in the fourteen-stripe *paired* pattern is required, or that only the earlier, seven-stripe mode is key to the functioning of the gene.

Alternatively, in the molecular view, gene products are made only in the cells where they are required. In this explanation, the molecular patterns at the blastoderm stage would give the best indication of the actual role of the gene product during development. Unexpected features of the phenotype of mutant embryos could be explained as secondary interactions between the cells once an abnormal pattern has been established at the blastoderm stage. Explanations of this kind demand that mutant phenotypes be

at least partially non-autonomous in genetic mosaics.

Although large-scale non-autonomy has not been observed in the analysis of segmentation phenotypes, the sample of loci tested so far is relatively small[15]. Also, it is not clear whether the techniques presently available for marking cells in *Drosophila* are sufficiently accurate to exclude the limited non-autonomy needed to explain the discrepancy between the phenotypes and transcript distributions. However, genetic mosaics ultimately provide the most direct technique for relating phenotypes to individual cell requirements, and the variety of mosaic techniques available in *Drosophila* should provide a better understanding of the relationship between the gene products and the patterning process. □

Mathematics

The class number problem

from Ian Stewart

SOME of the deepest mathematical theories have been built from very humble raw materials, and a classic case is number theory, which studies properties of ordinary whole numbers 1,2,3,... . It has long been remarked that, although it is easy to observe patterns in the behaviour of whole numbers, it can be astonishingly hard to prove that these patterns are generally valid. Number theorists have long been interested in the arithmetic of 'imaginary quadratic fields', systems of numbers in the form $x+y\sqrt{-D}$, where D is a whole number and x,y are rational.

Any whole number can be factorized into primes, and there is an analogous concept for such fields. For whole numbers, the prime factorization can be achieved in only one way. This is not always true for imaginary quadratic fields; and in his *Disquisitiones Arithmeticæ* of 1801, the fount of all modern number theory, Carl Friedrich Gauss in effect conjectured that unique factorization holds precisely when $D = 1, 2, 3, 11, 19, 43, 67$ and 163. This conjecture was proved more than a hundred years later by A. Baker (*Mathematika* **13,** 201; 1966) and independently by H.M. Stark (*Michigan Math. J.* **14,** 1; 1967). But Gauss also stated a more general conjecture, the class number problem, the solution of which by D.M. Goldfeld, B. Gross and D. Zagier has recently been described in a masterly survey by Goldfeld (*Bull. Am. Math. Soc.* **13,** 23; 1985).

The classic example of non-unique factorization occurs in the case $D = 5$. Here $6 = 2.3 = (1+\sqrt{-5})(1-\sqrt{-5})$ exhibits two distinct prime factorizations. (Each of the numbers 2, 3, $1+\sqrt{-5}$ and $1-\sqrt{-5}$ is prime in this particular number field.) The extent to which factorization is not unique can be measured by a quantity called the class number, h: when $h=1$, factorization is unique, and for larger values of h it is not unique. In some sense the larger h becomes the less unique factorization is. For a given D it is relatively easy to calculate the class number (for example, if $D = 5$ then $h = 2$) but the list of values so obtained varies in a very irregular way with D. This makes it hard to solve the inverse problem: given a value for h, find which Ds have that class number. And this is what Gauss's conjectures are about. The conjecture on unique factorization asks for a determination of all D such that the class number is 1, with the guess that they are precisely the 9 values listed above. The general class number problem is to prove that for any given class number h, the list of D having that value for h is finite.

Gauss actually phrased his conjectures in a slightly different setting, the theory of quadratic forms. This goes back to the time of Pierre de Fermat, who stated theorems of the following kind: "Every prime of the form $6n+1$ can be written as x^2+3y^2 for integers x and y." For example, 31 is such a prime, and $31 = 1^2+3.3^2$. The connection with quadratic fields is that $x^2+3y^2 = (x+y\sqrt{-3})(x-y\sqrt{-3})$, a factorization in the field corresponding to $D = 3$. So theorems about quadratic fields carry implications for quadratic forms, and conversely.

Gauss, and Joseph-Louis Lagrange before him, realized that it is not necessary to study all possible quadratic forms, because changes of variable can be used to turn one form into another. For example, if x and y are replaced by $x+2y$ and $x+y$, respectively, then the form x^2+3y^2 becomes $4x^2+10xy+7y^2$. Therefore, the numbers that can be represented in the form x^2+3y^2 are precisely those that can be represented in the form $4x^2+10xy+7y^2$, even though at first sight these are different questions. This led Gauss to the idea of 'equivalent' forms (transformable into each other by such changes of variable). He proved that there is only a finite number of distinct classes of equivalent forms, which is the class number of the associated quadratic field.

H. Heilbronn and E.H. Linfoot (*Q. Jl Math.* **5,** 293; 1934) showed that, apart from the nine known cases, at most one further field has class number 1. In 1952 Kurt Heegner claimed a proof that no such tenth field exists, which would solve the class number 1 problem. But as Goldfeld remarks: "Heegner's paper contained some mistakes and was generally discounted at the time. He died before anyone really understood what he had done."

Baker's proof uses new results from the theory of transcendental numbers (numbers that do not satisfy any polynomial equation with rational coefficients), whereas Stark's proof is much closer in spirit to Heegner's attempt. Then M. Deuring (*Inventiones Mathematicæ* **5,** 169; 1968) showed that the 'gap' in Heegner's attempted proof can be filled relatively painlessly. In 1971 Baker (*Ann. Math.* **94,** 139) and Stark (*Ann. Math.* **94,** 153), again independently, solved the class number 2 problem, finding exactly 18 values of D for which $h = 2$.

Although these results represent enormous progress compared with what was previously known, it is clearly not feasible to tackle the general problem one class number at a time, because the process will never end. The interest of such partial answers is that they suggest new methods. Goldfeld (*Astérisque* **41–42,** 219; 1976) exploited a connection between the class number problem and an elliptic curve, a type of cubic equation. He showed that if just one elliptic curve can be found with a particular property, then the class number problem is solved. Unfortunately, no such elliptic curve was then known. But later, Gross and Zagier (*C.r. hebd. Séanc. Acad. Sci., Paris* **297,** 85; 1983) established the necessary property for the elliptic curve $-139y^2 = x^3+4x^2-48x+80$. By such roundabout methods was Gauss's conjecture on the finiteness of the list of imaginary quadratic fields of given class number demonstrated.

Soon afterwards, J. Oesterlé (*Séminaire Nicolas Bourbaki* 631; 1984) obtained a specific estimate for the size of the largest D with given class number h, making is possible in principle to select values of h and find all possible Ds. As a result, the class number 3 problem (precisely which D gives $h = 3$?) has been solved, and many long-standing problems in number theory begin to appear tractable. For example, a solution of the class number 4 problem would answer a famous question: which integers can be expressed as a sum of three squares in exactly one way? The powerful and beautiful ideas laid bare by a 180-year assault on Gauss's conjecture strikingly attest to the quality of his insight into the deep properties of ordinary whole numbers. But the sad story of Kurt Heegner shows that genius is still not always appreciated during its lifetime. □

Evolution — the struggle continues

SIR—In an interesting and provocative article, Halstead[1] rejected the anti-darwinian views of the Japanese biologist Imanishi. His rejection is apparently based on his negative impressions of Japanese society. Halstead remarked that: "the ordinary Japanese [is] condemned... to the rigid authoritarian feudal society that masquerades as one of the advanced nations of the world."

Halstead sees the world as "demonstrably... [one]... of competition, struggle and disharmony". This is not surprising when one considers that the concept of competition is inherent to Neo-Darwinism and that Halstead is a staunch supporter of this theory. However, while Halstead may see the world in this way, the question remains — is there any evidence for the reality of what he sees?

Halstead states: "Recent research... [has]... demonstrated that interspecific competition takes place in 90 per cent of all cases studied". On the contrary, a critical review of a large number of cases by Underwood[2] suggests that this statement is grossly inaccurate. This also suggests that Halstead's claim that "the informational foundation of Imanishi's theory no longer stands" is incorrect. Irrespective of this, the conclusive demonstration of competition is unlikely to deter the Japanese public from supporting Imanishi's theory. As suggested by Brady[3], there may be more than one reason for accepting a theory. This is not an attribute unique to the Japanese scientific community, as suggested by Halstead, but a characteristic of the development of theories in general.

We agree with Imanishi that the selectionism of Darwin has its roots in Western society. In the same way Imanishi's theory has been influenced by Japanese society. However, while the theory was developed by a Japanese, it is not necessarily uniquely Japanese in concept and therefore judgement of the theory on the basis of the values of the society in which it was developed cannot be feasible. After reading Halstead's article, one is left with the distinct impression that this is exactly what he has done.

3. Brady, R.H. *Biol. J. Linn. Soc.* **17**, 79 (1982).

SIR—Halstead's commentary "Anti-darwinian theory in Japan" (*Nature* **317**, 587; 1985) introduces the theory of evolution advanced by Imanishi, at the same time rejecting it. We feel, however, that Halstead rejected Imanishi's theory of evolution without fully understanding it, and we wish to comment on the theory on purely scientific grounds.

First, Halstead introduces Imanishi's concept of habitat segregation and comments that this is but a "dream" attractive to members of Japanese society, which is actually extremely competitive. Leaving aside the rather meaningless discussion as to whether or not Japanese society is more competitive than that of Europe or America, we would like to know whether Halstead will recognize habitat segregation as a principle on which a wholly different theory of evolution could be built. We consider habitat segregation to be a real biological phenomenon.

Second, if Halstead recognizes habitat segregation as propounded by Imanishi as a possibility, he ought either by explaining habitat segregation by means of Darwinism, include it in Darwinism or clearly recognize Imanishi-ism as a view of evolution which is independent of Darwinism. Interestingly, Halstead does not attempt this but tries to give a "sociological" explanation of Imanishi's theory. We think that there is a relationship between the competitive exclusion principle of Gause[1] and Hardin[2] and Imanishi's concept of habitat segregation.

Third, Imanishi strongly refutes Darwin's hypothesis of the survival of the fittest and asserts that: "Survival is in most cases purely accidental. It is a matter of luck rather than selection". Darwin considers the struggle for existence to be fierce among individuals of the same species as well as between different species, but Imanishi is critical of this idea. Imanishi, as Halstead stresses several times, understands evolution as being a transformation only occurring to the species, and not to the individual. In contrast to Darwinism, which considers the individual to be the unit of evolution and expends great energy in explaining how the transformations of this individual are magnified in the transformations of the species, Imanishi asserts that the unit for explaining evolution is not the individual but the species.

We believe this idea of the species as a unit to be the essence of Imanishi's assertion that "all the individuals of a species change at once when the time to change comes" will be understood. Concerning this unit of evolution, we support Imanishi's ideas. In the case of the law of movement of heavenly bodies, the Earth and the Moon are considered the units regardless of their components. The minute examination of brain cells probably will not be able to tell us how humans think. Building theories to explain natural phenomena requires an appropriate unit. The originality of Imanishi's theory of evolution is the idea of the species as its unit. We would like to ask what Halstead's opinions are upon this point.

We consider that Darwinism and Imanishi's theories are two separate views of evolution. If Halstead feels that Imanishi's theory of evolution is unscientific, that it could not even stand as a hypothesis, he should give scientific reasons, and not literary or sociological explanations.

Kenyan finds not early Miocene *Sivapithecus*

SIR—In his recent commentary in *News and Views* questioning the assignment of the new Miocene hominoid specimens from Buluk, Kenya[1] to *Sivapithecus*, Delson[2] referred to a paper of ours in which we discuss the hominoid genus *Ouranopithecus* from Ravin de la Pluie, Greece[3]. As he states, we suggested a link with "hominines", but one based upon a particular assumption about character state polarities drawn from several alternatives, any of which, as we stated, might be correct.

He failed to note another argument in that paper which goes to the heart of the issue of the generic status of the Buluk specimens. As others have done, we argue for a *Sivapithecus*–orangutan clade based on a set of facial characters worked out by Ward[4] and Andrews[5] relating to the premaxilla and palate. As the clade is defined by these presumed shared derived features, any species included in *Sivapithecus* must also possess these character states. By these criteria, only *Sivapithecus* species from the Siwaliks of Indo-Pakistan and *S. meteai* from the Sinap series in Turkey are definitely included in *Sivapithecus*. *Ouranopithecus* from Ravin de la Pluie[3,6], *Rudapithecus* or *Dryopithecus* from Rudabanya, Hungary[7], *Kenyapithecus* from Nachola, Kenya[8], and the large hominoid from Lufeng, China (personal observation) clearly are not. The status of other thick-enamelled hominoid samples which lack specimens with the critical nasopalatal morphology, such as that from Buluk, must remain open, although in some other features Buluk specimens differ markedly from Asian *Sivapithecus*.

We have provided a specific diagnosis

of *Sivapithecus* based upon a set of character states that most now accept as being derived features showing phyletic affinity with the orangutan. It is a framework in which neither the definition nor the species inclusivity of *Sivapithecus* is as ambiguous as Delson suggests.

Quantum behaviour of superconducting rings

SIR—In a recent *Nature* (**319**, 726; 1986), U. Eckern discussed the applicability of quantum mechanics to macroscopic objects, for which superconducting rings incorporating weak link constrictions are considered to be very strong candidates. To set this in context, we wish to point out that there are modes of operation of weak link rings other than the one considered by Eckern. For these, experimental results already exist which are very strong evidence for the fact that such rings do indeed behave as macroscopic quantum objects.

The magnetic flux threading the superconducting ring ϕ and the electric charge localized at the weak link Q are the conjugate variables for a weak link ring. If it is a quantum object a Heisenberg relation for the flux and charge uncertainties $\Delta\phi\Delta Q \geq \hbar/2$ exists. Eckern addressed only the limit where the flux is exceedingly well defined compared to the quantum unit of flux ϕ_0 ($\phi_0 = \hbar/2e$ where $\hbar$ is Planck's constant and e the electric charge), so $\Delta\phi << \phi_0$, and thus $\Delta Q >> 2e$, $2e$ being the charge on a Cooper pair of electrons in the superconductor. Our experimental and theoretical work over the past few years has considered two other limits: (1) where the flux is quite well defined $\Delta\phi << \phi_0$, and the charge is fairly uncertain $\Delta Q >> 2e$. (2) Where the charge is quite well defined $\Delta Q << 2e$, and the flux is fairly uncertain $\Delta\phi >> \phi_0$. We have accumulated a large amount of experimental data which are in accord with the predictions made theoretically by considering weak link rings as quantum objects, and which to date have no alternative explanation.

Readers who are interested in the quantum mechanics of macroscopic objects but are unfamiliar with the published literature on superconducting weak link rings are referred, for example, to *Helv. phys. Acta* **56**, 789 (1983) and *Phys. Lett.* **104**, 375 (1984); **107**A, 133 (1985); **111**A, 199 (1985); **115**A, 125 (1986).

The stability of zoological nomenclature

SIR—The long letter on this subject by Erzinclioglu and Unwin (*Nature* **320**, 687; 1986) reveals some fundamental misunderstandings. But if they, or others prompted by their letter, will make constructive suggestions then a valuable purpose will have been served.

As stated in its introduction, the *International Code for Zoological Nomenclature* (3rd Edn, 1985) "provides guidance for zoologists needing to establish new names, and rules to determine whether any name, previously proposed, is available and with what priority..." It is a do-it-yourself manual and like any must be used with commonsense for the desired results, in this case stability coupled with taxonomic freedom.

The purpose of the International Commission on Zoological Nomenclature is the very opposite of that portrayed in the situation graphically described by Erzinclioglu and Unwin: "taxonomists... are kept in place by the tyranny of the Commission: the Code must be obeyed". Their statements that "[in some circumstances] a name must still be changed in spite of the confusion that will be caused" and "there is only one course open to us if sanity is to be restored and that is that some sections of the code must be consistently ignored" are not accurate and overlook the basic function of the Commission.

Some code of zoological nomenclature, internationally recognized, must clearly exist, and like any other set of 'rules' the existing one is imperfect and could not be otherwise. The number of zoological names runs into millions, and naturally rigid adherence to the code's prescriptions will sometimes cause confusion. Individual zoologists (in the widest sense of the word) cannot follow the recommendation of Erzinclioglu and Unwin and "consistently ignore some sections of the Code", because in the nature of things they would be inconsistent. The International Commission, at present of 25 scientists from 15 countries, exists largely to overcome this problem.

Anyone encountering a difficulty, for example a conflict between the priority of one name and the established usage of another (the blood-sucking maggot mentioned by Erzinclioglu and Unwin is a case), should submit the matter to the Commission. This does not then act in any tyrannical manner, but solicits the comments of zoologists by publishing the problem in the quarterly *Bulletin of Zoological Nomenclature*, and also by notifying appropriate journals. The Code (Article 80) provides that existing usage should be maintained meanwhile. Comments adding any new facts are published in the *Bulletin*, and in every case are brought to the attention of the Commission. After at least six months (commonly two years, although this is being reduced) the members of the Commission vote by postal ballot, and a two-thirds majority will suffice to set aside the provisions of the Code if appropriate. The outcome is published as an 'Opinion' in the *Bulletin*. Of course there is no power to enforce anybody either to approach the Commission or to abide by its conclusions, but it is in the common interest that they should do so.

The 1985 Code is a carefully considered result of very numerous contributed suggestions, although none were proposed as "devices to ensure unnecessary name changes"! Of course it needs amendments. One is proposed by Erzinclioglu and Unwin (although they are not the first), and concerns the requirement that the gender of generic and specific names should agree. This was clear in the past when naturalists knew Latin and classical Greek, but many feel it unsuited to the present day of computer information retrieval (see p.xix of the Code's introduction). The Commission invites views on this and on any matters concerning zoological nomenclature.

In the eye of the beholder

SIR—T. Nash (*Nature* **320**, 402; 1986) believes that the patches he sees in the out-of-focus image of a light point originate from individual light receptors in his retina. If he set about measuring their angular subtense, he would discover that they are about an order of magnitude larger than those of retinal cones. And how does he think he gets to "see" the spaces between the "receptors"? In fact, Nash is viewing entoptically the quality of his eye's optics and the transparency of his crystalline lenses.

Error rates in prenatal cystic fibrosis diagnosis

SIR—Pembrey and Malcolm[1] state that if a prenatal diagnosis is based on an empirical correlation between an amniotic fluid protein and fetal genotype, an attempt should be made to confirm diagnosis on the abortus after termination of pregnancy. This is certainly standard practice for α-fetoprotein-based diagnosis of neural tube defects, and has become part of our procedure for microvillar enzyme-based prenatal diagnosis of cystic fibrosis[2]. Apart from providing a continual updating of the sensitivity and specificity of the test, such procedures are useful for monitoring the inevitable errors of sample handling which creep into even the best-regulated laboratories.

What puzzles us is why Pembrey and Malcolm should feel that diagnosis based on linked DNA probes should be excluded from such quality control. The accuracy of such diagnosis is dependent on recombination frequencies. The derivation of recombination frequencies is a form of empirical correlation and only as good as the most recent set of data. In fact, because the total number of informative meioses observable can be quite small, recombination fractions may be subject to dramatic fluctuations. The linkage between the G8 probe and the Huntington's disease gene was initially very tight[3], but recombinants appeared with the acquisition of new family data[4,5]. The same is true for linkage between the cystic fibrosis gene and the probes, pJ3.11 and met[6,7]. Recombination fractions are usually stated as lying within a given confidence interval, to indicate the uncertainties inherent in their estimation.

There is also the question of genetic heterogeneity. Pembrey and Malcolm suggest that careful linkage studies in a large number of families from different populations will allow exclusion of significant non-allelic heterogeneity. But what do they mean by significant? An average non-allelic heterogeneity level of 5 per cent would be very significant if it meant that a similar proportion of prenatal diagnoses were wrong. It is difficult to see how this figure can go much below 5 per cent when the error rate in diagnosing cystic fibrosis is believed to be of this order[8].

The point that we were making in our earlier letter[9] is that the whole edifice of quality control is not based on pedantry but on the realization that laboratories do make mistakes. It is possible that, as first-trimester prenatal diagnosis becomes more widely available, the standard procedure of confirmation of diagnosis on abortuses will have to be abandoned. We should, nonetheless, continue to collect and analyse the outcomes of as many of these pregnancies as is possible, since it will improve the reliability of the linkage data. And let us be clear what we are doing, and not imply — as do Pembrey and Malcolm — that we have acquired new procedures which are now error-free.

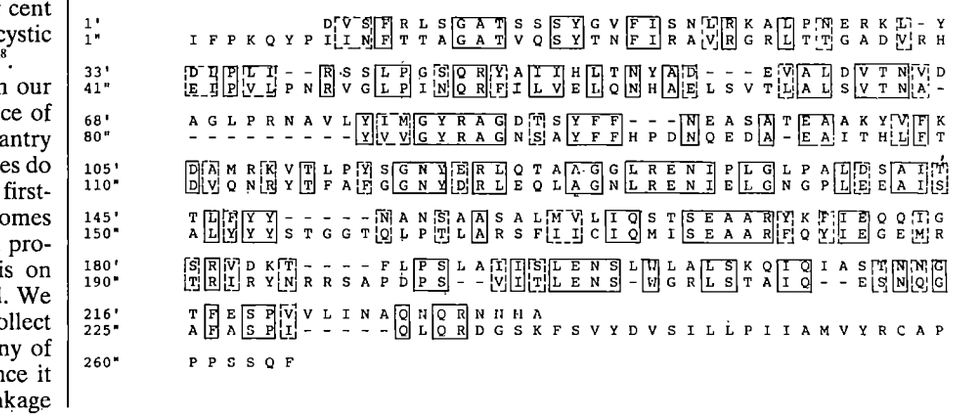
Homology of trichosanthin and ricin A chain



SIR—Trichosanthin is a plant protein extracted from a Chinese herbal medicine, the root tuber of *Trichosanthes kirilowii maxim,* Cucurbitaceae. It has been shown to bind to the trophoblastic syncytial layer killing the cells quite selectively. It can therefore be used clinically to terminate pregnancy and inhibit trophoblastic tumours[1]. This basic single-chain protein consists of 234 amino acid residues. Its sequencing has recently been completed[2,3] and a molecular model has been derived from the X-ray analysis[4]. Here we report a striking degree of sequence homology between trichosanthin and subunit A of ricin-D (ricin A for short). It is the first example of the complete sequence comparison between a ribosome-inactivating protein and cytotoxin.

In recent years, much attention has been paid to cytotoxins and the like for theoretical reason and because of their potential as immunotoxins to treat cancers. Many cytotoxins consist of two kinds of subunits. The toxic action is associated exclusively with subunit A which enzymatically inhibits protein synthesis of eukaryotes, whereas one or more B subunits have the ability to bind to cell surfaces and aid subunit A penetration into cytosol. Among others, typical protein cytotoxins are diphtheria toxin, cholera toxin (from bacteria), ricin and abrin (from plants). However, it has also been found that many plants contain single chain proteins which are very similar to the toxic subunit A of the above cytotoxins in having the ability to inhibit protein synthesis. Pokeweed antiviral protein (PAP), momorcharin, wheat germ inhibitor and gelonin are good examples (for review see ref 5). *Momordica* and *Trichosanthes* are taxonomically closely related and all belong to the Cucurbitaceae family. It has been reported that momorcharin and trichosanthin have similar biological functions[6]. It led us to think that trichosanthin may also fall into the same group. To test for this possible relatedness, we therefore carried out sequence comparison studies. Sequence comparisons between short pieces of N-terminal segments of some ribosome-inhibiting proteins (RIPs) and cytotoxins have been recently reported[7,8]. Here we report the complete sequence comparison by computer analysis between trichosanthin and ricin A.

Figure 1 demonstrates our alignment of trichosanthin and ricin A, in which 91 residues are identical and 42 conservative. In our analysis, substitutions are taken as conservative only if two conditions are met — a minimum base change of one and that the two side-chain's physico-chemical properties are similar, as with Ser and Thr or Asp and Glu. The identical and conservative residues comprise at least 56 per cent of the trichosanthin sequence.

Further inspection shows that the identical and conservative residues are rather concentrated and that very little deletion needs to be assumed. In particular, there is no deletion at all from residues 97 to 149 in trichosanthin. We therefore believe that the sequence similarity between trichosanthin and ricin A is by no means a random event. It has been reinforced by the probability estimation of the alignment.

It is reportedly very rare for an identical pentapeptide to appear in different chains[9], the probability is estimated to be about 1×10^{-6}. One may then expect the

frequency of appearance of any identical pentapeptide in both trichosanthin and ricin A to be only about 0.05. In fact, three identical pentapeptides have been found. One is GYRAG in residues 80–84 of trichosanthin and 83–87 of ricin A. The second is LRENI in residues 128–132 of trichosanthin and 133–137 of ricin A. And the third is SEAAR in residues 166–170 of trichosanthin and 176–180 of ricin A. Thus the remarkable sequence homology between trichosanthin and ricin A seems not to be coincidental, and may well be of biological significance.

There is a pool of evidence indicating that it is an enzymatic process by which the toxic subunits of cytotoxins affect the host cell metabolism. For diphtheria toxin and cholera toxin, the subunit A acts on the elongation factor EF2 and GTP-binding protein respectively. Nevertheless they share a common mechanism — ADP= ribosylation. For plant toxins such as ricin and abrin, in spite of considerable efforts, the nature of their enzymatic activity is obscure. It is known, however, that they inactivate the 60S subunit of ribosomes (for review see ref. 5). It is likely that different cytotoxins may not use the same mechanism, but the sequence homology between trichosanthin and ricin A shown here strongly suggests that these two do act by similar mechanisms. Taxonomically, *Ricinus* belongs to the Dicotyledoneae Archichlamydeae Euphorbiaceae *Ricinus* L. and *Trichosanthes* belongs to the Dicotyledoneae Sympetalae Cucurbitaceae Trichosanthea L. They are not closely related. But the possibility can not be ruled out that they originate from a common ancestor.

There is a speculation[7] that in the ancient plants there was a special defensive protein which could inactivate eukaryotic ribosomes. In the evolution process, the gene coding for this toxic chain might have fused with the gene for some sort of sugar-binding proteins, resulting in cytotoxins with two different types of subunits as found in species like *Ricinus*. However, in some plants, such as pokeweed, the toxic chain remains independent and has been termed the ribosome-inactivating protein (RIP). The overall sequence homology between trichosanthin and ricin A strongly supports this hypothesis.

We thank Professor Wang Yu and his colleagues for their kindness in showing us the sequence of tricosanthin before publication. This work was supported by a special grant from the State Commission of Science and Technology of China.

Putting a charge on a quark

SIR—The magnitudes of the quark electric charges raise the perplexing question: what is the magnitude of the unit electric charge? When the proton and electron were thought to be the elementary particles of nature, it appeared quite acceptable to take the electronic charge as the unit and to express all other charges in terms of it but, if quarks are elementary particles, it is meaningless to speak of a unit charge in any unambiguous way; only charge ratios are meaningful.

It is thus sensible to ask why the charge on the *u* (*up*) quark is minus twice that on the *d* (*down*) quark and why the latter is one third that of the electron, but it is not meaningful to ask which of these is the unit charge. If it is desirable to work with integral charges, the *d*-charge should be taken as he unit; the *u*-charge is then −2 units and the electronic charge is +3 units. That the latter is universally accepted as the unit charge is merely a matter of a bias which perpetuates the belief that the electron is an elementary particle for which, at present there is no conclusive evidence.

Nothing in current particle theories even begins to answer the question why only two elementary charges exist in nature and why their ratio is −2. Nor can these theories indicate how the answer is to be found. Quantum chromodynamics confuses things even more for it raises the additional question as to why all colours of a given quark flavour have the same electric charge.

If the three quarks in a nucleon form a linear structure, with one of the quarks always at the centre, as I have already proposed in my gravitational linear rotator model of the nucleon, then a simple variational principle answers the questions about quark charges.

In a series of papers I have proposed a linear rotator model of baryons in which the constituent particle triplets are gravitationally bound unitons, particles of mass $m \simeq (\hbar c/G)^{1/2}$, where G is the universal gravitational constant. The gravitational binding force between any two such particles is thus larger than the electrostatic force by a factor of the order of 137. Accepting this model one sees that the overall dynamical configuration is determined essentially by the gravitational field and that the electromagnetic field plays only a minor role in it; that is, the linear arrangement of three unitons, with one at the centre, is a consequence of the large masses of the unitons and would persist if the three unitons were electrically neutral. Nevertheless, the assignment of electric charges to the unitons does matter, for only one such assignment among the various possibilities is preferred by the energetics of the problem.

I now show that one obtains this unique uniton charge distribution by imposing the condition that the electrostatic potential energy of the linear triplet be a minimum. I have assumed here that gravity is the dominant force in this linear nucleon model, but any strong force field that gives the same linear arrangement will do.

If Q is the charge on the nucleon and q_1, q_2, q_3, are the three quark charges, we have:

$$q_1 + q_2 + q_3 = Q \qquad (1)$$

where q may be positive or negative. Placing q_1 at the centre of the linear configuration and q_2 and q_3 at the ends, the electrostatic potential energy is:

$$E = \frac{1}{r}(q_1q_2 + q_1q_3 + \frac{1}{2}q_2q_3) \qquad (2)$$

where $2r$ is the length of the structure; or,

$$rE = q_1(q_2 + q_3) + \frac{1}{2}(q_2q_3)$$

$$= q_1Q - q_1^2 + \frac{1}{2}Qq_2 - \frac{1}{2}q_1q_2 - \frac{1}{2}q_2^2 \qquad (3)$$

where I have used (1) to eliminate q_3. Varying this with respect to q_2, keeping Q and q_1 fixed, leads to the condition that $d(rE)/dq_2 = 0$ if, and only if, $q_2 = q_3$.

In other words, regardless of the value of Q and which uniton is at the centre of the configuration, the charges on the two ends must be equal in magnitude and in sign. Moreover, from (1), $q_2 = \frac{1}{2}(Q - q_1)$ or $q_2 = \frac{1}{2}(1 - q_1)$ if Q is the unit charge of the proton.

If, now, quark q_2 is at the mid point of this configuration, $q_2 + 2q_1 = Q'$, where Q' is another value of the total charge, to be identified with that of the neutron, so that $q_2 = -2q_1$. But from the equivalent information for the proton $-2q_1 = \frac{1}{2}(1 - q_1)$, or $(1 + 3q_1) = 0$ or $q_1 = -1/3$ hence $q_2 = 2/3\, q_1$.

This is as far as one can go with this simple type of analysis, but its simplicity and its seeming meagreness hide its importance, for it clearly points to the linear rotatore with a uniton (quark) at its centre as the correct model of the nucleon. We are ineluctably led to this conclusion by the coefficient $-\frac{1}{2}$ in front of q_2 in equation (3); if it were numerically different, we would not obtain the important equality $q_2 = q_3$.

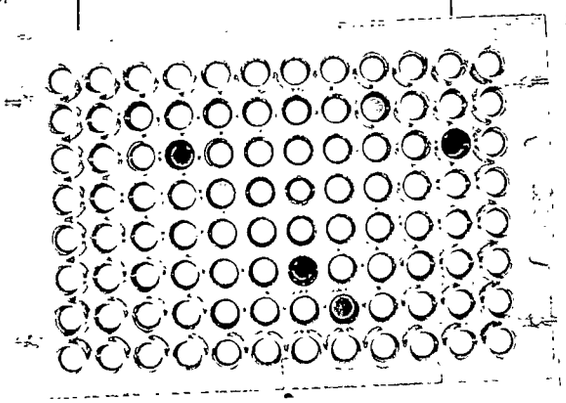
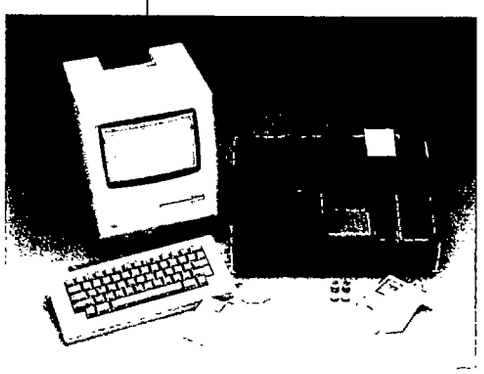
Everything For ELISA

From Bio-Rad, The Quality Choice

Monoclonal Antibody Screening Kits



Bio-Rad's mouse, human, and rat Clone Selector™ kits provide an efficient EIA method for selecting monoclonal antibodies. All 3 kits use high activity alkaline phosphatase labeled second antibodies which are highly antigen specific and are guaranteed to react with the most common monoclonal subclasses and isotypes. The anti-mouse and anti-rat reagents are cross-adsorbed to remove unwanted cross-reactivities. Each Clone Selector kit contains enough conjugate to screen 30,000 mouse, 5,000 human, or 5,000 rat supernatants and comes with everything required for fast, sensitive, and reproducible ELISA assays.



Hybridoma screening using Bio-Rad's Clone Selector system.

Mouse EIA Subtyping Kit

Bio-Rad's Mouse-Typer™ kit provides the most accurate ELISA method for identifying mouse Ig class and subclass. Monoclonal subtypes are identified quickly and easily by utilizing an ultra pure panel of rabbit anti-mouse typing reagents (IgG_1, IgG_{2a}, IgG_{2b}, IgG_3, IgM, and IgA). This method depends on antibody-antigen interaction, not antibody-antibody immunoadsorption, so background-free assays are guaranteed. The included protocol assures accurate typings, with positive wells having absorbances 3-6 times those of negatives. Each kit comes with all the essential reagents for 600 tests (100 typings).

Subtyping of mouse monoclonals using Bio-Rad's Mouse-Typer Kit.

Model 2550 EIA plate reader and Macintosh Computer.

EIA Grade Affinity Purified Antibody Conjugates and Substrates

Bio-Rad offers a broad selection of EIA grade antibodies conjugated to either horseradish peroxidase (HRP) or alkaline phosphatase (AP). These conjugates exhibit a high degree of specific enzyme activity, and most are cross-adsorbed to remove cross-reactivities. The high quality HRP and AP substrates specially formulated for use with the enzyme conjugates are safe, stable, 100% soluble reagents that produce chromophores with high extinction coefficients.

EIA Reader and Applications Software Speed Data Analysis

MacReader™ ELISA software, a complete data analysis package for the Model 2550 EIA reader, provides statistical analysis and data reduction of ELISA results in seconds. The combination of the speed and sensitivity of the EIA reader and the computing power of Apple's Macintosh™ computer produces a high performance ELISA system which reduces analysis time from hours to minutes.

MacReader™ is a trademark of Bio-Rad Laboratories

from Cold Spring Harbor Laboratory

Computer Graphics and Molecular Modeling

Edited by Mark Zoller, *Cold Spring Harbor Laboratory;* **Robert Fletterick,** *University of California School of Medicine, San Francisco*

COMPUTER GRAPHICS AND MOLECULAR MODELING summarizes work presented at a December 1985 Cold Spring Harbor Laboratory Banbury Center meeting at which a diverse group of researchers addressed issues such as protein sequence homology, three-dimensional structure homology in proteins, molecular design of functional, macromolecules, X-ray crystallography, hardware and software for displaying and analyzing three-dimensional macromolecules, and software for the analysis of the energetics and dynamics of proteins.

Molecular biologists, crystallographers, and computer specialists will find COMPUTER GRAPHICS AND MOLECULAR MODELING a useful collection of extended abstracts indicating directions for integrating the various approaches to the study of protein structure and function.

Translational Control

Edited by Michael B. Mathews,
Cold Spring Harbor Laboratory

Control of gene expression at the level of protein synthesis is a widespread phenomenon that has enjoyed a recent upsurge of interest, with great progress being made in explaining regulation at the initiation step. TRANSLATIONAL CONTROL is a collection of extended abstracts presented by some of the leading practitioners in this field at a small conference held at the Banbury Center of Cold Spring Harbor Laboratory in November 1985. Topics at the meeting ranged from the regulation of initiation factor activity and the influence of RNA structure to the effects of virus infection, heat shock, and interferon in organisms as diverse as *Volvox* and man. Mechanistic aspects of the problem were emphasized. Cell and molecular biology investigators and students and biochemists will find TRANSLATIONAL CONTROL an interesting survey of the latest developments in this field.

Plant Cell/Cell Interactions

Edited by Ian Sussex, *Yale University;*
Albert Ellingboe, *University of Wisconsin;*
Martha Crouch, *Indiana University;*
Russell Malmberg, *University of Georgia*

In much of plant growth and development, there is no new contact between cells that have not arisen together as clones after cell division. The rigid structure of the plant cell wall usually prohibits the sort of morphogenetic movements that are commonplace in animal development. This book, the result of an October 1985 Cold Spring Harbor Banbury Center meeting, presents current research aimed at analyzing exceptions to this rule. Converging from several quite diverse fields, the areas of research covered have in common the bringing together of plant cells with the consequent interactions of two distinct cellular genomes and developmental potentials.

The majority of the work presented focuses on two topics—plant self-incompatibility and host/pathogen interactions. Both the formal and molecular genetic approaches are discussed, as well as attempts to study the biochemical reactions that are subsequent to the interactions of the plant and pathogen phenotypes. In addition, discussions of plant cell/cell interactions during normal and graft chimeral development and in the mating-type biology of some fungi and algae are included.

Workers in the fields of plant pathology, plant development, and plant molecular biology will find much in this volume of current interest.

THE MANAGEMENT OF AIDS PATIENTS

Edited by DAVID MILLER, JONATHAN WEBER and JOHN GREEN

The Management of AIDS Patients is the first comprehensive guide to the practical clinical management of patients with AIDS or HTLV III infections. The book avoids the sensational aspects of the disease, offering solid advice and information for all people involved in patient care.

The editors and many of the contributors come from St Mary's Hospital, London one of the foremost centres in Britain for the treatment of AIDS patients. The knowledge and experience of these experts has been combined to provide a much-needed book for doctors, nurses, dentists and indeed for health-care professionals everywhere.

THE IMAGE OF PERFECTION

Artek's New 982B Image Analyzer. It's the perfect addition for your lab. Using a unique combination of hardware and software, the Artek 982B provides highly accurate, reproducible total counts as well as aperture or object area in less than one second. Change simultaneously from edge to density detection. Select circular, square and rectangular apertures. Set size detection thresholds (down to increments of .025mm in the macro mode). And/or switch from positive to negative images. All without interrupting statistical software routines. The Artek 982B is ideal for all kinds of micro and macro applications, from analyzing petri dishes to counting 96 well micro plates. It's also available with an X,Y stage mover. For more information, write or call Artek today.

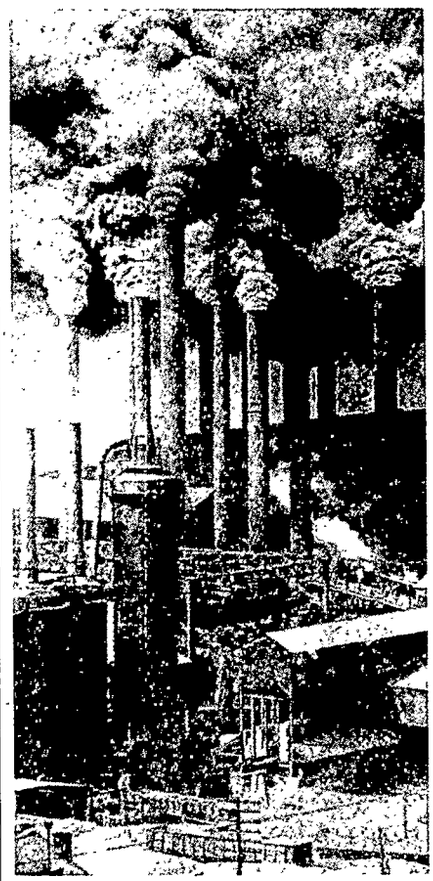
Consent — or compulsion?

Eric Ashby



National Styles of Regulation: Environmental Policy in Great Britain and the United States. By David Vogel.
Cornell University Press: 1986. Pp.325. Hbk $39.95; pbk $14.95.

IT WAS Winston Churchill who is reputed to have said: "The English never draw a line without blurring it". This comment would be a fair summary of David Vogel's verdict on the regulation of environmental policy in Britain: guidelines rather than rigid standards, persuasion through advisory committees rather than compulsion through the courts, "best practicable means" for the abatement of pollution rather than "best available technology". Behind this policy there is an important assumption, namely that the concept of zero risk is a mirage but acceptable risk is a reality. Politicians rely on this reality when they make regulations to control the exploitation of land, air and water. The result, to a non-British observer, is piecemeal policy which its supporters call pragmatic and its critics call sloppy. And, as David Vogel concludes after a scholarly examination of the evidence, it works quite well.

In the United States the policy for regulating the state of the environment is set out in sharp lines, no blurring. "The 1972 amendments to the Clean Water Act required all [*sic*] of the nation's waters to become 'fishable and swimmable by July 1, 1983'." Section 112 of the Clean Air Act amendments of 1970 required the Federal Environmental Protection Agency to regulate particularly hazardous pollutants to zero risk, with an "ample margin of safety" and regardless of cost. This policy, to a non-American observer, seems unrealistic, impracticable, and to offer a picnic to lawyers. But this policy, too, David Vogel concludes, works quite well. By "works quite well", I mean that there are better safeguards for health and amenity in Britain and the United States than there are in many other industrial societies. Risks are abated to what are, on the whole, levels acceptable to the public (though, when one considers the horrible harvest of road accidents in these countries, one is alarmed at the public perception of what constitutes "acceptable").

Vogel considers in detail the politics of control of pollution and land-use-planning in Britain and the United States. But his book is much more than a prosy "compare-and contrast" essay. He uses his material to examine a much deeper issue, namely how governments in democratic countries can control the Externalities — the economist's technical word — produced by autonomous industry. And this again is part of an even deeper issue: how to control the social behaviour of corporations. Both in Britain and the United States there has been progress in this policing of behaviour, but there are extraordinary contrasts in style. What is the reason for these contrasts? Why are there so few signs of convergence in means to achieve what are essentially the same ends?

Part of the answer to these questions is to be found in history. Britain suffered from the social misbehaviour of industry long before it affected the United States. By the year 1900 no fewer than 21 bills had been put before parliament for the abatement of smoke. Most of them failed because it could not be proved that smoke was actually a hazard to health, and in any case smoke-abatement would have been difficult and costly. But Britain was learning how to control the social behaviour of industry: in 1863, when the Alkali Act was passed to control the emission of hydrochloric acid from alkali works, it had the support not only of conservationists and landowners, but of the alkali industry itself. This was because the hazards of hydrochloric acid were evident and conrol was easy and cheap. The Act was administered by consensus, rarely by compulsion, although the Alkali Inspector had punitive powers. It would be an oversimplification to say that this set the pattern for regulation in Britain; what is more likely is that this pattern reflected the style of British politics over some — though not all — social issues, a style that seeks to persuade, to generate a willing compliance from the very people who are prone to unsocial behaviour. It is often criticized as a cosy consensus between the gamekeeper, paid to protect the environment, and the poacher, bent on exploiting it for his own profit. There is some justice in this criticism, but in the long run — perhaps because Britain is a small country where the leaders of industry belong to the same class as the leaders in politics — many industries do behave in a socially responsible way, induced to do so by desire to keep a bright public image fortified by fear of punishments held in reserve for intractable anti-social behaviour. What the critics call collusion between government and industry over industry's social behaviour is in fact sometimes genuine cooperation; the issues are settled over lunch in the club and subsequently validated by the issue of some regulation or guideline.

Pollution past — industrial smokestacks in Pittsburgh in 1906. The picture is taken from Introduction to Environmental Science, 2nd Edn, *by Joseph M. Moran* et al., *recently published by W.H. Freeman. Price is $29.95, £29.95.*

This is in striking contrast to the adversarial style of control in the United States where the impression is one of antagonism between the legislator and the industries against which he is legislating. The wrangles end up in the courts of law. At any one time there are hundreds of prosecutions going on. And no wonder. If the line is blurred its exact position can be a matter for compromise between non-lawyers. If the line is sharp and, as for the 1972 amendments to the Federal Clean Water Act, utterly unrealistic (it was estimated that it would have cost the entire gross national product of the United States for a year to achieve its declared intention), then of course there is hostility from industry and recourse to the courts. Vogel discusses one of the many difficulties that arise from this: that policy-making on environmental problems, which in Britain is still greatly influenced by scientific and technological experts, is, in the United States, in the hands of lawyers, who are less familiar with the scientific uncertainties and unsympathetic towards ambiguity. Hence some of the decisions of the courts in the United States are not the kind that would be made if

experts in environmental sciences had been in control.

Vogel does not pronounce judgement on the relative merits of the two systems of control. The American system is more time-consuming and expensive in legal costs. The British system relies on flexibility which can become mere laxity. Perhaps the secret of a successful policy is to be inflexible over principles (for example over the environmental quality standard ultimately desired) but flexible in the manner and pace at which one proceeds toward the desirable goal. Doubtless, on the statute book, the United States has the best-protected environment in the world; but the words of the statute book have not reached many of the rivers nor much of the atmosphere. The British statute book is more modest in its aspirations for the environment; but it does not often prescribe what could not be enforced without constant applications to the courts. Transferred to Vogel's larger canvas, this shows an interesting and (I suspect) controversial picture. Are the mild British regulations, the preference for self-disciplined industry, signs of weakness in Westminster, or of a strong and respected government which can afford to rely on voluntary compliance? And is the American "reliance on rule-oriented enforcement" a sign that Washington can bring to heel unsocial behaviour in industry, or is it a sign of weakness in a government which does not command the loyalty of its industrial corporations?

It is no mere academic exercise to reflect on these questions. Expand Vogel's theme from environmental control to the control of trade-unions, corporation-cartels and local government, and you see its significance. Upon the answers to these questions depend the patterns of government Britain and the United States will have in the twenty-first century. □

Lord Ashby is a Fellow of Clare College, Cambridge CB2 1TL, UK. He was Chairman of the Royal Commission on Environmental Pollution from 1970 to 1973, and sometime member of the House of Lords Select Committee which deals with environmental directives from the European Economic Community.

Fuss over nothing

W.D. Hackmann

Leviathan and the Air-Pump: Hobbes, Boyle, and the Experimental Life. By Steven Shapin and Simon Schaffer. *Princeton University Press:1986. Pp.440. $60, £43.*

THE air-pump, more than any other scientific instrument, was the emblem of the revolution in physics that took place in the mid-seventeenth century. Other devices, such as the telescope, microscope, thermometer and barometer, preceded it, and all of them had a dramatic impact on how scientists conducted research and viewed the world. But the air-pump was the first mechanical device which made it possible for experiments to be carried out in a controlled laboratory environment — in this case, inside a glass bell-jar. It was also the seventeenth-century equivalent of "Big Science": very expensive, difficult to manufacture and temperamental to operate. Only a handful were made and each one was a prototype. The pump did become commercially available in the late 1670s, but it remained a costly instrument affordable only by wealthy virtuosi.

Until the middle of the seventeenth century, vacuum experiments were done in the small space above the mercury in the Torricellian barometer tube. Then, in about 1654, Otto von Guericke captured the public imagination with a startling performance of his "Magdeburg hemispheres"; two teams of burly horses could not pull the hemispheres apart after the air within them had been exhausted by the first mechanical air-pump ever constructed. Robert Boyle's interest was aroused after reading about von Guericke's device in a book published in 1659, by the Jesuit Kaspar Schott, a prolific writer on scientific subjects. Boyle, and his assistant Robert Hooke, immediately set to work to develop a better pump. More significantly, Boyle began an experimental programme to delineate the properties of the vacuum inside the bell-jar of his pump. The results and conclusions were published in *New Experiments Physico-Mechanical Touching the Spring of Air* (1660), where Boyle consolidated his ideas about what he considered to be the proper experimental method (upon which much of our present-day science is based). *New Experiments...* touched off a series of controversies in the 1660s and 1670s that went far beyond what we would conventionally consider to be the realms of science. It is these controversies that are the subject of Shapin and Schaffer's impressive book.

The chief protagonists were Boyle and the philosopher Thomas Hobbes, one-time mathematics tutor to Prince Charles (Charles II). While Hobbes became best known for his political philosophy, expressed in *Leviathan* (1651), he also took a deep interest in science. The fullest statement of his philosophy of science is to be found in *Dialogus physicus* (1661), written in response to Boyle's experiments on the spring of air and here appearing for the first time in English translation.

Boyle distinguished between "obvious experiments" — simple observations of naturally occurring phenomena — and "unobvious" or "elaborate experiments" in which artificial phenomena were produced by apparatus, in this case the air-pump. The difficulties faced by Boyle are not unfamiliar to the modern experimental scientist: problems with the physical integrity of his pump (leakage, for example), with standardizing or calibrating the phenomena, and with replication. All these matters led to disputes with his fellow scientists but, as Shapin and Schaffer demonstrate, the confrontation with Hobbes was much more profound and went to the heart of the experimental method. For Hobbes not only rejected the existence of the vacuum in nature but (to borrow from Wittgenstein) he played a different "language-game", arguing that only reason or philosophy, not Boyle's "engine philosophy", could yield reliable knowledge.

Public display — a demonstration of Otto von Guericke's air-pump in Germany, in the mid seventeenth century, reproduced from Technica curiosa sive mirabilia artis *(1687).*

According to Shapin and Schaffer, this controversy was not so much about science as about social order. They examine the social conventions established for producing knowledge, and Boyle's techniques for making his experimental results acceptable to the scientific community. Thus (as the authors put it), the book is an exercise in the "sociology of scientific knowledge" and is written primarily for the community of scientific historians. Scientists may find this community's particular language-game at times rather off-putting, with its terms such as "literary technology" and "boundary-speech", and they will not find out how Boyle discovered the gas law (for which his air-pump was not necessary). But they should gain some thought-provoking insights into the complex relationship between experiment, theory, and the political and intellectual community. □

Brain failure after eighty years

T.J. Crow

Normal Aging, Alzheimer's Disease and Senile Dementia: Aspects on Etiology, Pathogenesis, Diagnosis and Treatment. Edited by C.G. Gottries. *Editions de l'Université de Bruxelles, Avenue Paul Heger 26, Bruxelles, Belgium:1985. Pp.308. FB 992.*

In 1907, Alois Alzheimer described the thickening and tortuosity of fibrils within the neuronal cytoplasm of almost every fourth cell of the cerebral cortex of a 51-year-old woman who had been suffering from dementia. At that time he can have had little conception of the growth of interest in the phenomenon 80 years later. What may then have seemed an isolated pathological curiosity now appears as but one manifestation of an ubiquitous process whose relevance to ageing itself is the centre of discussion. What has become known as "Alzheimer-type dementia" is now generally agreed to include not only the unusual cases of presenile dementia (onset before 65 years of age) such as Alzheimer described, but also the great mass of dementias of old age. The prevalence of this condition is 5–8 per cent of the population at the age of 65, rising to 20 per cent at age 80 and 40–50 per cent above the age of 90 years.

The neuropharmacological aspects of the subject have been one of the features of recent research, and these proceedings record the contributions to two symposia at the Collegium Internationale Neuro-Psychopharmacologicum in Florence in 1984. Since 1976 it has been recognized that the cholinergic projections to the cerebral cortex are lost, giving rise to hopes that cholinergic replacement therapy might ameliorate some part of the psychological deficit. Such hopes are as yet unfulfilled. One problem, well documented in this volume, is that the cholinergic losses are far from isolated—there is evidence of loss of adrenergic and serotonergic projections as well. Whether the primary change occurs in the cell bodies of origin of the ascending systems, or whether these systems are affected secondarily to changes in the cortex itself (the temporal areas being a probable site of early change), is still a matter of debate, although opinion is swinging towards the latter possibility. Whichever viewpoint is correct, the anatomical and chemical selectivity of the process is surprising; in the cortex, for example, somatostatin-containing neurones are affected and cholecystokin and vasoactive intestinal polypeptide-containing cells are spared (see *Nature* **314**, 92–94; 1985). This may yet provide a clue to the origin of the Alzheimer process.

Contributions to the book are not confined to neuropharmacology. They touch also on aetiology, both with respect to the enigmatic role of aluminium and to genetic factors (Alzheimer's disease shares with two other neurodegenerative conditions, Parkinson's disease and amyotrophic lateral sclerosis, a tendency to an earlier age of onset when there is greater incidence of familial cases). Aluminium is now known to be present in high concentration in the amyloid plaque, the structure which, together with the neurofibrillary tangle described by Alzheimer is the hallmark of the disease. Whether the element accumulates as a secondary effect or plays a pathogenic role remains unclear. In a short chapter, D.R.C. McLachlan speculates that aluminium could interact with calcium to contribute to the pathology. That electrolyte changes may be relevant to the aetiology of neurodegenerative disease is also suggested by Gajdusek and Garruto; they attribute the high incidence of amyotrophic lateral sclerosis and Parkinson's disease on Guam, the Kii peninsula of Japan and an area of New Guinea to low concentrations of calcium and magnesium in the soil, and the subsequent decline in incidence to correction of these mineral deficiencies. Such secular changes challenge the therapeutic nihilism which may be generated by the suspicion that these diseases, along with Alzheimer's dementia, are inseparable from the molecular genetic mechanisms of ageing.

This volume thus deals with a number of aspects of recent progress on Alzheimer's disease. There is relatively little reflection of the current interest in the protein structure of the plaques and tangles, but drug treatment strategies, although as yet of little practical value, are well covered. □

Plenum: Making It Happen

Forthcoming ...

CHEMISTRY BY COMPUTER
An Overview of the Applications of Computers in Chemistry
by **Stephen Wilson**
In this wide-ranging survey, Dr. Wilson covers the techniques of computational chemistry and shows how they may be applied to problems ranging from interstellar chemistry to molecular biology.
0-306-42152-6/approx. 200 pp./Jul./1986

DIGITAL RADIOGRAPHY
Selected Topics
edited by **James G. Kereiakes, Stephen R. Thomas,** and **Colin G. Orton**
Many of the significant developments resulting from the applications of physics and engineering to digital radiography are described here by noted authorities in the field.
0-306-42188-7/approx. 200 pp./Jul./1986
$39.50 ($47.40 outside US & Canada)

PRINCIPLES OF ENDOCRINE PHARMACOLOGY
by **John A. Thomas** and **Edward J. Keenan**
Thomas and Keenan discuss a wide range of drug induced alterations in glandular secretions, drug-hormone interactions, and effects of drugs on clinical chemistry tests. Advances in recombinant DNA technologies are covered as they pertain to endocrine pharmacology, especially revolving recombinant human insulin and recombinant human growth hormone.

NUCLEAR POWER AND ITS ENVIRONMENTAL EFFECTS

For the Layman, Nuclear Technician, Manager

Places the effects of possible nuclear radiation in perspective. Meets the need for a better understanding of radiation and its consequences especially after the TMI accident.

All vital aspects of nuclear power generation are considered, from fundamental principles to plant licensing, from uranium mining to disposal of waste. The safe operation of nuclear power plants, to prevent the escape of dangerous amounts of materials in case of an accident, is fully covered.

On common ground in Scandinavia

Chris Stillman

The Caledonide Orogen — Scandinavia and Related Areas. Edited by D.G. Gee and B.A. Sturt. *Wiley:1986. Two volumes, pp.1,266. £150, $214.50.*

LIKE most scientists, geologists work within a paradigm, and their main paradigm for the past quarter-century has unquestionably been the theory of plate tectonics. One of the fundamental concepts of this theory involves the formation of orogens — mountain belts — by the spreading and closing of ocean basins. The Caledonide Orogen evolved through the Palaeozoic period by the movements of North American, Baltic and European continents around a proto-Atlantic ocean; a full understanding of its development thus requires correlation of the rock units and their history throughout these extensive and now widely separated regions.

The decade 1974–1984 saw the flowering of one of the International Geological Correlation Programme's most successful ventures. This was Project 27, "The Caledonide Orogen", the objective of which was to establish a geological frame of reference for the whole orogen by encouraging researchers to get together and pool their knowledge. A series of annual meetings was arranged in each of the participating countries in turn, at which all concerned could meet, compare notes, deliver papers and visit the actual geological locations. In August 1981, Uppsala was the venue for the meeting at which the Scandinavian Caledonides were displayed, and the papers read there form the basis for this beautifully presented two-volume work.

This is a fine example of the book-maker's art — a lavish production, with excellent illustrations and extremely useful maps (the best being a 1:2,000,000 tectono-stratigraphic map of the Scandinavian Caledonides) — but its main value lies in the fact that it is the first major compilation of modern work on the Scandinavian Caledonides to become widely accessible. Rocks belonging to this orogen dominate Norway and much of Sweden; traditionally, the view taken on their geological history was determined by the perspective from either side of the national boundary (a point effectively made by the cartoon from 1896 illustrating the nappe controversy, here used to preface the section on regional geology). Until recently, publication in national and local journals tended to perpetuate the differences, hence the need for a comprehensive, integrated review. It is our good fortune that the review arose from an international meeting, the proceedings of which could be published in clear English and made widely available to geologists throughout the world. We are doubly fortunate in that the editors represent both traditions; they have succeeded in pulling together a stylistically uniform and coherent review, and have produced a major step forward in Scandinavian geology.

Nevertheless, for all that the two volumes are a thorough and accurate reflection of how things stood in 1981, time has moved on. The whole style of approach to the problem has begun to change. Even before the publication of these books, awareness was growing of the logical improbability of achieving the orogen-wide correlation that was the *raison d'être* of the Project. Many now favour a way forward by applying terrane analysis, a strong hint of which is given in a short contribution by Duncan Keppie entitled "The Appalachian Collage". This, perhaps, increases the value of the books — in a subject which changes its ground rules so frequently, it is often difficult to achieve a correct perspective for judging the publications of previous years, but through the consistency of direction applied by the editors this compilation has a built-in spirit level.

The volumes are properly focused on Scandinavia, with 62 contributions dealing with the geology of the Scandinavian Caledonides, but the regional context is not forgotten and 22 other papers add wider-ranging though not particularly representative reviews. Indeed, while Greenland and Britain are obviously related areas, the addition of Sardinia, Kazakhstan and Mongolia is bizarre. The main body of the Scandinavian contributions is arranged with regional reviews followed by sets of papers on stratigraphy, structure, igneous rocks and metamorphism, each with introductory chapters. A final section includes various interpretations of the general tectonic evolution of the mountain belt. The reader wishing to obtain an overview need do little more than read the regional reviews and the introductory contributions to the subsequent sections. For the specialist, there is ample material in many of the individual papers, which are not just bare outlines of conclusions but properly present the supporting data. Access to the contents is greatly facilitated by the excellent subject index.

Those wondering whether or not to purchase this work should bear in mind that although the cost is great, so are the rewards. The coverage is high and wide, and the books themselves are handsome. Geologists around the world can learn much from them, and they may yet provide the seed for many more ideas on Caledonide orogenesis. □

Chris Stillman is an Associate Professor in the Department of Geology, Trinity College, Dublin 2, Ireland.

FEBS LETTERS

An International journal established for the most rapid possible publication of essentially final short papers in the fields of biochemistry, biophysics and molecular biology

Published by Elsevier Science Publishers B.V.
on behalf of the Federation of European Biochemical Societies

One of the world's leading journals in biochemistry, FEBS Letters is renowned both for its quality of content and speed of production. Bringing together the most important developments in biochemistry, biophysics, molecular and cellular biology, FEBS Letters provides an international forum for minireviews, research results, commentaries, meeting reports and hypotheses which merit urgent publication.

FEBS Letters' annual **Index of Biochemical Reviews** lists titles, authors and sources of reviews and lectures from a large range of publications in related biological sciences. Entries are indexed under subject headings to serve the research and teaching interests of all biochemists, biophysicists and molecular biologists.

Remote Sounding of Atmospheres

J.T. HOUGHTON, F.W. TAYLOR and **C.D. RODGERS**

This book describes how measurements can be made of the Earth's and other planets' atmospheres using the techniques of remote sounding. It includes descriptions of the scientific principles, technical implementation, mathematical methods and discussions of the phenomena that have been found.

351 pp. 0 521 31065 2 **Paperback £12.95 net/$24.95**

GENETICS/PHYSIOLOGY

Regulation of Gene Expression – 25 Years On

Edited by **IAN R. BOOTH** and **C.F. HIGGINS**

This volume deals firstly with regulation of gene expression in the context of cellular physiology and then examines the major new developments in our understanding of the molecular basis of gene control. The authors primarily discuss bacterial systems, but some consideration is also given to lower eukaryotes.

Society for General Microbiology Symposium 39
309 pp. 0 521 32201 4 **£32.50 net/$59.50**

The Biotechnological Challenge

S. JACOBSSON, A. JAMISON and **H. ROTHMAN**

The socio-economic implications for developing countries of various biotechnologies are analysed in this unique volume, which discusses both the technologies themselves and case studies of their application in the Third World.

181 pp. 0 521 30775 9 **£22.50 net/$34.50**

Receptors in Tumour Biology

Edited by **C.M. CHADWICK**

This book discusses the phenomenon of recognition at the molecular level, examining specifically its relevance to metastatic disease. The contributors emphasise various aspects of cancer that can be traced to changes in the cell surface.

Intercellular and Intracellular Communication 2

MAMMALIAN PROTEASES:

A Glossary and Bibliography

Volume 2 **Exopeptidases**

J. K. McDonald and **A. J. Barrett**

May 1986, 373pp., $34.00/£21.00 (UK only), ISBN 0 12 079502 7

As an effective key to the literature for the study of exopeptidases this book will be invaluable to those working in biochemistry, medicine, biology, physiology and pathology, from undergraduates to researchers and teachers

Contents: Preface. Contents of Volume 1 Introduction *A Brief History of the Study of Mammalian Exopeptidases* Aminopeptidases Tripeptidases Dipeptidyl Peptidases. Tripeptidyl Peptidases Carboxypeptidases Peptidyl Dipeptidases. Dipeptidases. Omega Peptidases Index

Volume 1 **Endopeptidases**

August 1980, 435pp., $48.50/£35.50 (UK only), ISBN 0 12 079501 9

ESSAYS IN BIOCHEMISTRY

Volume 21

Edited by **R. D. Marshall** and **Professor K. Tipton**

December 1985, 162pp., $19.50/£12.00 (UK only), ISBN 0 12 158121 7

CHEMISTRY AND TOXICOLOGY OF PYRROLIZIDINE ALKALOIDS

A. R. Mattocks

March 1986, 367pp., $88.00/£55.00 (UK only), ISBN. 0 12 480570 1

Contents: Structures and Plant Sources of Pyrrolizidine Alkaloids Extraction, Separation and Analysis of Pyrrolizidine Alkaloids Syntheses of Necines, Pyrrolizidine Alkaloids and Analogues and Pyrrolic Derivatives Physical Properties and Spectroscopy of Pyrrolizidine Alkaloids and Related Compounds. Chemical Properties of Pyrrolizidine Alkaloids and Their Dehydroderivatives Metabolism, Distribution and Excretion of Pyrrolizidine Alkaloids. Toxicology of Pyrrolizidine Alkaloids in Animals Further Toxic and Other Biological Actions of Pyrrolizidine Alkaloids, Analogues and Metabolites. Effects of Pyrrolizidine Alkaloids in Humans Mutagenic Antimitotic and Other Cell-damaging Effects of Pyrrolizidine Alkaloids. Pyrrolic Derivatives and Analogues. Carcinogenicity and Antitumour Activity of Pyrrolizidine Alkaloids and Plants Containing Them Relationships between Structure, Metabolism and Toxicity. References Index

EXPERIMENTAL MODELS IN ANTIMICROBIAL CHEMOTHERAPY

Edited by: **O. Zak** and **M. A. Sande**

Volume 1, May 1986, 380pp., $63.50/£39.50 (UK only).
ISBN: 0.12.775401.6
Volume 2, June 1986, 416pp., $65.00/£38.00 (UK only).

Modulation of the epidermal growth factor receptor by mitogenic ligands: effects of bombesin and role of protein kinase C **Ian Zachary and Enrique Rozengurt**

The EGF receptor: structure, regulation and potential role in malignancy **David M Thompson and Gordon N Gill**

The colony-stimulating factors and myeloid leukaemia **Nicos A Nicola and Donald Metcalf**

Cancer Surveys focuses on a new topic every quarter. Each edition provides a definitive and up-to-date account of the present state of knowledge in the chosen area. Guest Editors, with specialist knowledge of that field, provide general assessments. Contributors review the areas where they have made important contributions, include research which may not have been published elsewhere and relate epidemiological and laboratory research to clinical problems.

Each issue costs £13.50(UK), US $29 (N. America), £15.50 (Elsewhere) or take out a year's subscription: £47 (UK), US $95 (N. America), £53 (Elsewhere). Cancer Surveys is published quarterly.

New and Forthcoming Titles from Springer

Cadmium

Editor: **E. C. Foulkes,** University of Cincinnati
1986. 59 figures. XIV, 400 pages (Handbook of Experimental Pharmacology, Volume 80). Hard cover DM 490,-
ISBN 3-540-16025-6

Contents: The Estimation of Cadmium in Biological Samples. – Cadmium in the Environment and its Entry into Terrestrial Food Chain Crops. – Absorption of Cadmium. – The Chronic Toxicity of Cadmium: Influence of Environmental and Other Variables. – Effects of Cadmium Exposure in Humans. – The Nephropathy of Chronic Cadmium Poisoning. – Cadmium and the Cardiovascular System. – Role of Metallothionein in Cadmium Metabolism. – Immunotoxicity of Cadmium. – The Effect of Dietary Selenium on Cadmium Cardiotoxicity. – Cellular Resistance to Cadmium.

New Neuromuscular Blocking Agents

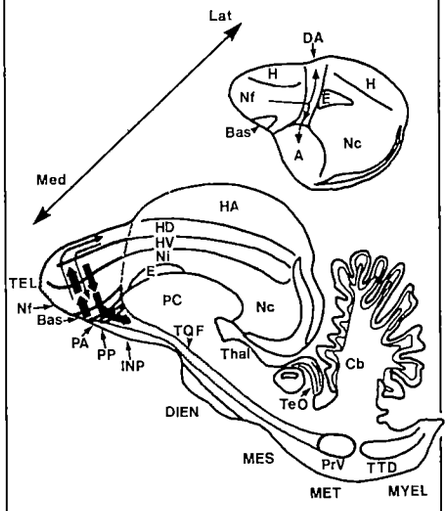
Basic and Applied Aspects
Editor: **D. A. Kharkevich,** Moscow
1986. 128 figures. XXIV, 741 pages (Handbook of Experimental Pharmacology, Volume 79). Hard cover DM 780,-
ISBN 3-540-15771-9

This volume contains data on the relationship between chemical structure and neuromuscular blocking activity in some series of compounds. Chapters dealing with the structure of endplate acetylcholine receptors, pre- and post-synaptic action of the agents considered, and their effects on the autonomic and central nervous systems are included.

Medical Informatics Europe 85

Proceedings, Helsinki, Finland, August 25–29, 1985
Editors: **F. H. Roger,** Brussels; **P. Grönroos,** Tampere; **R. Tervo-Pellikka,** Helsinki; **R. O'Moore,** Dublin
1985. XXVII, 823 pages. (Lecture Notes in Medical Informatics, Volume 25). Soft cover DM 118,-. ISBN 3-540-15676-3

From the contents: Hospital Information Systems. – Departmental Patient Data Systems. – Decision Support and Expert Systems. – Medical Record Management and Classification Problems. – Application Development and Software Tools. – New Technology. – National Policy and Management. – Privacy and Data Protection. – Medical and Clinical Research and Epidemiology.



Advances in Anatomy, Embryology and Cell Biology

Volume 96
C. L. Veenman, K.-M. Gottschaldt, University of Göttingen

The Nucleus Basalis-Neostriatum Complex in the Goose (Anser anser L.)

1986. 41 figures. VIII, 85 pages. Soft cover DM 68,-. ISBN 3-540-15338-1

This work provides insight into telencephalic sensor-motor aspects in Anserformes and other birds possessing a similar system, which can be compared with the corresponding circuit in mammals. This comparison will help researchers gain a better understanding of the principles governing the organization of higher vertebrate central nervous systems.

Volume 98
K. Hinrichsen, University of Bochum

The Early Development of Morphology and Patterns of the Face in the Human Embryo

1985. 82 figures. VII, 79 pages. Soft cover DM 68,-. ISBN 3-540-15848-0

The morphological changes accompanying the development of the human face are studied here for the first time in a consecutive series of photographs of embryos by Scanning Electron Microscopy (SEM) technique. The changes documented occur in the embryo between stage 12 and stage 23. This unique presentation with SEM photographs offers a new morphological basis for research into malformations.

The Influence of Antibiotics on the Host-Parasite Relationship II

Editors: **D. Adam,** University of Munich, **H. Hahn,** Free University of Berlin; **W. Opferkuch,** University of Bochum
1985. 98 figures, 60 tables. XIV, 298 pages
Hard cover DM 124,-. ISBN 3-540-15843-X

Contents: The Influence of Antibiotics on the Morphology and the Surface of Bacteria. – The Influence of Antibiotics on Immunogenicity. – The Influence of Antibiotics on the Interaction of Bacteria with Host Defence Mechanisms. – The Influence of Antibiotics on the Pathogenicity Factors and Virulence.

Advances in Forensic Haemogenetics

11th Congress of the Society for Forensic Haemogenetics
Editors: **B. Brinkmann,** Münster; **K. Henningsen,** Copenhagen
1986. 126 figures, 119 tables. Approx. 535 pages. Soft cover DM 98,-
ISBN 3-540-16500-2

This book offers a survey of the latest results in forensic haemogenetics. The topics covered include formal genetics, population genetics, and the biochemistry and serology of nearly all hereditary blood group polymorphisms, with several reviews of isolated subjects such as the HLA system, enzyme polymorphisms, protein polymorphisms and DNA polymorphisms. Legal considerations are also discussed.

Skin Models

Models to Study Function and Disease of Skin
Editors: **R. Marks,** Cardiff; **G. Plewig,** Düsseldorf
1986. Approx. 217 figures, approx. 87 tables
Approx. 385 pages. Soft cover DM 178,-
ISBN 3-540-15330-6

Considerable information on the physiological disturbances of disorders such as psoriasis and atopic dermatitis has accumulated, which permits a rational approach to treatment. Here the successful use of antimitotic agents, immunomodulators and retinoids may be cited as examples. This book provides specialists with the models of skin that have proven particularly helpful.

NEW JOURNAL – Issue one to be published June 3rd 1986 by Macmillan Press

BONE MARROW TRANSPLANTATION

Editor:
John Goldman
MRC Leukaemia Unit, Hammersmith Hospital, London

Co-Editor (USA and Canada)
Robert Peter Gale
Division of Hematology and Oncology, UCLA School of Medicine, Los Angeles

Associate Editors:
Elaine Gluckman, *Paris*
Alberto Marmont, *Genoa*
Tohru Masaoka, *Osaka*
George Santos, *Baltimore*
Don Thomas, *Seattle*
Jon van Rood, *Leiden*

Contents of Issue One

Short editorial comment – Goldman (Hammersmith)
Review of the contribution of the International Bone Marrow Transplant Registry – Gale (Los Angeles)
Bone marrow transplant for thalassaemia – Slavin (Jerusalem)
Bone marrow transplant for myeloma – Tura (Bologna)
Results of second transplants after graft failure – Bolger (Seattle)
Soy-bean lectin fractionation of marrow for prevention of graft versus host disease - Slocombe (London Hospital)
Comparison of cyclosporin and methotrexate for prevention of GVHD – Ringden (Stockholm)
Campath-1 for T-depletion before BMT for chronic myeloid leukaemia – Apperley (Hammersmith)
Toxoplasmosis after bone marrow transplant – Derouin (Paris)
Bone marrow transplant for ALL in second CR – Bacigalupo (Genova)
Bone marrow transplant for lymphoma – Ernst (Copenhagen)
Race as prognostic factor after BMT – Klingerman (Seattle)
Porphyria cutanea tarda revealed by bone marrow transplant – Dopfer (Tubingen)

THIS IMPORTANT NEW JOURNAL WILL INCLUDE:

- clinical results in man and experimental results with animals
- allografting and autografting
- HLA determination and other methods of selecting donors
- aspects of graft-versus-host disease, its prevention and treatment
- many other topics associated with bone marrow transplantation
- correspondence section for exchange of topical and controversial ideas
- stimulating editorials and book reviews

Announcement: XIII Annual Meeting European BMT Group, Interlaken, 1-5th March 1987. Further details from Dr A. Gratwohl Division of Haematology, Kantonsspital, Basel, Switzerland.

Ecological consequences of nuclear war

from S.J. McNaughton, R.W.Ruess and M.B. Coughenour

Simulations of the ecological effects on grassland ecosystems projected from the proposed climatic changes that would follow a nuclear war indicate that temperature and light reductions below ambient mean levels exceeding 10°C and 28%, respectively, are required for severe ecosystem deterioration to occur and that thresholds between promotion and decline are very abrupt.

ESTIMATES of the mass of smoke particles that would be injected into the atmosphere by fires following a nuclear war indicate that the resultant attenuation of light by suspended elemental carbon could substantially increase the optical depth of the atmosphere, producing major, rapid reductions of temperature and incident radiation at the Earth's surface[1], a phenomenon termed nuclear winter[2]. Climatic models using various degrees of structural and dynamic detail have provided diverse predictions of the global climatic effects of atmospheric soot loading, but all are in general agreement that fires of the extent and intensity now reasonably projected to follow a nuclear war that included significant targeting of urban centres would lead to major falls in surface light intensities, temperature and, less certainly, precipitation[3-5]. More complex models have tended to predict both a longer duration and a broader geographical scale of climatic effects[6]. Transitory surface temperature reductions of more than 40°C and extended reductions of 20°C below mean ambient levels and light reductions to 0.01 and 0.1 of normal have been predicted. To place these estimates in perspective, the seventeenth century 'little ice age' is believed to have been caused by only a 1°C decline below mean ambient temperature[7], and major glacial and interglacial periods may involve only 10–15°C peak-to-trough changes[8]. The potential biological and ecological consequences of the climatic changes projected to follow nuclear war could obviously be devastating[9,10].

Initial evaluations of the potential ecological effects of nuclear winter have been, of necessity, largely qualitative[9,10]. Here we present quantitative results obtained by applying a wide range of the climatic effects currently predicted to result from atmospheric soot loading after a nuclear war to a documented, detailed, mechanistic simulation model of grassland ecosystem processes[11-13].

Procedures

We used nuclear winter climatic predictions to modify climatic sub-models of the Grassland Research and Serengeti Systems Model[11-13], hereafter referred to as GRASS. It combines plant physiological processes; plant growth processes; plant morphometry; shoot demography; and grazing, with carbon, nitrogen, radiation and water sub-models. The principal focus or our research is the grazing ecosystem in the Serengeti region of Tanzania and Kenya[15-18], so both biotic and abiotic parameters were drawn from studies of that ecosystem.

Experimental studies leading to parameter values have previously been documented[19-21]. Because the productivity of cultivation agriculture would probably be severely reduced after a nuclear war, forage agriculture and particularly non-subsidized rangelands, might be major food production systems for human survivors in non-combatant countries, many of which might be located in tropical-to-subtropical locations[19].

We parameterized the GRASS simulations described here for mid-height grasses with a terminal canopy height of 50–150 cm, growing in an equatorial location at an elevation of 1,500 m with a mean annual rainfall of 793 mm and a rainfall-determined growing season of 296 days. We produced rainfall events probabilistically by GRASS and included all microclimatic parameters that might reasonably be modified by decreased light, lower temperatures and modified rainfalls. We ran diurnal variables at 2-h time steps and all others at 2-day time steps. For grazing simulations, we harvested the canopy uniformly to a height of 4 cm above the soil surface every 50 days, the optimum defoliation level for maximum mass yield to grazers in previous simulations[12].

The climatic predictions that have resulted from modelling nuclear war scenarios can be applied to ecological modelling in various ways. We chose the imposition of fixed changes on normal seasonal progression for the entire courses of growing seasons as we wanted to saturate a reasonable climatic factor space with ecological simulations that would produce response surfaces over as broad a range of conditions as was relevant, feasible and interesting.

We ran 90 full growing-season simulations, 45 each under grazed and ungrazed conditions, and modified precipitation by applying fixed percentages of −50, −30, −10, + 10 and + 30 to each rainfall generated by the weather simulator sub-model of the model. We simulated both increased and decreased rainfall because of the uncertainty of precipitation predictions from climatic modelling[6]. Because light intensity and temperature co-vary upon the injection of smoke into the atmosphere[1-6], we coupled values for those variables down to near freezing night-time temperatures, which terminated growth. Tropical pasture species are both chilling-sensitive and frost-intolerant, although species with ranges that extend outside the equatorial belt often have cold-tolerant populations in cooler habitats[22-24]. We did not simulate mean temperature reductions lower than 13°C once initial screening indicated that these temperatures produce periodic night-time frosts.

In addition to control conditions, we performed temperature- and light-intensity reductions at °C/% light combinations of −1°C/−6%; −2°C/−12%; −3°C/−16%; −5°C/−22% and −10°C at light reductions of −28%, −50%, −65% and −88%. The last two light reductions simulated atmospheric optical depths near 1 and 2, which might be widely distributed during post-war periods in non-combatant geographical locations[1-6]. Although we did not apply a time-varying post-war trajectory to climatic variables, the typical seasonal patterns of GRASS were preserved, producing characteristic seasonal progression of precipitation, humidity, cloud cover and other normal weather variables. Control mean temperature was 21°C with a mean diurnal range from 28°C daytime highs to 14°C night-time lows. A given temperature reduction reduced maximum, minimum and intervening 2-h interval temperatures by that fixed amount. We superimposed radiation reductions on diurnal patterns and the cloud cover simulator and then fed them into sub-models of radiation and water balances to affect their performance and the resultant temperatures of plant tissues and

soils. Hence, we simulated total productivity, both above- and below-ground.

Baseline validation

Published data on below-ground primary productivity are scarce and our model produces reasonable outputs when compared with the available data[11]. More widely available are data on above-ground productivity of ungrazed grasslands. We used three such data sets for a model validation internal to the simulations presented here. Data sets of above-ground primary productivities of ungrazed grasslands have been fit to regressions on annual rainfall for the Serengeti ecosystem[18], eastern and southern Africa[25] and the world[26]. There are many similar fitted curves in the literature but we used these three for baseline comparisons because they are both extensive, relevant to the ecosystem modelled, and have no data overlap.

The most complete data set for 52 worldwide sites[26] produces a best fit (r^2 = 0.51)-line of ANP = 0.5 (rain) − 29, where ANP is above-ground net primary productivity in g m^{-2} yr^{-1} and rainfall is in mm. A Serengeti dataset for 20 locations subject to neither excessive drainage nor runoff water influx[18] produces a best fit (r^2 = 0.48) line of ANP = 0.69(rain)−102 and the other African dataset of 33 values[25] produces a line (r^2 = 0.67) of ANP = 0.85(rain)−20.

Simulated above-ground productivities of ungrazed grasslands at ambient light and temperatures, and rainfalls less than 900 mm, above which both simulated and measured[27] productivities become asymptotic to the abscissa, produces a line (r^2 = 0.97) of ANP = 0.48(rain)−48, as similar to the empirical lines as they are to each other. Together with previous comparisons of model performance with published empirical results[11–14], these results indicate that GRASS produces realistic grassland performance over a wide environmental range. Still, the application of post-war climatic predictions, themselves of uncertain surety, to any ecological model is a venture into uncharted predictive realms unamenable to experimental verification. But, where verification is feasible, GRASS performance is in good accord with empirical datasets and the climatic projections considered here deal mainly with conditions close to normal climatic variation, rather than extremes of extended cold, dark conditions.

Aftermath simulations

Our control conditions for simulations are 793 mm of rain at normal light and temperature; our baseline is the rainfall span at unreduced light and temperature. The total, above- and below-ground, simulated productivities of ungrazed grasslands are very sensitive to rainfall near

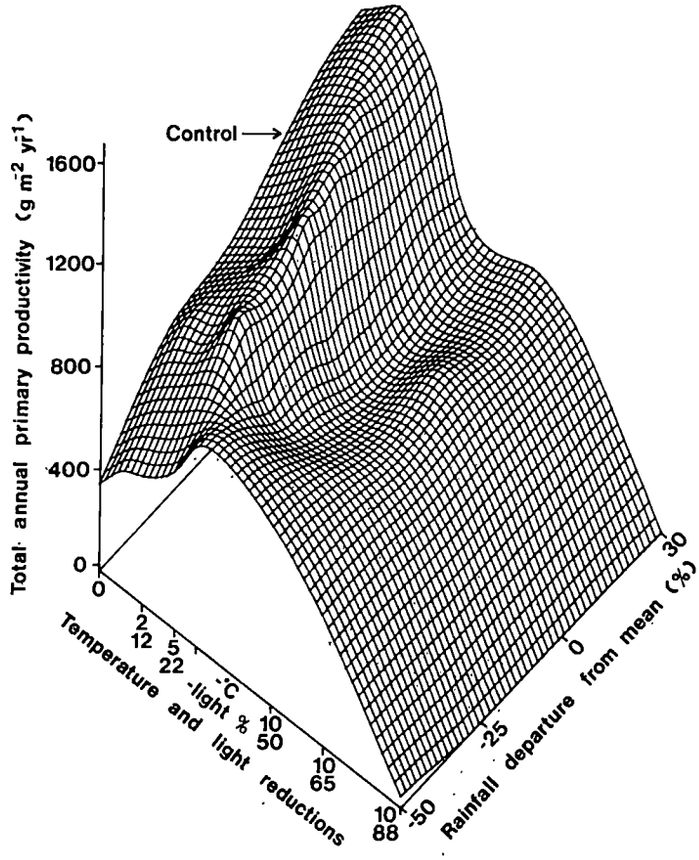

Fig. 1 Simulated total primary productivity in g m^{-2} yr^{-1} of ungrazed grasslands in relation to deviations of precipitation and temperature-radiation environments from the long-term mean condition, the indicated by arrow labelled control. Note that the *y*-axis is linear in light intensity and non-linear in temperature. Data were fitted with the bivariate spline interpolation and graphed with the PROC 3D procedure of the 82.2 enhancements and update release of SAS/ GRAPH (SAS Institute, Cary, North Carolina, 1982). Tilt, 60°; rotation, 50°.

normal light and temperature conditions, but are resistant to light and temperature departures from normal until mean reductions approach 28% and 10°C, respectively, below mean ambient levels (Fig. 1). This results in a substantial shelf where primary productivity is near or above control values for moderate climatic changes projected to follow a nuclear war. The upper level of the response surface is twisted by the tendency for cooler, darker conditions to compensate for reduced rainfall.

At the lowest rainfall level, in fact, primary productivity continues to increase at light-temperature reductions that significantly reduce production at higher rainfall levels. Therefore, reduced light and temperature have much greater water-conserving effects at low rainfalls than at higher rainfalls. These environmental interactions were expressed, in part, through compensatory changes in plant water potential, averaged over all shoots. Midway during the growing season, plant water potentials increase from −1.73 MPa at control light/temperature to −0.49 MPa at the 10°C/28% reduction under the lower rainfall conditions. At the highest rainfall conditions, the increase is only from −1.03 to −0.17 in this range.

Plant water potential regulates productivity by influencing net photosynthetic rates and tissue growth rates, and these compensatory interactions are propagated through GRASS performance. In addition, greater rainfalls increase leaf longevity, producing greater average ages of active canopy tissues, which are accompanied by declines in leaf nitrogen content and resultant rates of net photosynthesis. So no simple explanation suffices to explain the twisted response surface; rather, it is a complex consequence of plant growth and metabolic responses to interacting environmental variables. Because of the diagonal crest, productivity at high rainfall levels drops much more precipitously as the more severe region of the factor space is penetrated. The greatly reduced light levels indicate that the grasslands have a broad ability to compensate for light reductions after the initial drop, producing a shelf extending to the light

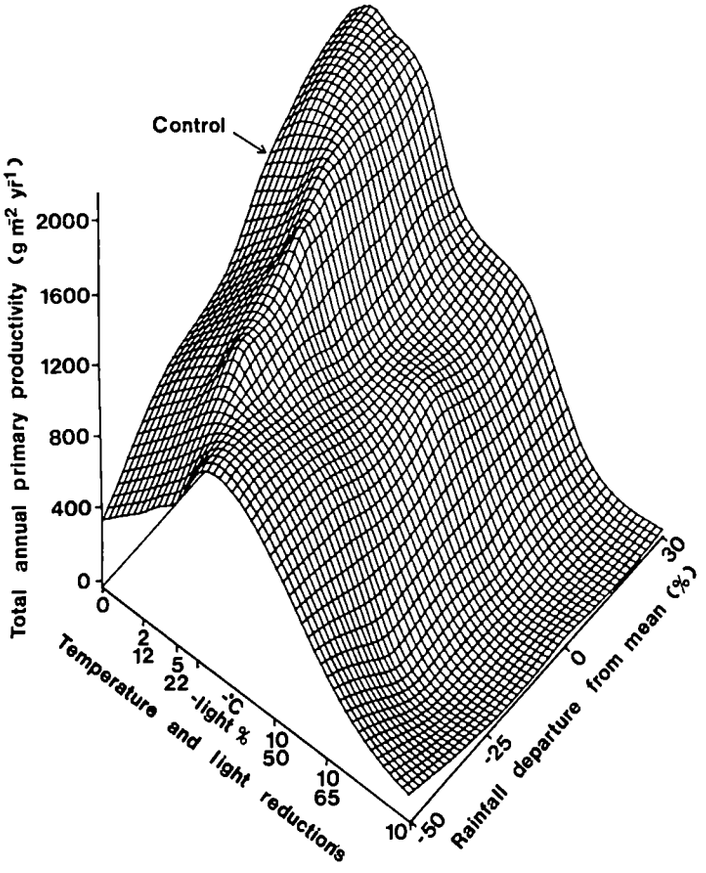

Fig. 2 Simulated total primary productivity in g m^{-2} yr^{-1} of grazed grasslands in relation to deviations of precipitation and temperature-radiation environements from the long-term mean condition, indicated by an arrow. Note that the *z*-axis scale differs from Fig. 1 if comparing the two response surfaces. Data were fitted and plotted as described in Fig. 1 legend. Aspect as in Fig. 1.

intensities produced by an atmospheric optical depth of one. At that optical depth, productivities are 79% of baseline at low rainfall levels, 61% at normal levels, and 46% at the highest simulated rainfall. Beyond an optical depth of 1, however, productivity again plunges precipitously to near zero at an optical depth of 2 and this surface of steeply decreasing primary productivity was rainfall-independent.

More interesting than the obvious fact that severe temperature and light reductions will drive production to zero is the finding that productivities are increased by most simulated post-war light and temperature reductions of moderate extent at a broad range of rainfalls. The minimum productivity on the upper response shelf, equivalent to 41% of control, is produced by the 50% rainfall reduction with no changes in temperature and light. The maximum productivity of the ungrazed simulations, 44% above control, occur at the highest simulated rainfall level accompanied by temperature and light reductions below ambient of 2°C and 12%, respectively. The diagonal crest is produced by the tendency for very minor light/temperature reductions to produce maximum productivities at higher rainfall levels, whereas low rainfall systems continued to exhibit increased productivity at substantial light/temperature reductions. Beyond this crest productivity in low rainfall simulations declined steadily to zero levels, lacking the shelf that occurs at higher rainfalls. These results have important implications for potential yields from water-limited ecosystems in post-war environments.

Grazing stimulates the primary productivities of grasslands at higher rainfall levels but not at low rainfalls; as a consequence, the overall grazed response surface has simpler but much steeper contours (Fig. 2). Primary productivity has a more convex shape under grazed than ungrazed conditions because of higher peaks, steeper contours and more abrupt thresholds. The diagonal crest on the upper shelf is more pronounced because of the tendency for primary production at high rainfall to decline after a slight rise with minor light/temperature reductions and an extension of the ameliorating range of those reductions at the lowest simulated rainfalls. Net primary productivity is stimulated a maximum of 38% above control conditions by the combination of highest rainfall with a light/temperature reduction of just 1°C and 6%. At baseline conditions, the lowest simulated rainfall reduces the productivity of grazed grasslands to only 28% of the value at control conditions. There is little evidence of a shelf of resistance to light reductions at temperatures above freezing.

Grazed grasslands are generally able to maintain reasonable levels of primary productivities down to a light reduction of 50% below normal, but they are severely inhibited by the reductions produced by an atmospheric optical density of 1. At that level, primary productivities are 19% of baseline at low rainfalls, 12% at normal rainfalls, and 9% at the highest rainfall simulated. Compared with the ungrazed simulation, this result suggests that the trophic web would collapse under conditions still allowing significant primary productivities in ungrazed grasslands.

The ameliorating effects of light and temperature reductions produce steeper responses under grazed conditions over the upper productivity shelf. For example, at control rainfall the productivity of ungrazed systems is 17% below normal at the 10°C/28% temperature/light reduction. In the grazed ecosystem, in contrast, net primary productivity under those conditions is still 13% above baseline. As a consequence, the descent of productivity as the limiting factor space is penetrated is much more precipitous for grazed than for ungrazed ecosystems.

As grasses must be converted into animal products for uncultivated vegetation in grassland climates to support human populations, secondary productivity is of particular importance to consideration of the potential consequences to humans of climatic changes that might follow a nuclear war. There are two fundamentally different approaches to estimating secondary productivity from model output. The simplest, but perhaps least revealing, is to convert the plant mass consumed by grazers to animal biomass by assuming some conversion efficiency based on animal feeding trials[27]. That approach assumes that forage quality does not vary across the range of conditions simulated and has the virtue of converting forage consumption per unit area directly into animal yield per unit area.

When we applied a 10% conversion efficiency[28,29] to animal forage consumption output from GRASS, with that output varying according to both forage amount and its availability due to canopy geometry[12], we found (r^2 = 0.87, $P < 0.001$)

that secondary productivity = 0.052 × total primary productivity, the units of productivity are in mass area^{-1} yr^{-1} for the 40 environmental combinations above zero. Secondary productivity then, under this assumption, would reproduce the response surface of Fig. 2, but with absolute values 95% lower on a mass density basis.

A second and, we believe, more realistic approach to estimating secondary productivity is to account for differences in forage quality. Both wild[30] and domestic[31] ungulates, particularly in tropical locations, are more often limited by forage quality than by its quantity. Higher mass productivities produced by GRASS are generally accompanied by lower forage quality because nutrients such as nitrogen are diluted by carbon accumulation in plant tissue, consistent with real ecosystems[32]. Over the range of non-zero conditions simulated here, the relationship between the nitrogen content of forage consumed and the mass of carbon that is consumed is

$$\%N = 1.93 - 0.00386\,gC$$

where $r^2 = 0.92$, $P<0.001$ and gC is grams of carbon consumed per square metre of land surface per year.

As a consequence of this negative relationship between forage quality and mass availability, the amount of N consumed was asymptotically related to the amount of forage carbon consumed ($r^2 = 0.86$, $P<0.001$) with gN = (2.27 ln gC) −5.2 where units are masses of N and C m^{-2} yr^{-1}. This conundrum relating forage quality and quantity of further exacerbated by a positive relationship between forage nitrogen content and the digestibility of that nitrogen (ref. 33). Therefore, as a more realistic approach to estimating potential secondary productivities of post-war ecosystems, we multiplied N yield to grazers in gN M^{-2} yr^{-1} by the digestibility of that N predicted from the linear relationship between forage N content and digestibility of N (ref. 33). This yielded digestible gN m^{-2} yr^{-1} consumed by grazers. Additional assumptions that we are unwilling to make at this stage would be required to convert the areal yield of digestible N to animal production, but the shape of the response surface is more likely to reflect the secondary productivity potentials of post-war ecosystems than the simple conversion from Fig. 2.

The quality-based secondary productivity response surface produced by GRASS varies markedly from both primary productivity surfaces (Fig. 3). Maximum secondary productivity, 38% above the control value, is produced at moderate drought and no reduction of ambient light and temperature. Minimum secondary productivity potential outside the severe factor space is at the highest rainfall with temperature-light reductions of 5°C/22%, where the value is only 36% of the control. This response surface is caused by a greater reduction in plant-carbon assimilation than of nutrient assimilation by mild environmental stress, a phenomenon documented empirically[34,35] and that GRASS reproduces. As a consequence, there was a pronounced peak of secondary productivity potential at a rainfall reduction to 30% below normal in baseline light and thermal environments. Values drop precipitously around this optimum, particularly at lower rainfall levels and no light/temperature reduction. But the surface is convoluted with folds and pockets, especially as severely limiting conditions are approached. Reduced light levels at non-freezing temperatures produce a broad secondary shelf of slightly increasing secondary productivity potential with a reversal of the rainfall field leading to higher potentials at higher rainfalls. At light intensities above half normal, potential secondary productivity drops sharply to zero. Compared with control conditions, all higher rainfall simulations and all reduced light and temperature conditions under the normal rainfall regime result in secondary productivity potential lower than the control. But many of the climatic conditions predicted to follow a nuclear war, that is, combinations of reduced rainfall with cooler, darker conditions, result in significant enhancements in the yield of digestible N to herbivores.

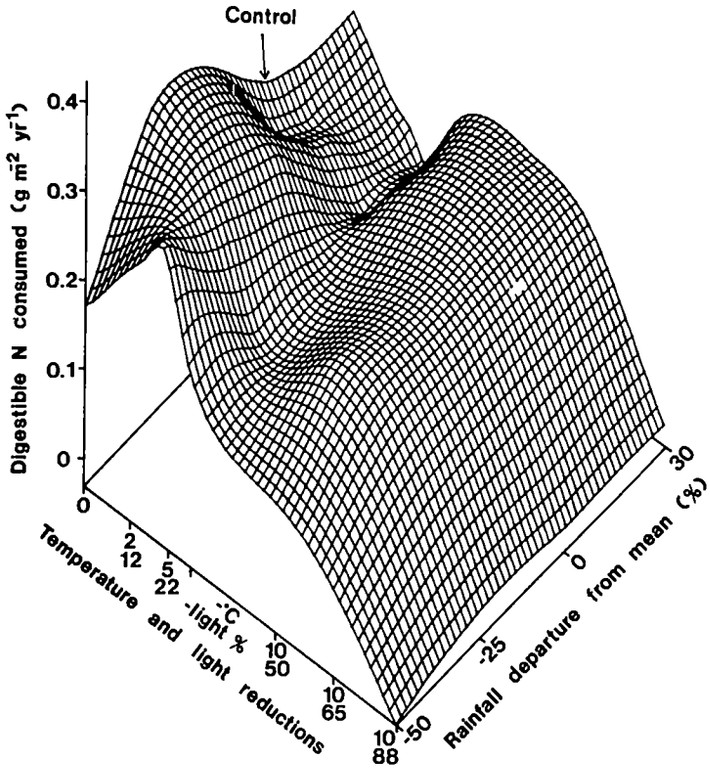

Fig. 3 Simulated yield of digestible N to grazers in g m^{-2} yr^{-1} in relation to deviations of precipitation and temperature-radiation environments from the long-term mean condition, indicated by an arrow. Data were fitted and plotted as described in the legend for Fig. 1. Aspects as in Fig. 1.

When compared with the primary productivity simulations and simple extrapolations of secondary productivity from them, these simulations highlight two significant features of ecosystems. First, countervailing processes make it difficult, if not impossible, to optimize all performance standards simultaneously. Second, simple extrapolations are incapable of providing meaningful estimates of the effects of complex biological responses to environmental variation.

Implications

We make no claim for the ultimate accuracy with which GRASS simulations could predict the ecological aftermath of a nuclear war. But we do believe that those projections are fundamentally realistic; that they provide reasonable boundary conditions for severe declines in ecosystem carrying capacity; and that they prudently reflect the ecological conditions that could be expected to occur in many grassland and other water-limited ecosystems following such a war. Primary productivities under both grazed and ungrazed conditions, and secondary productivity potentials, are stimulated by cli-

matic conditions that would be relatively severe under normal conditions, although they can be characterized as mild compared with the more extreme nuclear winter conditions predicted by some models. The abrupt interfaces between stimulatory and degradative effects emphasize the hazards associated with deductions from imprecise climatic predictions.

The sensitivity of our simulations to the countervailing effects of precipitation and radiation-temperature changes within the non-severe factor space indicates that it would be profitable to devote more effort in climatic modelling to precise definitions of the coupling between precipitation and radiation-thermal regimes, perhaps at the sacrifice of global spatial scales where the models are in general, if not precise, agreement. Because climatic effects have post-war meaning only through their ecological effects, more attention to ecological modelling is clearly also warranted.

Our simulations indicate several areas where additional empirical research could contribute fruitfully to a better understanding of both the potential ecological consequences of nuclear war and basic ecological knowledge. We terminated temperature reductions at levels just above those producing periodic nighttime frosts as tropical pasture plants are both chilling sensitive and frost intolerant[22–24]. However, strains of a widely cultivated tropical grass, *Cynodon dactylon*, have been produced that are tolerant of winter conditions to near 40° N in central North America[36], and tropical species with ranges extending outside equatorial locations have frost tolerant genotypes[22,23]. This suggests that there is sufficient genetic variability in tropical grasses to produce freeze-tolerant genotypes, and natural selection accompanying severe nuclear winter would be intense. If some tolerant genotypes survived as either dormant individuals or as seeds, ecosystem recovery might be possible following even the most severe nuclear winter. We know of no extensive evidence on the freeze tolerance of drought-dormant rather than actively growing tropical grasses. Nuclear winter during the tropical dry season might not result in extensive plant mortality if drought-hardened individuals are also cold tolerant; information on the relationships between these adaptive traits would allow more realistic estimates of the expected recovery potentials of tropical and subtropical ecosystems if severe nuclear winter penetrated those geographical regions. Information is also limited on the seed banks of tropical soils and the freeze tolerance of those seeds[23]. Nuclear winter would expose seeds to cold, dry, dark environments, which in many cases are optimal for increasing seed longevity.

Secondary productivities can also be influenced by many factors in addition to the limitations imposed by food quantity and quality. Radiant heat load[37], availability of water, wind speed[28], mineral nutrient availability[31,33] and the shield of veterinary practices protecting both wild and domestic ungulates from potentially epidemic disease[38,38] could all be modified by post-war conditions. In addition, cold rains accompanying periodic smoke cover and chilling that precipitates water out of the atmosphere might have devastating effects on tropical animals. Realistic estimates of such ecological effects would add precision to estimates of the post-war carrying capacity of ecosystems.

But even with the many uncertainties, we believe that the results of simulations with GRASS have three principal implications for the carrying capacities of ecosystems were a nuclear war to modify climate in the directions now envisaged. First, mild (by the standards of nuclear winter) climatic changes tending to reduce heat loads and evaporative demands of the atmosphere might increase the productivities of many water-limited ecosystems. Such ecosystems occupy major expanses of Earth's surface.

Second, distinctly different conditions lead to performance optima at different levels in the trophic web. Those optima, therefore, cannot be attained simultaneously. Grain production, for example, would probably track the response surface that we obtained for primary productivities of ungrazed vegetation. Because grassland climates are centres of grain production, increases in precipitation and/or reduced evaporative demands could tend to increase substantially the grain production potential of post-war ecosystems. Animal production, on the other hand, would probably be inhibited by the same conditions.

Third, and, we believe most important, the transition between non-catastrophic (even favourable) environmental changes and those that are calamitous may be extremely abrupt. The presence of those thresholds in all three simulation results suggests that the ecological effects of a nuclear war are very unpredictable and may change drastically over narrow environmental ranges. A population of human survivors in tropical-to-subtropical locations might encounter an increased carrying capacity for certain climatic perturbations only to be plunged into destruction by a seemingly minor drift away from those conditions. Overall, our results emphasize the uncertainty that must be attached to any predictions about the ecology of a post-war Earth, and suggest that ecological unpredictability itself could be one of the most damaging consequences of post-war climatic effects.

Development of GRASS was funded by the US National Science Foundation's Ecosytem Studies Program. Its application here was funded by Syracuse University. That application was prompted by two workshops sponsored by the ENUWAR unit of SCOPE, University of Essex (attended by S.J. McN.) None of those organizations necessarily endorses the conclusion of the research reported. □

Laboratory investigation of the electrodynamics of rock fracture

B. T. Brady & Glen A. Rowell

Denver Research Center, US Department of the Interior, Bureau of Mines, Denver, Colorado 80225, USA

Light produced by the failure of rocks subjected to uniaxial compression in various atmospheres has been analysed spectroscopically in the visible and near-infrared. In each case, the observed spectrum was unique to the ambient atmosphere. Spectrographical and electromagnetic investigations support an exoelectron bombardment mechanism to explain the observed light emission. Several implications of this result are discussed.

OBSERVATIONS of light emissions and other lower-frequency electrical phenomena associated with rock fracture in mines and earthquakes have been reported for several centuries[1-4]. These reports did not attract serious scientific attention until photographs of light emissions were obtained during the 1965 Matsushiro, Japan, earthquake swarm[1]. Although many theories as to the source(s) of these light emissions have been presented[1-6], it is only within the past few years that serious attempts have been made to conduct laboratory investigations of this phenomenon[7-12]. Due to the absence of precise experimental data, the lack of consensus regarding the possible explanations of the light-producing mechanism(s) from fracturing rock is understandable. The mechanisms most commonly proposed[5] include: (1) rock fragments frictionally heated to incandescence; (2) electrostatic discharge produced by the deformation of piezoelectric minerals or due to charge separation on fractured surfaces; (3) plasmas produced by rapid and intense heating of rock material; and (4) excitation of the ambient atmosphere by particle (electron and/or positive or negative ion) bombardment.

As each of the above mechanisms produces an optical spectrum having characteristic features, spectroscopic analysis in the visible region (10^{14}–10^{15} Hz) offers an experimental means of elucidating the process by which the light is produced. For example, rock fragments frictionally heated to incandescence would produce a continuous spectrum approximating that of a black-body radiator at a temperature corresponding to that of the heated rock. An electrostatic discharge caused by deformation of piezoelectric minerals would normally produce line spectra characteristic of the excited elements: little or no background continuum would be observed, and transitions from both neutral and ionized states might occur. In addition, because this type of excitation can be best categorized as 'spark-like', microwave emantions would be expected. A plasma originating from the rock sample during catastrophic failure would produce a background continuum closely approximating that of a black-body radiator. Atomic emission lines, characteristic of electromagnetic interactions occurring within the plasma, would be superimposed on this spectrum. Transitions from neutral as well as ionized species might also be observed. The plasma temperature could be inferred from the ratio of the line-to-background intensities[13]. Finally, excitation of the ambient atmosphere by particle bombardment would produce molecular and atomic line spectra. The spectrum would be determined by the chemical properties of the atmosphere as well as by the energy, mass and charge of the particles. Spectroscopic examination and characterization of the emitted light should determine which, if any, of the above models are valid.

Experimental philosophy

Experimental conditions and materials were chosen to enable positive differentiation between the four proposed light causing mechanisms. Five ambient atmospheres were chosen: argon, helium and air at atmospheric pressure; water and a vacuum of 1×10^{-6} torr.

The monatomic rare gases, argon and helium, were selected because of their relatively simple atomic line spectra[13]. These gases have been the subject of extensive spectroscopic investigations and the energy levels of both neutral and ionized species are well established. Because the first ionization potentials for argon and helium are 15.8 and 24.6 eV, respectively, the minimum energy available to the excitation process can be deduced from the observed transitions.

The high-vacuum ($\sim 10^{-6}$ torr) experiments were designed to determine whether the emitted light originated in the ambient atmosphere or in the rock material. Since the mean free path of nitrogen and oxygen is $\sim 10^{4}$ cm at 10^{-6} torr and 25 °C, vacuum conditions would seem to preclude the production of light from collisional excitations[14]. Should light be observed during rock fracture in the vacuum experiments, then either the ambient atmosphere (gas remaining in the vacuum chamber) is being excited by a mechanism other than an electric field or the rock material itself (including any excited gases that might exist within the rock pores) is the source of the light.

Water was chosen as an ambient fluid because a liquid has a much higher density than does a gas, an important consideration if collisional processes cause the light emission. Additionally, tap water is a relatively good conductor (~ 200 μS)[14] and would minimize the possibility of any capacitive charge buildup caused by piezoelectric minerals present on the sample surface.

A fine-grained granite from Salida, Colorado, and a fine-grained basalt from Table Mountain near Golden, Colorado, were the two rock materials chosen for the tests. Basalt was chosen specifically because of the absence of quartz or other strongly piezoelectric minerals. All rock samples except those used in the high-speed movies were drill cores, of diameter 2.2 cm and length 5 cm. All samples were prepared to ASTM standards.

Preliminary experimental results

Figure 1 illustrates the typical fracture behaviour of a 5.4-cm-diameter × 10.8-cm-long specimen of Salida Granite from high-speed movies (3,000 frames s^{-1}). Several observations are noteworthy. First, the dust cloud (composed of finely ground rock particles) forms during the main shock ($t = 0$) and not as a result of frictional sliding along crack (fault) surfaces. Second, the loading platens exhibit no significant motion until the sample has disintegrated; that is, the stiffness of the loading system may be irrelevant to the fracture process in brittle materials. Third, the process of fracture in brittle materials, such as rock, is explosive. Implications of these observations will be discussed elsewhere (in preparation).

Figure 2 illustrates typical light emission from rock fracture. This photograph was obtained using a night-vision scope. Generally, light produced by rock fracture can be viewed only in

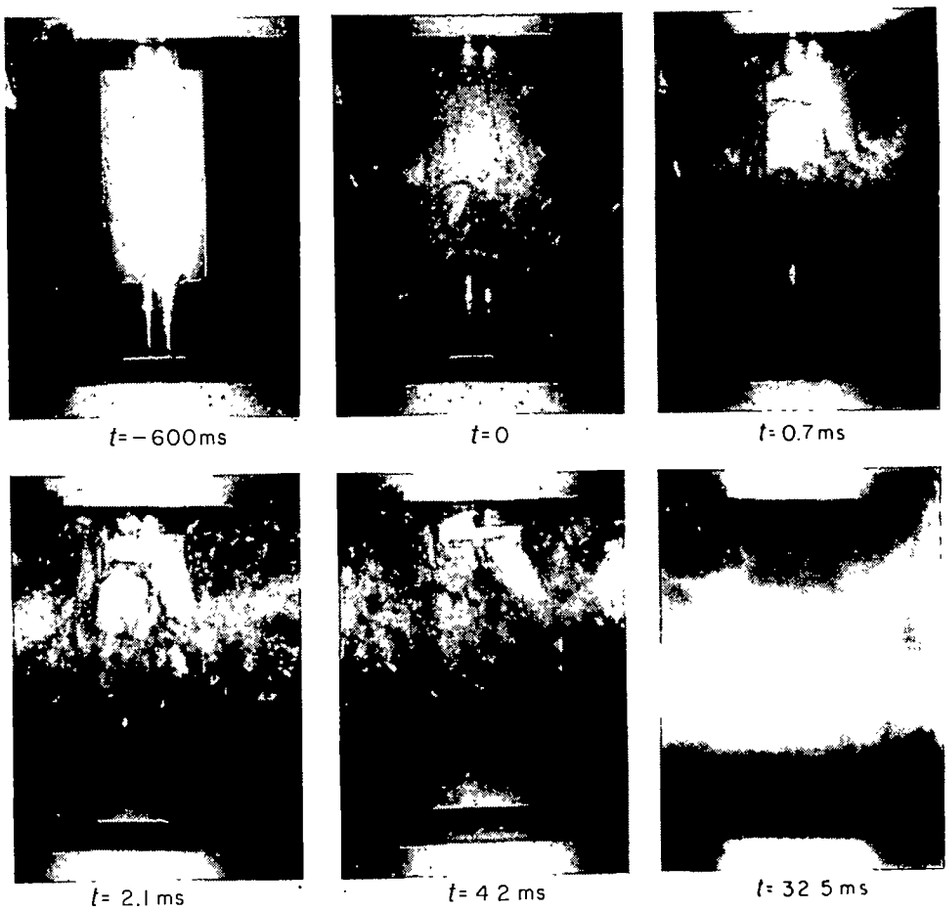

Fig. 1 Sequence of high-speed (3,000 frames s^{-1}) photographs illustrating fracture of Salida Granite.

darkness by an observer with night-adapted vision. Photodiode experiments show that the light emission is composed of a few discrete pulses, each persisting for only ~100 μs. Figure 3 illustrates typical photodiode and applied load outputs versus time for the two rock types studied in this investigation. (Note that the response time of the PIN (positive/insulated/negative) diode and recording system is ~1 μs, and the fall time is much slower because of the amplifying electronics.) Therefore, the major problem of this investigation was low light intensity of short duration. This point is amply shown in Fig. 4*a*, *b*. Figure 4*a* shows a sample of Salida Granite photographed during catastrophic failure and illustrates the formation of the 'dust' plumes and other larger pieces of rock in the process of spalling. Of particular interest is the nature of the 'dust' plumes emanating along fracture surfaces. In several fractures, the plumes occur only along discrete segments, with no plumes occurring elsewhere along the fracture surface. Figure 4*b*, taken through a single-stage image intensifier, illustrates the light emission emanating from a different sample of Salida Granite and supports the observation that the light duration is short ($<10^{-3}$ s); if the light duration were greater than several milliseconds, discrete emissions would be smeared. In addition, the discrete nature of the light emissions along selected fracture surfaces is evident and similar to the plume distribution shown in Fig. 4*a*.

Experimental procedures

The final design of our spectrographic system resulted from these preliminary tests and much trial and error. Because of the low light intensity and short duration, priority was given to optical speed, with resolution a secondary consideration. A variable slit prism spectroscope with a two-stage image intensifying system (two night-vision scopes mounted in series) was used to observe spectra. The image formed by the spectroscope was focused on the photocathode tube of the first stage intensifier. The final image was then viewed directly on the screen of the second stage or recorded photographically.

Because light emission from rock failure has been the subject of considerable controversy, it was important to acquire photographic spectra. In addition to the short time duration and low intensity of the light produced by rock fractures, the problem

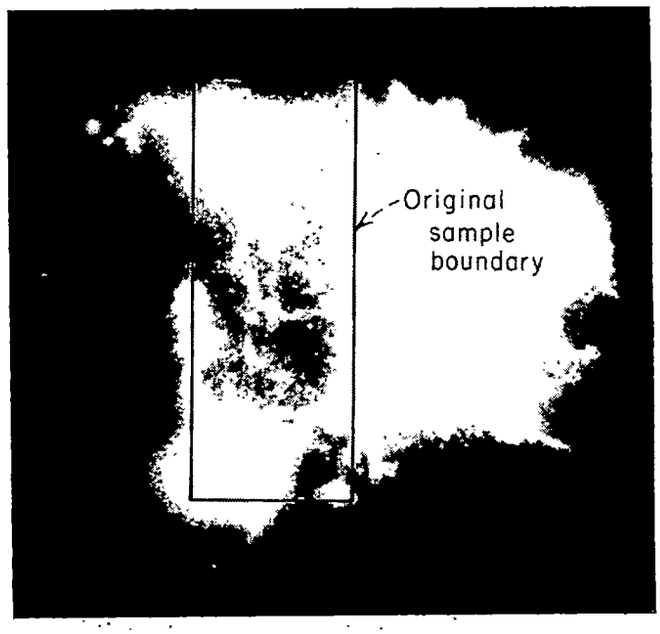

Fig. 2 Typical light emission observed from fracture of Salida Granite.

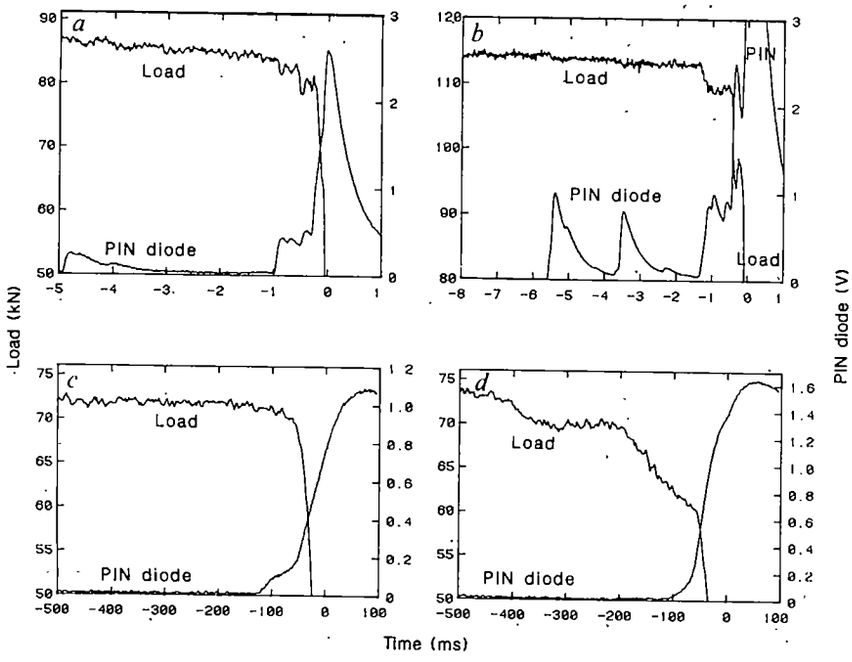

Fig. 3 Typical photodiode and applied load outputs versus time for Salida Granite (*a*, *b*) and Table Mountain Basalt (*c*, *d*).

of photographing a spectrum was complicated by inexact knowledge of when the rock sample would fail and the unfavourable signal-to-noise ratio of operating both image intensifiers at maximum gain. On the other hand, operating the system at less than maximum gain produced images too faint to photograph.

The spectra were finally recorded on Polaroid type 612 film, with an ASA rating of 20,000. The ultra-high speed of this high-contrast black and white film made it ideally suited to our experiment. Accordingly, an XL Graflex camera with a Polaroid back was placed at the exit of the second image intensifier to take photographs. With both image intensifiers set at maximum gain, 1/10 s at $f/5.6$ was the longest exposure able to produce acceptable images compared with the background noise. Output from a load cell was used to activate a digital oscilloscope which sent a pulse to a circuit which activated a low-mass solenoid which triggered the camera shutter. This 'Rube Goldberg'-type system afforded a probability of ~0.5 of the camera lens being open during rock failure to record the spectra of any light emission.

The rock specimens were isolated in a cylindrical (7.6 cm inner diameter) Lexan chamber to prevent damage to the spectroscope. To maintain a gas-tight seal, a sliding steel disk at each end of the chamber was fitted with O-rings. Brass platens were placed between the rock sample and the steel disks. The chamber assembly was then placed in the press and a slight force applied to align the components. Next, gas was introduced into the chamber through one port, and the end of a tube from the exit port was placed under water to maintain a slight positive pressure within the chamber. The laboratory was then darkened and the spectrum from a reference lamp recorded on film. The camera shutter and solenoid were reset, the oscilloscope trigger was armed, and the image intensifiers were turned to maximum gain. By this time, the chamber had been sufficiently flushed of air, and the sample was loaded rapidly (strain rate $\dot{\varepsilon} \simeq 10^{-2}\ s^{-1}$) to failure. The photographic print was removed from the film pack and developed.

Results

Figure 5*a* is the spectrum resulting from the fracture of Salida Granite in argon. The reference spectrum at the top of the photograph was produced by a low-pressure argon lamp. Several prominent lines are identified. Of particular importance is the observation that no spectral lines are produced by the failure of Salida Granite in argon other than the lines present in the reference spectrum. All lines observed are produced by neutral atomic argon. No transitions from ionized states are observed. The 7,635-Å line is prominent, and the fact that the upper state of this transition lies 13.2 eV above the ground state indicates that at least this much energy is available for the excitation process. Finally, there is no evidence of a background continuum. The random dots in Fig. 5*a*–*e* adjacent to the spectral lines are caused by Johnson noise in the image intensifier system.

Figure 5*b* is the spectrum produced by the fracture of Salida Granite in helium. The apparent broadening of the 7,065-Å line in the top reference spectrum was caused by overexposure. As in the case of argon, this spectrum shows only neutral atomic transitions. The upper state of the 7,065-Å transition lies 22.7 eV above the ground state. There is no evidence of a background continuum.

Figure 5*c* is the spectrum of Table Mountain Basalt (no piezoelectric minerals) in argon. This spectrum is similar in every feature to that produced by the failure of Salida Granite in argon. Again, the 7,635-Å line is prominent, and no lines are present other than those of the argon spectrum. There is no evidence of a continuum background.

Fig. 4 *a*, Photograph of Salida Granite during failure. Maximum load at failure was 300 MPa. Load during photograph was 205 MPa. *b*, Light emission from failing Salida Granite. Note discrete emissions along failure surfaces. Samples shown in *a* and *b* are different.

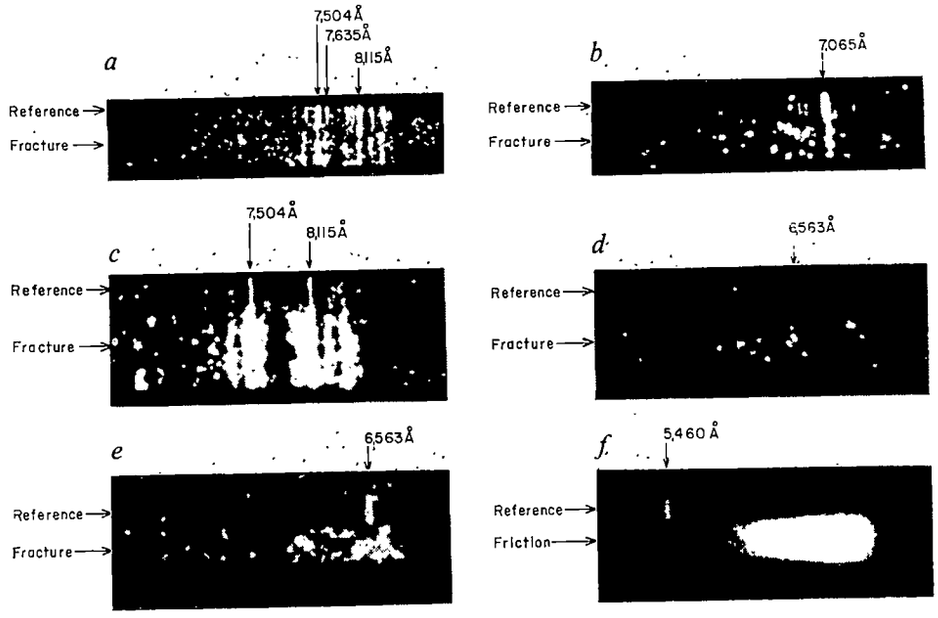

Fig. 5 *a*, Spectrum from Salida Granite fracturing in argon atmosphere. Top spectrum is the reference gas spectrum. *b*, Spectrum from Salida Granite fracturing in helium atmosphere, *c*, Spectrum from Table Mountain Basalt fracturing in argon atmosphere. *d*, *e*, Spectra from Salida granite fracturing in water. Top reference spectra are Hα. *f*, Spectrum produced by frictional heating of two pieces of bulk quartz in air atmosphere. The reference line (5,460 Å) appears at top. No image intensifier used.

Figure 5*d* and *e* are spectra from Salida Granite being fractured in water. The single line in the top reference spectrum is hydrogen α (Hα), 6,563 Å (12.1 eV). The spectra have several important features. First, as seen in Fig. 5*d* and, in particular, visually through the spectrometer, radiation occurring at the 6,563-Å position can be positively identified as being Hα, produced by atomic hydrogen. In Fig. 5*e*, radiation centred around the Hα position has been broadened into a band. This spectral broadening is attributed to perturbation of the atomic hydrogen energy levels by potential interactions in the liquid water. A second band of radiation extends from ~5,700 to 6,200 Å. This is identified as unresolved structure of the molecular hydrogen spectrum[13]. No other transitions are observed, and no background continuum is present. Thus, the spectra from Salida Granite being fractured in water indicate that both atomic and molecular hydrogen are produced during fracture.

Figure 5*f* is the spectrum produced from rubbing (frictionally heating) two pieces of quartz in air. No image intensifier was used in this experiment. A mercury reference spectrum appears at the top, with the 5,460-Å line prominent. The spectrum is a continuum. It is characteristic of a black-body radiator at a temperature of ~1,500 K, inferred from the spectral energy distribution. No line or band features are observed.

Regrettably, the photographic spectra from the fracture of Salida Granite in 10^{-6} torr vacuum are even less clear than those already discussed; therefore, only the results of visual observation are reported. The spectra observed exhibited typical molecular band structure. Comparison of the best photographic spectrum with that produced by a 10^{-3} torr air Geissler tube indicated that the spectrum was that of air. No line structure was detected visually or photographically and, consistent with the other experiments, no continuum radiation was observed.

Figure 6 is a photograph of the light emissions from fracturing a core of Salida Granite in an air atmosphere. The photograph was taken with ASA 400 film by turning out the room lights, opening the camera shutter, breaking the core, and then closing the shutter. The light source was determined to result from burning chips of steel scoured from the steel platens by the exploding rock fragments. The spectrum produced from this light is a continuum representative of oxidizing steel. That the light source was oxidizing steel was demonstrated in two ways. First, an increase in the oxygen content of the ambient atmosphere dramatically increased the light intensity, and second, by covering the upper platen with a thin piece of rubber, this comparatively bright light disappeared, even in a 50% oxygen atmosphere.

Discussion

An important and surprising result of this investigation is the complete lack of spectroscopic evidence for continuum radiation. Continuum radiation would be produced by material heated to incandescence by frictional sliding. That such a continuum is produced by frictionally heated rock material and is easily detectable is confirmed by Fig. 5*f*. Other experiments were performed in which drill cores of various rock types were lightly ground together, and similar continuum radiation spectra were produced. The lack of continuum radiation from fracturing rock indicates that frictional heating does not produce the light observed during fracture and provides corroborative evidence of the explosive character of fracture shown in Figs 1 and 4*a*. Furthermore, the lack of continuum radiation also indicates that the finely ground dust material produced during rock fracture is not formed by frictional sliding, as is commonly believed. Microscopic examination of the rock dust shows euhedral surfaces with no apparent smoothing or roughening characteristic of frictional grinding. Thus, our results suggest a tensional origin for these fine-grained particles, such as could be produced by shock waves propagating through the rock structure during catastrophic failure.

An additional feature common to all recorded spectra is the absence of emission lines from ionized species. The absence of both continuum radiation and emission lines from ionized species eliminates the possibility that a plasma is a source of emitted light. However, note that the most significant argon (II) lines are located towards the ultraviolet end of the visible spectrum.

The absence from all the spectra of lines produced by the elemental constituents of the rock material is significant. Although the strongest silicon lines are in the ultraviolet region[13], highly sensitive calcium, sodium and potassium lines occur in the visible and would have been readily detectable had they been present. There is no evidence of excitation of the constituent rock minerals. The spectra in all cases are those of the ambient atmosphere.

The piezoelectric excitation model[1,3,7] has been seriously considered as a light-producing agent because many rock materials contain minerals known to be piezoelectric. In terms of an excitation mechanism, a piezoelectric discharge is best charac-

terized as spark-like, that is, a high-voltage differential with low current in which the excitation is due primarily to a high electric field. No ionized line spectra, such as typically produced by a spark discharge, were detected. The spectrum of basalt broken in an argon atmosphere is of interest in this case. Petrographic analysis confirmed that the basalt was free from any strongly piezoelectric minerals. Yet the spectrum of basalt in argon is identical to that produced by granite in argon. While deformation of piezolelectric minerals does occur during fracture of rocks, our evidence is that a piezoelectric mechanism is not responsible for the observed excitation of the ambient atmosphere. Finally, the absence of microwave emanations during the time interval in which the light is observed confirms the observation that a piezoelectric discharge is not the source of visible light[11].

Although most of our experimental evidence is indirect, there is substantial support for an excitation mechanism entailing electron bombardment. The tendency of a particle to produce ionizing events is a function of the particle's energy, mass and charge. An α-particle will typically produce 10^3 times more ionizing events in a medium than a β-particle of the same energy. The absence of spectra from ionized species argues against the excitation of the ambient atmosphere by α-particles or heavier nuclei. The fracture of Salida Granite in water produced both atomic and molecular hydrogen. The formation of these gases is similar to their generation when water is irradiated by β-particles (electron bombardment).

We conclude that exoelectron excitation of the ambient atmosphere is the mechanism responsible for the light emissions observed during rock fracture. For this mechanism to explain light emissions produced during massive failures in mines or earthquakes, it would be necessary for the fracture to reach the surface to allow exoelectron excitation of the ambient atmosphere. Recent observations have shown that light emissions, coincident with acoustic emissions resulting from rock spalling off the surface, have occurred along highly stressed drifts on the 5,400-ft level of the Consolidated Silver venture near Osburn, Idaho (J. Suveg, personal communication). Here the light emission is probably due to exoelectrons emitted from fresh fracture surfaces exciting the air. Of course, for this mechanism to be a source of light when the fracture does not reach the surface, as in deep crustal earthquakes where surface cracking does not occur, would require that sub-surface stress changes induced by the earthquake preparation process cause cracks on the surface which could then emit electrons. Note that surface cracking was observed in earthquakes where light emissions were reported, such as the 1965 Matsushiro earthquake swarm[15,16] and the 1976 Tangshan earthquake (T. K. Tan, personal communication). Resolution of the light problem in mines and earthquakes will require spectroscopic analysis. An exoelectron excitation type of illumination is not likely to cause isolated light sources to appear several hundred metres above the Earth's surface, as is reported to occur in some earthquake-prone regions.

Last, our study shows that energy levels of the observed atomic and molecular transitions indicate a minimum of 23 eV is available from the exoelectron excitation mechanism. The molecular dissociation of water by rock fracture producing atomic and molecular hydrogen suggests that fracture might produce interesting chemical effects within a fluid or gas-saturated rock mass. For example, we speculate that exoelectron emission occurring within fracturing coal or potash rock masses may result in dissociation of methane, thereby producing hydrogen gas which could, in suitable conditions, be of importance in igniting a gas outburst. We believe that insufficient consideration has been given to the role of rock fracture in fluid (H_2O) and gas (CH_4, CO_2, H_2S, and so on) saturated rock masses in promoting molecular dissociations by exoelectrons and the role of this process in initiating chemical reactions of geological and biological interest. This problem needs to be thoroughly investigated.

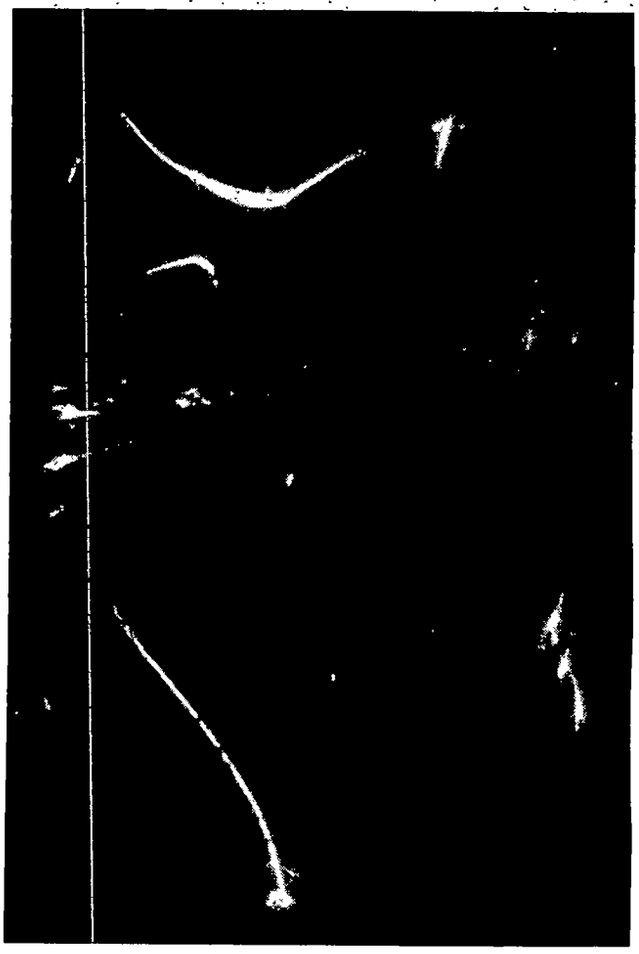

Fig. 6 Light emissions (discrete) from failing Salida Granite in air. Steel platens used in test. Light emissions are produced by oxidation of steel particles abraded from platens by high-velocity ($v \simeq 2 \times 10^3$ cm s^{-1}) rock dust.

We thank Stuart Hoenig, Tom Dickinson, John Derr, Michael Persinger, and Glynn Cress for conversations; Glen and Karen Winters (Winter Productions, Los Angeles, California), for exciting our interest in examining light emissions from fracturing rock and their role in explaining the occurrence of such emissions before earthquake-related phenomena; and last the research staff at the Denver Research Center for aid with the difficult experimental procedures.

Isolation of the *paired* gene of *Drosophila* and its spatial expression during early embryogenesis

François Kilchherr, Stefan Baumgartner, Daniel Bopp, Erich Frei & Markus Noll

Department of Cell Biology, Biocenter of the University of Basel, Klingelbergstrasse 70, CH-4056 Basel, Switzerland

We have cloned the paired *gene of* Drosophila melanogaster, *a pair-rule gene required for the establishment of proper segmentation. The transcriptional pattern in young embryos shows developmental polarities along the antero-posterior and dorso-ventral axes. Transcripts, initially expressed with a double-segment periodicity, switch to a single-segment repeat during syncytial blastoderm.*

SEGMENTATION, an important process of animal development, is the most conspicuous event of compartmentalization. A systematic search for mutations affecting segmentation in the fruitfly *Drosophila* has revealed that it is governed by ~30 genes which can be divided into four classes according to their mutant phenotypes[1,2]. In the first class, the gap mutants, various overlapping non-terminal subregions of the larva are deleted. The second class contains the segment-polarity mutants which exhibit defects that are reiterated in every segment; whereas in the third class, the pair-rule mutants, structures are deleted at a two-segment periodicity (Fig. 1). These three classes of mutants suggest that segmentation involves three different units of spatial organization: one of a single-segment periodicity; one of a two-segment periodicity and a third comprising groups of adjacent segments and exhibiting no obvious periodicity. Mutants of the fourth class, the coordinate mutants, are all maternal and show global effects on the segmentation pattern. Their phenotypes have been explained by a defect in the expression of maternal components that regulate the genes of the three other classes[1,2].

In *Drosophila*, segmentation becomes visible as early as 1 h after the onset of gastrulation[1]. Even earlier, however, during cellular blastoderm, cell lineage may already become restricted to segments[3-7]. At the molecular level, this is probably reflected by the spatially restricted expression of the pair-rule gene *fushi tarazu* (*ftz*) at cellular blastoderm, which shows a repetitive pattern of seven evenly spaced bands[8] that correspond to the primordia of the regions deleted at a two-segment periodicity in homozygous *ftz* mutants[1,2]. More recently, another pair-rule gene, *hairy*(*h*), has been cloned[9,10]. Its expression, as analysed by *in situ* hybridization to blastoderm sections, exhibits a pattern of the same periodicity as *ftz* but is shifted anteriorly with respect to *ftz*, by slightly more than one segment primordium[10]. In addition, *h* transcripts are found in a band of the anterior dorsal blastoderm, extending from 85 to 95% of the egg length (EL)[10].

Here we report the isolation of the pair-rule gene *paired* (*prd*) whose mutant phenotype is shown in Fig. 1. Transcripts of *prd* exhibit a pattern of seven evenly spaced bands during late syncytial blastoderm, reflecting a double-segment periodicity similar to the previously analysed pair-rule genes *ftz* and *h*. However, in contrast to the patterns of *ftz* and *h*, this pattern of *prd* transcripts is expressed only transiently and changes during cellularization of the blastoderm to a pattern with a single-segment repeat length of 14 regularly spaced bands. In addition, *prd* transcripts are detected in a dorsal band close to the anterior pole at a position similar to that seen for *h* transcripts[10] and corresponding to 87 to 93% of EL.

Chromosomal walk from *esc* to *prd*

Recently, we cloned and identified the *extra sex combs* (*esc*) gene from DNA sequences at the cytogenetic locus 33B1,2 on the left arm of chromosome 2 (refs 11, 12). The initial clones, obtained by microdissection of salivary gland chromosomes[13], were spread over a region of 500 kilobase pairs (kb) comprising the entire deletion *Df(2L)esc*[10]. The most proximal clones, 1b.1 and 1b.8, were located just to the right of the deficiency *esc*[10] and at the left end of a deficiency of *paired*, *Df(2L)prd*[1 7 20] (ref. 1). The *prd* gene has been mapped previously by the deficiency

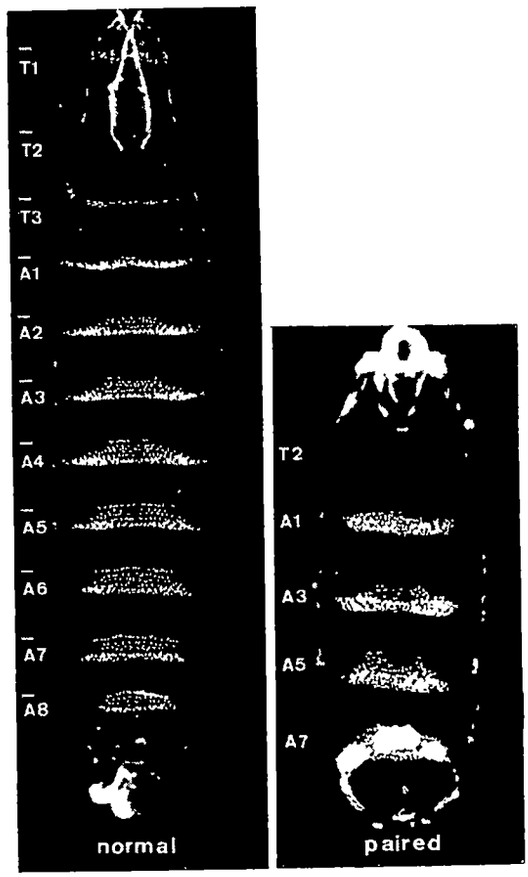

Fig. 1 Ventral cuticular pattern of a wild-type and a homozygous *prd*⁻ *Drosophila* larva. In the wild type the three thoracic (T) and eight abdominal (A) segments are indicated. In *prd*⁻, a pair-rule mutant, analogous portions of segments are deleted at a two-segment periodicity, giving rise to only half the normal number of segments[1]. Because the missing portions include every other segment boundary, the segments are of a composite nature[1]. For example, in the A1/A2 segment the anterior part is derived from A1, the posterior part from A2. Accordingly, the designation of segments in the *prd* mutant refers to the character of the anterior parts of the composite segments[2]. Courtesy of C. Nüsslein-Volhard (from ref. 1).

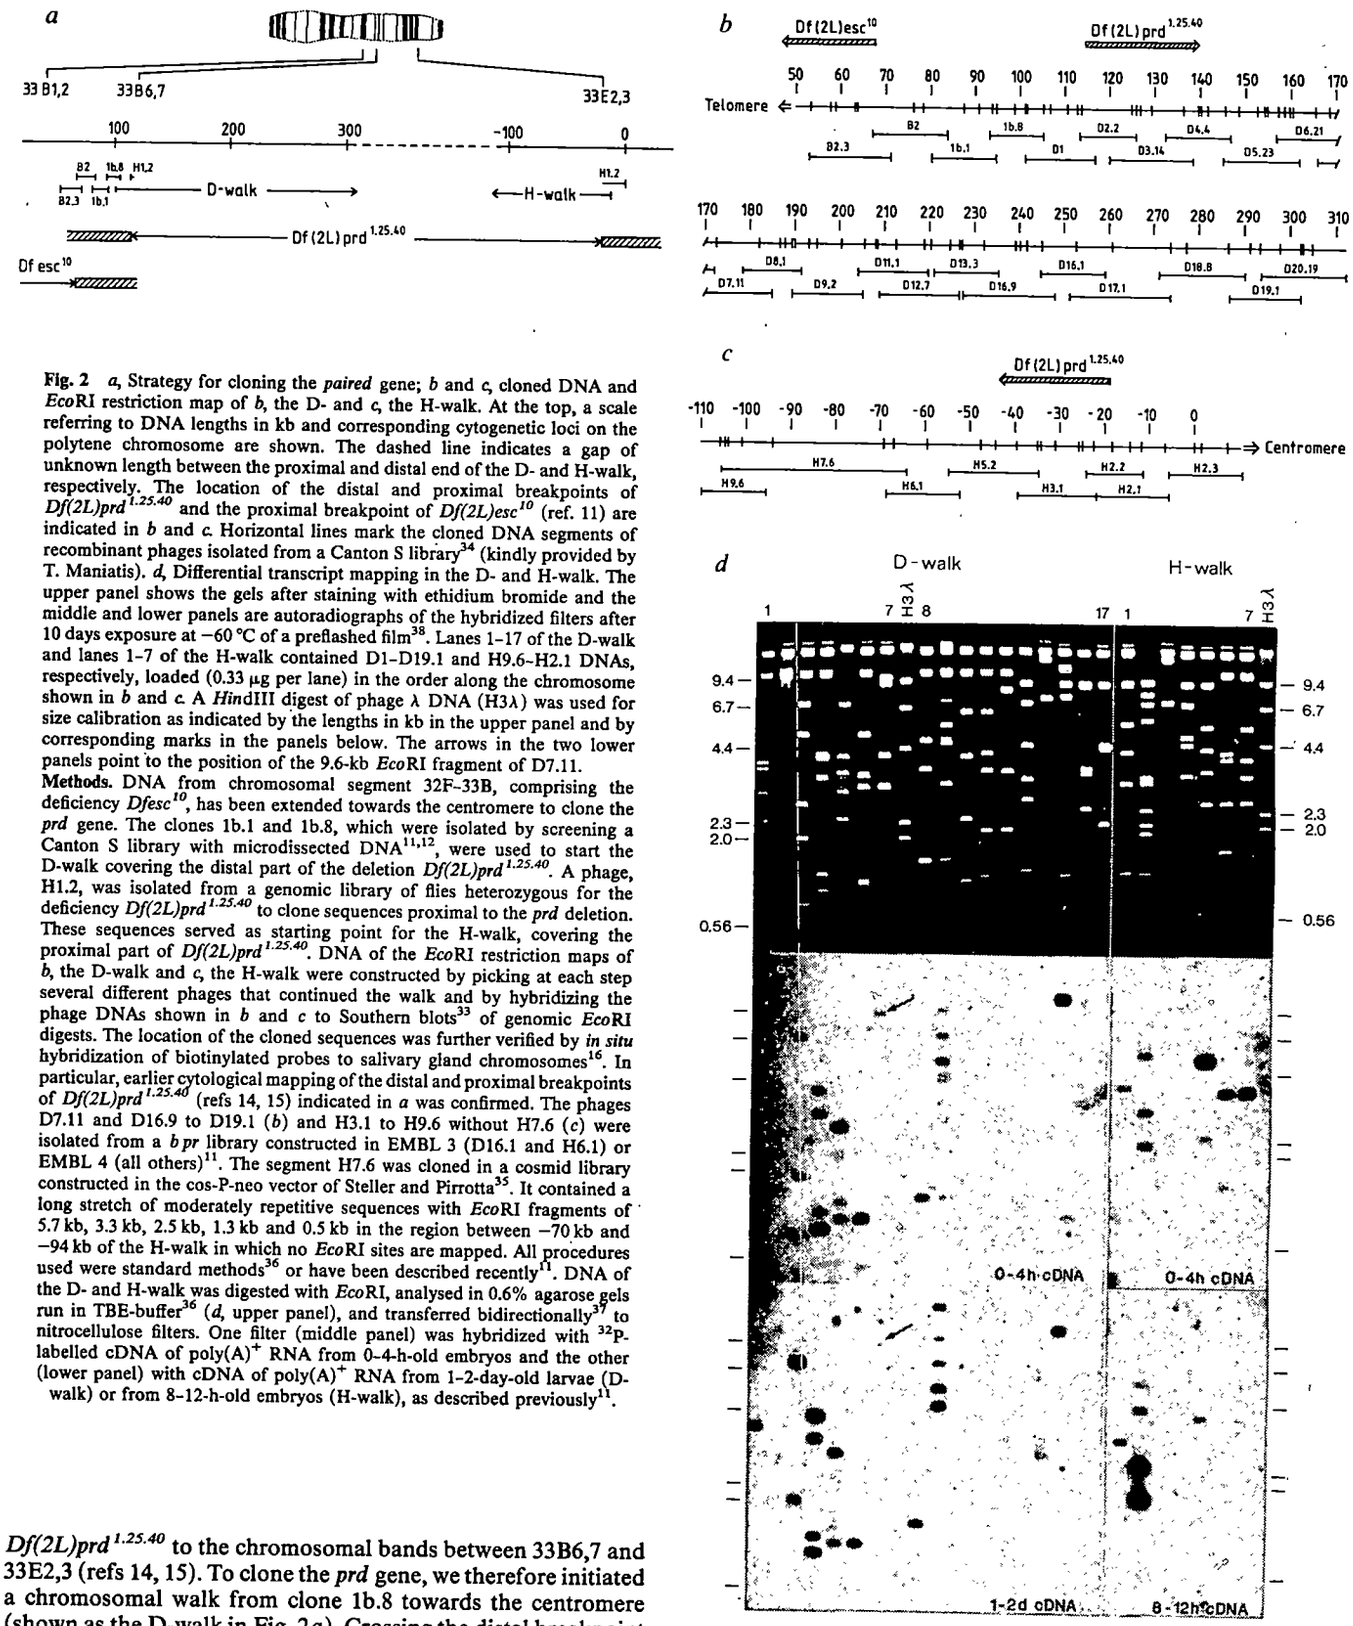

Fig. 2 *a*, Strategy for cloning the *paired* gene; *b* and *c*, cloned DNA and *Eco*RI restriction map of *b*, the D- and *c*, the H-walk. At the top, a scale referring to DNA lengths in kb and corresponding cytogenetic loci on the polytene chromosome are shown. The dashed line indicates a gap of unknown length between the proximal and distal end of the D- and H-walk, respectively. The location of the distal and proximal breakpoints of *Df(2L)prd*$^{1.25.40}$ and the proximal breakpoint of *Df(2L)esc*^{10} (ref. 11) are indicated in *b* and *c*. Horizontal lines mark the cloned DNA segments of recombinant phages isolated from a Canton S library[34] (kindly provided by T. Maniatis). *d*, Differential transcript mapping in the D- and H-walk. The upper panel shows the gels after staining with ethidium bromide and the middle and lower panels are autoradiographs of the hybridized filters after 10 days exposure at −60 °C of a preflashed film[38]. Lanes 1–17 of the D-walk and lanes 1–7 of the H-walk contained D1–D19.1 and H9.6–H2.1 DNAs, respectively, loaded (0.33 μg per lane) in the order along the chromosome shown in *b* and *c*. A *Hin*dIII digest of phage λ DNA (H3λ) was used for size calibration as indicated by the lengths in kb in the upper panel and by corresponding marks in the panels below. The arrows in the two lower panels point to the position of the 9.6-kb *Eco*RI fragment of D7.11.

Methods. DNA from chromosomal segment 32F–33B, comprising the deficiency *Dfesc*^{10}, has been extended towards the centromere to clone the *prd* gene. The clones 1b.1 and 1b.8, which were isolated by screening a Canton S library with microdissected DNA[11,12], were used to start the D-walk covering the distal part of the deletion *Df(2L)prd*$^{1.25.40}$. A phage, H1.2, was isolated from a genomic library of flies heterozygous for the deficiency *Df(2L)prd*$^{1.25.40}$ to clone sequences proximal to the *prd* deletion. These sequences served as starting point for the H-walk, covering the proximal part of *Df(2L)prd*$^{1.25.40}$. DNA of the *Eco*RI restriction maps of *b*, the D-walk and *c*, the H-walk were constructed by picking at each step several different phages that continued the walk and by hybridizing the phage DNAs shown in *b* and *c* to Southern blots[33] of genomic *Eco*RI digests. The location of the cloned sequences was further verified by *in situ* hybridization of biotinylated probes to salivary gland chromosomes[16]. In particular, earlier cytological mapping of the distal and proximal breakpoints of *Df(2L)prd*$^{1.25.40}$ (refs 14, 15) indicated in *a* was confirmed. The phages D7.11 and D16.9 to D19.1 (*b*) and H3.1 to H9.6 without H7.6 (*c*) were isolated from a *b pr* library constructed in EMBL 3 (D16.1 and H6.1) or EMBL 4 (all others)[11]. The segment H7.6 was cloned in a cosmid library constructed in the cos-P-neo vector of Steller and Pirrotta[35]. It contained a long stretch of moderately repetitive sequences with *Eco*RI fragments of 5.7 kb, 3.3 kb, 2.5 kb, 1.3 kb and 0.5 kb in the region between −70 kb and −94 kb of the H-walk in which no *Eco*RI sites are mapped. All procedures used were standard methods[36] or have been described recently[11]. DNA of the D- and H-walk was digested with *Eco*RI, analysed in 0.6% agarose gels run in TBE-buffer[36] (*d*, upper panel), and transferred bidirectionally[37] to nitrocellulose filters. One filter (middle panel) was hybridized with ^{32}P-labelled cDNA of poly(A)$^+$ RNA from 0–4-h-old embryos and the other (lower panel) with cDNA of poly(A)$^+$ RNA from 1–2-day-old larvae (D-walk) or from 8–12-h-old embryos (H-walk), as described previously[11].

Df(2L)prd$^{1.25.40}$ to the chromosomal bands between 33B6,7 and 33E2,3 (refs 14, 15). To clone the *prd* gene, we therefore initiated a chromosomal walk from clone 1b.8 towards the centromere (shown as the D-walk in Fig. 2*a*). Crossing the distal breakpoint of the *Df(2L)prd*$^{1.25.40}$ deletion allowed us to clone the DNA fragment H1.2, containing sequences from both sides of the deletion (Fig. 2*a*), by screening a genomic library constructed from flies heterozygous for the deficiency *Df(2L)prd*$^{1.25.40}$. From proximal sequences of the clone H1.2, a second walk was then started into the *Df(2L)prd*$^{1.25.40}$ deletion (shown as the H-walk in Fig. 2*a*). The D- and H-walks are shown in Fig. 2*b*, *c*. Together they cover ~300 kb of the *Df(2L)prd*$^{1.25.40}$ deletion.

Screening for the *prd* gene

Although the converging sequences of the D- and H-walk had not joined, a screen for possible candidates of the *prd* gene by differential transcript mapping was carried out, similar to the screen that proved successful when the *esc* gene was identified[11,12]. Radioactively labelled complementary DNAs of poly(A)$^+$ RNA isolated from egg follicles, 0–4- and 8–12-h-old

embryos and 1-2-day-old larvae were hybridized to Southern blots of *Eco*RI digests of the D- and H-walk (Fig. 2*d*). We screened for DNA fragments that were labelled with cDNA from 0-4-h-old embryos (middle panel of Fig. 2*d*) but remained unlabelled when hybridized to cDNA from later stages of development (lower panel of Fig. 2*d*) or egg follicles (not shown). This expectation was based (1) on experiments with a temperature-sensitive *prd* allele showing zygotic expression during the blastoderm stage[1] and (2) on the absence of a maternal effect of the *prd* gene[15]. In the D-walk, only one such fragment was found, a 9.6-kb *Eco*RI fragment of phage D7.11 (arrows in Fig. 2*d*). In the H-walk, two regions at the proximal end, the 3.9-kb *Eco*RI fragment of H2.2 and the 2.6-kb *Eco*RI fragment of H3.1 (which comprises the 1.6-kb left terminal fragment of H2.2) were transcribed in 0-4-h-old embryos but not in 8-12-h-old embryos (Fig. 2*d*). However, these fragments of the H-walk are unlikely to harbour the *prd* gene because they are also heavily labelled by cDNA of poly(A)$^+$ RNA from follicles (data not shown). Therefore, if the *prd* gene was located within the 300 kb of the *Df(2L)prd*$^{1.25.40}$ that had already been cloned, the most likely location was the 9.6-kb *Eco*RI fragment of D7.11, at about 170-180 kb in the D-walk or 240 kb to the right of the *esc* gene[11,12].

Mapping the mutant *prd*$^{2.45.17}$

To test whether the *prd* gene was contained within the cloned 300 kb, and specifically within the 9.6-kb *Eco*RI fragment of D7.11, the D- and H-walk DNA of an X-ray-induced *prd* mutant, *prd*$^{2.45.17}$, was compared with that of its parent strain by whole genome Southern analysis of *Eco*RI digests. No differences were detected except for a 1.1-kb insertion into the 9.6-kb *Eco*RI fragment of D7.11 in the *prd*$^{2.45.17}$ mutant (data not shown). The mutated DNA was isolated from a λ phage library of the heterozygous *prd*$^{2.45.17}$ mutant, and the 4.0-kb *Bam*HI fragment containing the 1.1-kb insert was subcloned. We compared its restriction map with that of the corresponding 2.9-kb BamHI fragment of the *prd*$^+$ DNA to locate the insertion more precisely. As shown in Fig. 3, in *prd*$^{2.45.17}$ a 1.1-kb DNA sequence has been inserted into a 0.41-kb *Sma*I fragment of the *prd* DNA. When a biotinylated probe consisting of the 1.5-kb *Sma*I fragment from *prd*$^{2.45.17}$ (Fig. 3) was hybridized to salivary gland chromosomes[16] of an Oregon R strain, it labelled more than 100 bands scattered over all chromosome arms (not shown).

Developmental profile of the *prd*$^+$ transcript

Although both differential transcript mapping as well as whole genome Southern analysis suggested that the *prd* gene was located in D7.11, the possibility remained that a gene with a developmental profile similar to that of *prd* was present in D7.11 and that the 1.1-kb insert was fortuitous and did not result in an altered gene expression at its location. This objection was excluded by Northern analysis of the *prd*$^{2.45.17}$ mutant in this region. As shown in Fig. 4, two poly(A)$^+$ RNAs of 2.5 and 3.6 kb were detected in embryos of heterozygous *prd*$^{2.45.17}$ parents whereas only a single RNA species of 2.5 kb was found in *prd*$^+$ embryos. Hence, the insert in the mutant DNA is located within a transcript that exhibits the developmental profile expected for the *prd* gene. The *prd* mRNA, while absent in oocytes, accumulates to a sharp peak in 2-4-h-old embryos (blastoderm and early gastrula), followed by a precipitous decline (Fig. 4). Essentially no 2.5-kb transcripts were detectable after 12 h of embryonic development (stages after 18 h are not shown) which is consistent with the results obtained with a temperature-sensitive allele of the *prd* gene[1].

Spatial transcription pattern

Genetic analysis[1] and the developmental profile shown in Fig. 4 suggest that the main period of *prd*$^+$ activity occurs around cellular blastoderm. In addition, inspection of the cuticular pattern of homozygous *prd*$^-$ larvae (Fig. 1) reveals that the

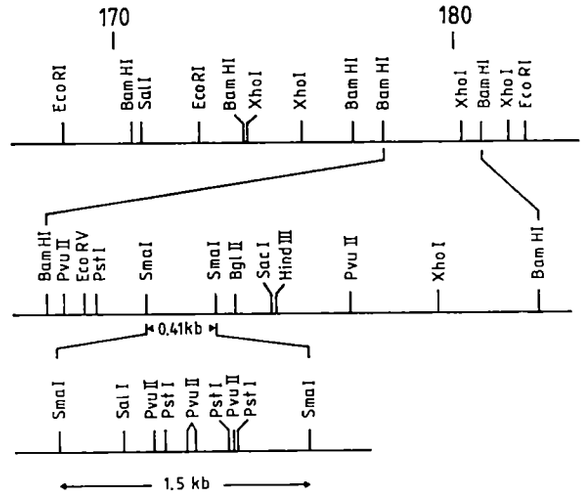

Fig. 3 Restriction map of DNA containing the *paired* gene and of *prd*$^{2.45.17}$ mutant DNA. A restriction map of the *paired* region, obtained from D7.11, is shown at the top. Below, the 2.9-kb *Bam*HI fragment, subcloned from D7.11, has been mapped in more detail. At the bottom a restriction map of the *prd*$^{2.45.17}$ mutant DNA, containing the 1.1-kb insertion of a repetitive element, is illustrated. This region was mapped by isolating the mutated DNA from a *prd*$^{2.45.17}$/*prd*$^+$ library according to standard methods[36] and mapping a subclone of the corresponding 4.0-kb *Bam*HI fragment containing the inserted DNA.

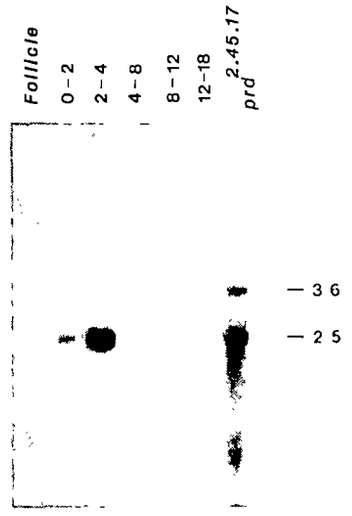

Fig. 4 Northern analysis of the *prd*$^+$ and *prd*$^{2\,45\,17}$ transcripts. For size calibration, end-labelled fragments of a partial *Rsa*I digest of pBR322 (4.36 kb, 3.68 kb, 2.80 kb, 2.25 kb, 2.12 kb, 1.57 kb and 0.68 kb) were used (data not shown).

Methods. Poly(A)$^+$ RNA (2 μg each), isolated from wild-type egg follicles and 0-2-h, 2-4-h, 4-8-h, 8-12-h and 12-18-h-old embryos and from 0-4-h-old embryos of heterozygous *prd*$^{2.45.17}$/*prd*$^+$ parents, as previously described[11], were run in a 1.1% agarose gel containing formaldehyde[39]. The RNA was transferred in 20× SSC to a nitrocellulose filter according to Southern[33] and hybridized with a cDNA fragment, c73.2, nick-translated[40] with [α-^{32}P]dATP (3,000 Ci mmol^{-1}) and consisting of 400 base pairs (bp) at the 3′ end of the *prd*$^+$ transcript located to the immediate left of the 0.9-kb *Bam*HI fragment (Fig. 3). The same 2.5-kb RNA was observed after hybridization with the genomic 0.9-kb *Bam*HI fragment and with the genomic fragments to its left (*Xho*I-*Bam*HI) and right (*Pvu*II-*Pvu*II), whereas no RNA was detected in a region of at least 2 kb to the right of the *Xho*I site at 180 kb (Fig. 3). A 2.3-kb cDNA clone, c7340.6, isolated from a cDNA library constructed from poly(A)$^+$ RNA of 0-4-h-old embryos, spanned the same region, labelling only DNA within the 4.7-kb *Xho*I fragment between 175 and 180 kb on the genomic map (Fig. 3).

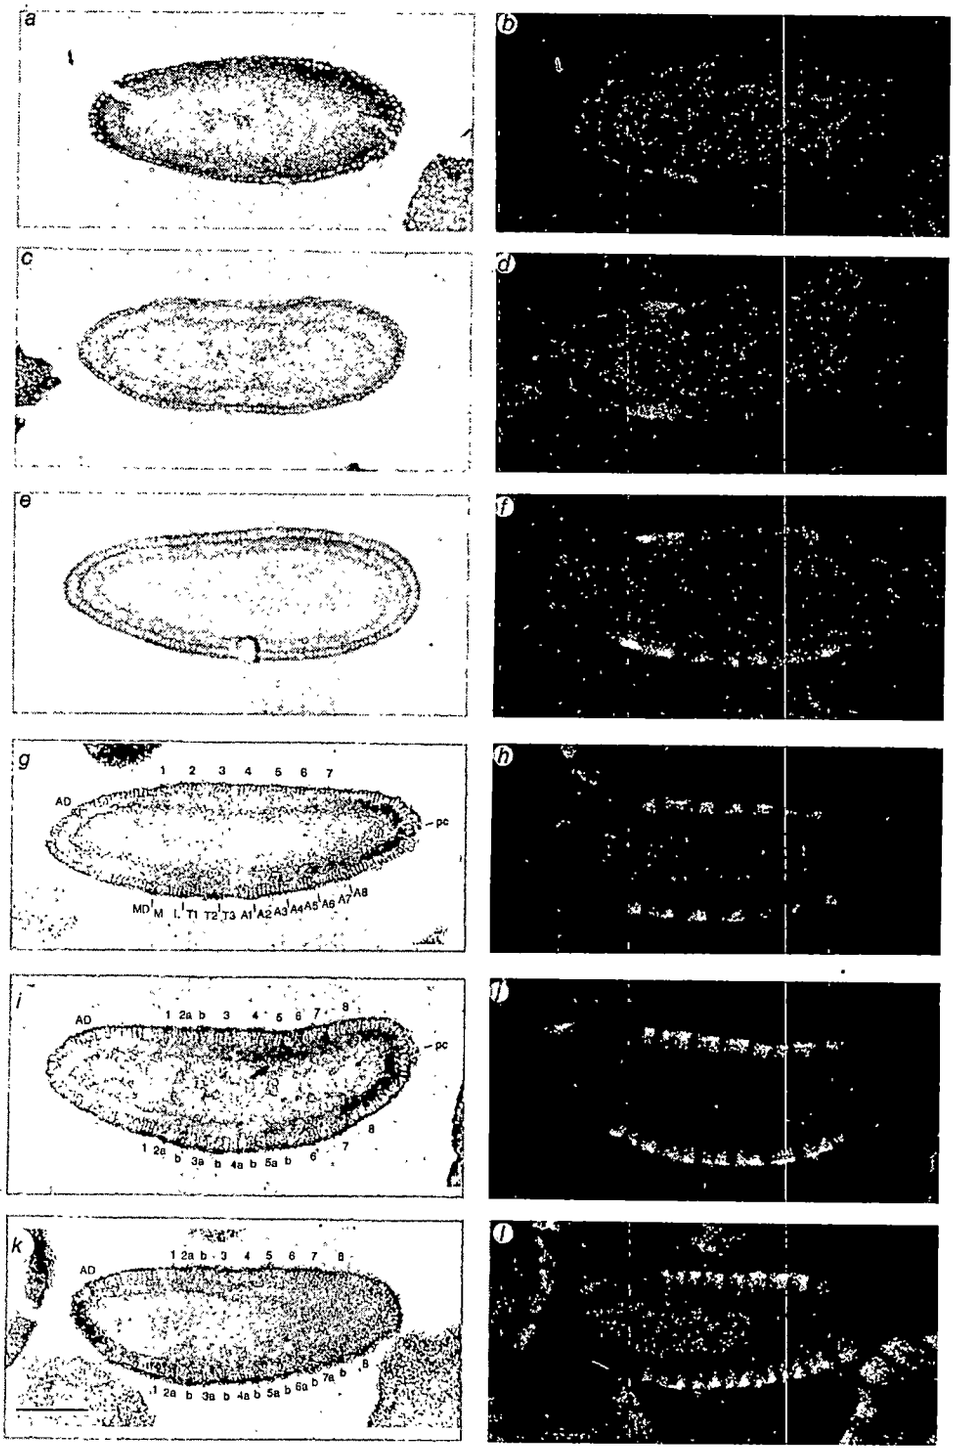

Fig. 5 Localization of *prd* transcripts in tissue sections of embryos at syncytial and cellular blastoderm. The panels show photomicrographs of the same embryos taken under phase contrast (left) or dark-field illumination (right). Sagittal or parasagittal sections through embryos during the 12th (*a*,*b*), 13th (*c*,*d*) and 14th nuclear cycle (*e*–*j*) of syncytial blastoderm, or at cellular blastoderm (*k*, *l*), are shown. Tissue sections are oriented with their dorsal side up and their anterior end to the left. The orientation was determined by morphological markers such as pole cells (pc) visible in other sections exhibiting very similar labelling. The presumptive locations of thoracic (T1–T3), abdominal (A1–A11), as well as labial (L), maxillary (M), and mandibular (MD) head segment primordia are indicated. The bands are labelled AD (anterior dorsal), 1–7 at early, and 1a–7b and 8 at late cellular blastoderm. The horizontal bar in *k* indicates a length of 0.1 mm. **Methods.** Tissue sections through young embryos were prepared, hybridized *in situ* with ^{3}H-labelled 2.2-kb *prd* cDNA, c7340.1 and exposed according to Hafen *et al.*[41]. Autoradiographic exposure was for 29 days except in *f*, which shows a 20-day exposure.

equivalent of one segment is missing for every two segments[1,2]. From previous studies on the pair-rule genes *ftz* (ref. 8) and *h* (ref. 10), in which the structures deleted in the mutants correspond approximately to the wild-type primordia in which the genes are transcribed, we would expect *in situ* hybridizations of embryonic tissue sections with ^{3}H-labelled *prd*-cDNA to show a double-segment periodicity expressed at cellular blastoderm. Surprisingly, we do not observe such a strict correlation between the mutant phenotype of *prd* and the spatial distribution of its transcripts in the wild-type embryo (Fig. 5).

Localized *prd* transcripts are first observed during syncytial blastoderm (nuclear cycle 12; ref. 17) in a band 6 nuclei wide which is stronger on the ventral than on the dorsal side and located at a distance of approximately 13 nuclei from the anterior end; that is, between 63 and 77% of EL (Fig. 5*a*, *b*). During the following nuclear cycle, the band widens to ~12–16 nuclei on the ventral and 8–10 nuclei on the dorsal side (Fig. 5*c*, *d*). It is separated by ~16–20 nuclei from the anterior pole and thus extends between 60 and 75% of EL, corresponding to the location of the primordial head segments[6,18]. The nuclei in the anterior portion of the band are labelled more strongly than those in the posterior half. The transcripts clearly accumulate in the cortical part of the cytoplasm surrounding the nuclei, as has been observed previously for transcripts of *ftz* (ref. 8) and *h* (ref. 10). During the fourteenth nuclear cycle, at late syncytial blastoderm when nuclei begin to elongate, five additional bands

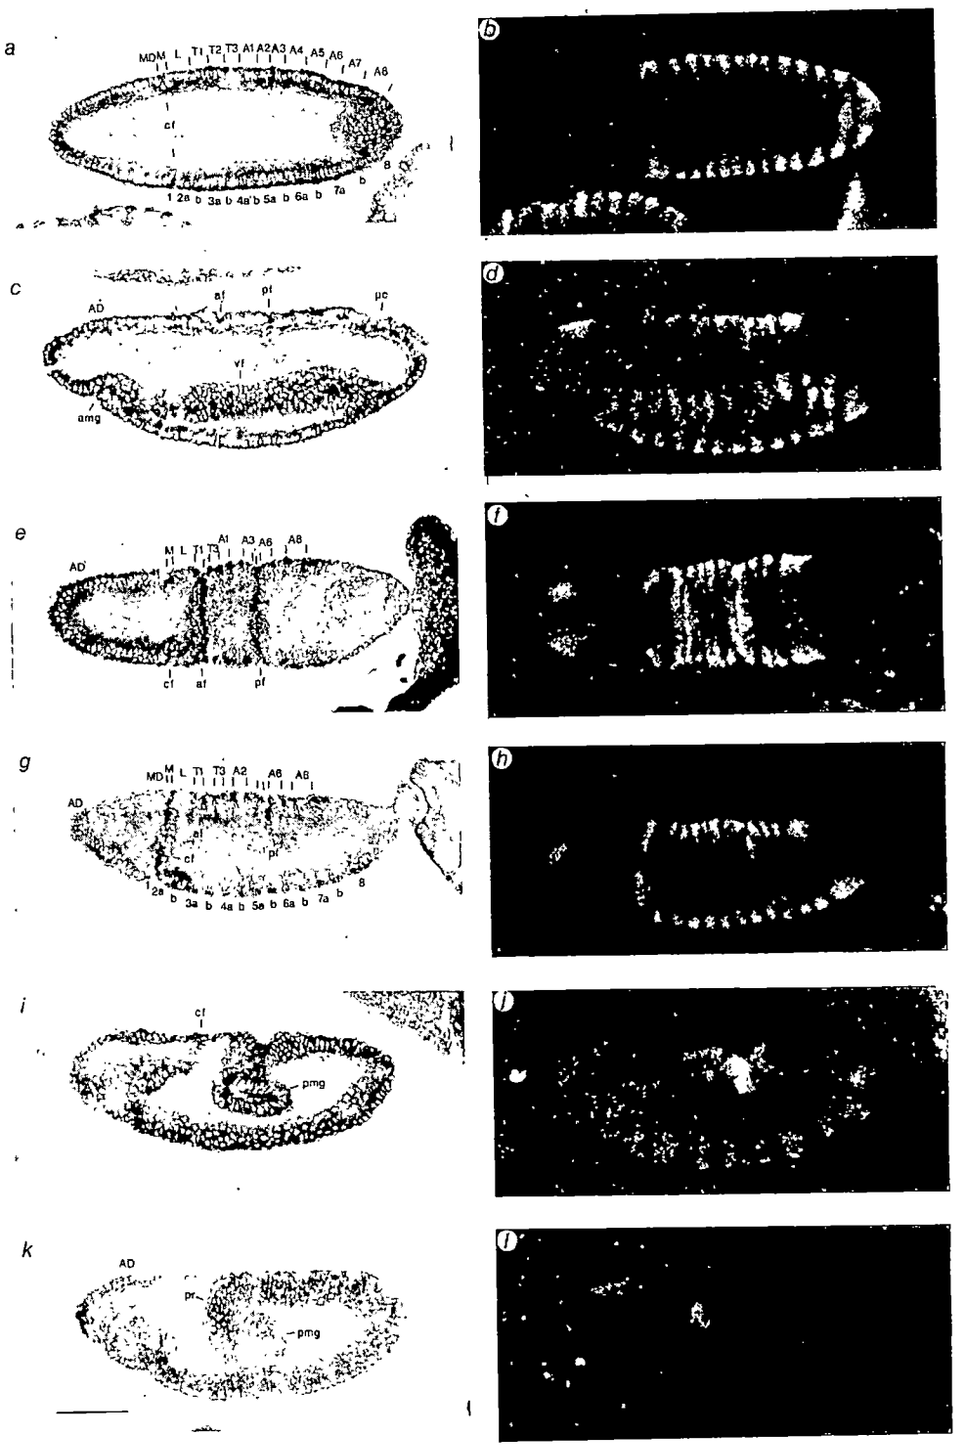

Fig. 6 Localization of *prd* transcripts in gastrulating embryos. Photomicrographs of embryonic tissue sections, prepared and treated as in Fig. 5, were taken under phase contrast (left) or dark-field illumination (right). The following developmental stages are shown: *a, b*, formation of the cephalic furrow; *c, d*, formation of the ventral furrow; *e–h*, beginning of germ-band extension at 3.5–4 h; *i, j*, germ-band extension at 4–4.5 h; *k, l*, end of germ-band extension at ~5 h development at 25 °C. The sections chosen were *a, b*, midventral and *e, f*, superficial dorsal horizontal sections; *c, d, g–l*, median or lateral sagittal sections. The anterior end is oriented to the left and, in sagittal sections, the dorsal side up. Autoradiographic exposure was for 20 days (*a–d, i–l*) or 29 days (*e–h*). The probes used for hybridization in Figs 5 and 6 comprise two short regions of the *prd* gene that are homologous with sequences elsewhere in the genome (G. Frigerio and M.N., unpublished results). However, the same patterns of hybridization are observed when a probe is used from which these *prd*-cDNA sequences have been deleted. Bands and primordial segments are labelled as in Fig. 5. The horizontal bar in *k* indicates a length of 0.1 mm. Abbreviations: af, anterior transverse fold; amg, anterior midgut; cf, cephalic furrow; pc, pole cells; pf, posterior transverse fold; pmg, posterior midgut invagination; pr, proctodeum.

of transcripts appear at approximately equal intervals. These bands are located posterior to the first band and extend to ~20% of EL, that is, to the eighth abdominal segment primordium[6,18]. At the same time, the early anterior band splits into two bands equal in width to the five posterior bands (Fig. 5*e, f*). At this stage, therefore, *prd* transcripts occur in seven bands located between 20 and 75% of EL. The spacing of the bands is regular but closer on the dorsal than on the ventral side, and the signal intensity of the newly formed five posterior bands is again weaker dorsally than ventrally, indicating a dorso-ventral polarity of pattern development (Fig. 5*e, f*). These seven bands increase in intensity as the nuclei elongate and plasma membranes grow inwards (Fig. 5*g, h*). While the width of the posterior six bands remains unchanged at 5–7 cells, the most anterior band is reduced in width to about four cells. This results from an elimination of transcripts in the cells of the anterior portion of the first band. In each of these six posterior bands, however, the labelling intensity is skewed in such a way that cells of the anterior half exhibit less *prd* transcripts than cells of the posterior half. The cells transcribing the *prd* gene are separated by gaps of ~2–3 cells in which no *prd* transcripts are detectable. At the same time transcripts begin to accumulate in cells located close to the anterior pole of the embryo, forming a band six cells wide (Fig. 5*g, h*) which extends between 87 and 93% of EL (Fig. 5*i, j*). In contrast to the other bands, this new band covers only the dorsal half of the embryo (Fig. 5*g–j*).

At a slightly later time, shortly before the completion of cellular blastoderm, two conspicuous events take place (Fig. 5*i, j*). First, an additional band (8) appears posterior to band 7, extending the banding pattern to ~13% of EL. Second, bands 2 to 7 begin to split into an anterior and a posterior band, a process that moves from the anterior to the posterior pole. At the stage shown in Fig. 5*i, j*, the splitting of band 2 is nearly complete whereas that of bands 6 and 7 is barely visible. This band splitting is accomplished by elimination of the transcripts in the two middle cells of each band. As a result of this process, band 2 is split into an anterior band 2a and a posterior band 2b, band 3 into 3a and 3b, and so forth. By the time of cellular blastoderm, the splitting of bands 2–7 is complete, and the width of band 1 has been further reduced from 4 to its two most posterior cells (Fig. 5*k, l*). Thus, when cellularization of the blastoderm is nearly complete, 13 bands have arisen that are about two cells wide and are separated by gaps of about two cells on the ventro-lateral side. Dorsally, splitting of the bands occurs later and is complete only in band 2 at the stage illustrated in Fig. 5*k, l*. In addition, the intensity appears to be skewed in that more transcripts accumulate in the posterior than in the anterior band. The most posterior band (8) remains unsplit and is about five cells wide. Thus, both the formation of the transcript pattern exhibiting a double-segment periodicity and its transition to one with a single-segment repeat are oriented in an anterior–posterior as well as in a ventral–dorsal direction.

Transcript distribution and morphology

To assess the morphological significance of these transcription patterns, we have attempted to relate the spatial distribution of the label to morphological features that are well known from microscope studies[19–21]. This required an extension in time to gastrulation when such features are beginning to appear. Initially, gastrulation is marked by the formation of the ventral and cephalic furrows. As evident from Fig. 6*a, b*, the first two bands (1 and 2a) migrate into the anterior and posterior part of the cephalic furrow. In a similar manner, as the ventral furrow forms, giving rise to the mesodermal germ band, cells transcribing *prd* migrate into it. This is evident from the persistence of the banding pattern in register across the ventral furrow (Fig. 6*c, d*). Similarly, at a slightly later stage when the dorsal transverse folds appear, cells of bands coinciding with the locations of these folds move into them (Fig. 6*e–h*). At this stage, the dorsal portions of the bands have also completed their splitting (Fig. 6*e–h*). From the end of cellular blastoderm to this stage no dramatic change in band intensities is observed. However, during the next stage of germ-band extension, all bands fade with the exception of the anterior dorsal band (Fig. 6*k, l*) and the unsplit band 8, located at the proctodeal invagination (Fig. 6*i, j*). The intensity with which these two bands persist is remarkable. Only after germ-band retraction, shortly before the beginning of head involution, have these bands disappeared (data not shown).

ftz transcripts and segment primordia

Previous determinations of the positions of the *ftz* bands in the blastoderm embryo[8,22] allow us to identify the blastoderm primordia expressing the *prd* gene. When hybridizing three consecutive sections with probes for either *prd* or *ftz*, or with both probes, we found that the pattern of *prd* transcripts is shifted to the anterior of the *ftz* bands. Whereas band 1 of *prd* does not overlap with *ftz* signals, the anterior borders of bands 2–7 (2a–7a) and band 8 of *prd* coincide with the anterior borders of bands 1–7 of *ftz* (Fig. 7). As the *ftz* bands are only about four cells wide and are spaced by gaps of about four cells[8,10,22,23], cells between the seven *prd* bands at late syncytial blastoderm (Fig. 5*g* and *h*) also remain unlabelled by *ftz* (data not shown). At the later stage of cellular blastoderm, when the repetitive pattern of *prd* transcripts consists of 14 bands (Figs 5*k, l*; 7*a*),

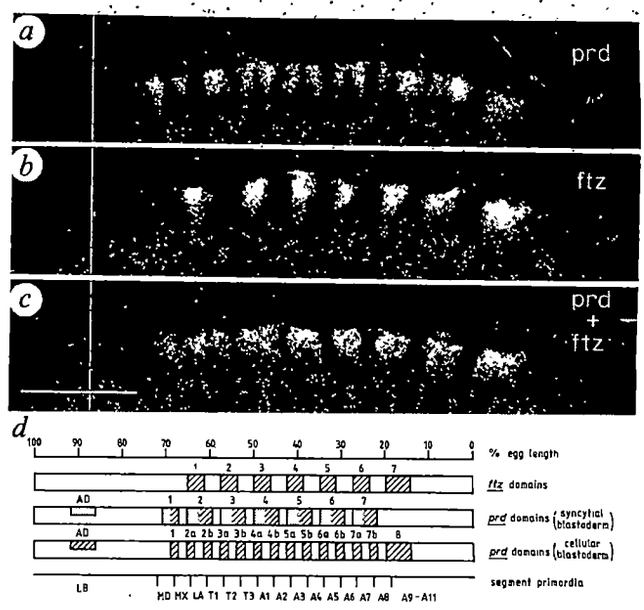

Fig. 7 Localization of *prd* relative to *ftz* transcripts. Three consecutive ventral horizontal sections through an embryo at cellular blastoderm were hybridized with *a*, ^{3}H-labelled c7340.1 *prd* cDNA; *b*, p523B *ftz* DNA[8,42,43]; *c*, the two probes combined and exposed for 29 days according to Hafen *et al.*[41]. Only one lateral side of the embryo is shown under dark-field illumination. The anterior end is oriented to the left. In *d*, the domains of *ftz* and *prd* expression are illustrated schematically relative to each other and the segment primordia. Stippled and hatched areas indicate blastoderm regions showing low and high numbers of transcripts, respectively. The *ftz* domains represented are those seen at syncytial blastoderm when they are about four nuclei wide and regularly spaced by gaps of about four nuclei[8,22]. By the time of cellular blastoderm (*b*), *ftz* domains have been reduced in width to about three cells[22]. The most posterior *ftz* domain is broader and about six cells wide, as previously noted[10]. The horizontal bar in *c* indicates a length of 0.1 mm.

the cells of every second gap still express *ftz* (Fig. 7*b*). Thus, in the combined pattern of *prd* and *ftz* transcripts, we still observe a narrow anterior band two cells wide, consisting only of *prd* transcripts, and seven wide posterior bands, about six cells wide, separated by gaps of about two cells (Fig. 7*c*). Because the third *ftz* band covers the posterior compartment of the metathoracic and the anterior compartment of the first abdominal segment primordium[8,22,24], we conclude that band 4a of *prd* transcripts spans the T3/A1 segment boundary, as indicated in Figs 6*a, b* and 7*d*. If we assume that the four-cell repeat length of the *prd* banding pattern observed at this stage corresponds to the length of one segment primordium, we find that the most anterior *prd* band (1) crosses the boundary between the mandibular and maxillary segment primordia and that band 7b crosses the boundary between the seventh and eighth abdominal primordial segments (Figs 6*a, b*; 7*d*). Accordingly, the most posterior band (8) would cover the posterior compartment of A8 and probably the segment primordia of A9–A11 (Figs 6*a, b*; 7*d*). Our interpretation of the positions of the *prd* bands relative to those of *ftz* is confirmed by their relative positions with respect to the cephalic furrow. Whereas the most anterior band of *ftz* labels the posterior portion of the cephalic furrow[8], bands 1 and 2a of *prd* are situated at its anterior and posterior edge (Fig. 6*a, b, e–h*).

Knowing how the banding pattern of *prd* RNA at early gastrula (Fig. 6*a, b*) develops from that at late syncytial blastoderm (Fig. 5*g, h*), we may trace back the location of *prd* transcripts with respect to the primordial segments at blas-

toderm. Thus, we find that the more strongly labelled posterior portions of bands 1–7 cross the boundaries between mandibular and maxillary, labial and first thoracic, second and third thoracic segment primordia, and so on, as indicated in Figs 5*g*, *h*, 7*d*. Similarly, we may identify segment primordia and relate them to morphological markers during later developmental stages by following the fate of cells labelled with *prd* transcripts. Accordingly, the prothoracic segment gives rise to the anterior transverse fold while the fourth and fifth abdominal segments coincide with the posterior transverse fold (Fig. 6*e–h*).

Discussion

Our analysis of the spatial distribution of *prd* transcripts during embryogenesis has revealed a more complex pattern than anticipated on the basis of results from previous studies with the pair-rule genes *ftz* (ref. 8) and *h* (ref. 10). Transcripts of *prd* appear first during the twelfth nuclear cycle in the region where the primordial head segments form. During subsequent nuclear divisions of the syncytial blastoderm, a pattern of seven bands builds up posteriorly along the antero-posterior axis and dorsally along the ventral–dorsal axis. At the end of this process, the *prd* pattern is similar to that of *ftz* (ref. 8) or *h* (ref. 10), showing a periodicity corresponding to two primordial segments. However, in contrast to the *ftz* and *h* patterns, the seven *prd* bands are wider and hence each covers more than one segment primordium. Thus, no simple correlation of the location of *prd* transcripts with the *prd* phenotype[1,2] (Fig. 1) exists. To derive such a correlation, as has been possible for *ftz* (ref. 8) and *h* (ref. 10), it might be postulated that only those portions of segments are deleted in the mutant that exhibit strong transcription of the *prd* gene in the corresponding wild-type primordial segments during late syncytial blastoderm. As evident from Fig. 5*g*, *h*, these are the posterior parts of each of the seven *prd* bands, corresponding to the posterior mandibular plus anterior maxillary segment, posterior labial plus anterior first thoracic segment and so on (Fig. 7*d*). That this pattern of transcripts corresponds reasonably well to that of fused and deleted segments in the mutant[1,2] (Fig. 1) may indicate that determination of segments and segment boundaries occurs already at this early stage and hence would not depend entirely on a cell-autonomous expression of *prd*.

The pattern of seven *prd* bands exists only transiently and develops during late syncytial blastoderm into a regular pattern of 13 bands of equal width and spacing. This transition of the pattern exhibiting a two-segment periodicity into one of a single-segment repeat occurs again in an anterior to posterior direction and spreads from the ventral towards the dorsal side. Such polarities of pattern development have been observed also for *engrailed* (*en*) and *ftz* transcripts[23] and may suggest a common control mechanism. It is interesting that the pair-rule gene *prd*, initially transcribed with a two-segment repeat, is later switched to be expressed with a single-segment periodicity. Spatial expression patterns of *en* (refs 23, 25) and *ftz* (ref. 23) are also switched from longer to shorter periodicities. A switch in the pattern of *ftz* expression occurs also at a later developmental stage, as shown by the finding that the *ftz* gene product is detected in neuroblasts and ganglion cells of every segment[26,27]. Such changes in patterns would be expected if regulatory interactions among segmentation genes occur and we anticipate that, as more of these genes are studied, more examples of such temporal changes in pattern will be discovered.

The patterns of *en* (refs 23, 28, 29) and *prd* transcripts are very similar at the end of cellular blastoderm. The two most anterior bands of both *en* (ref. 23) and *prd* label the anterior and posterior portion of the cephalic furrow. The two patterns may even coincide as *en* is probably expressed in posterior compartments of each segment[23,28–31] and our spatial assignments of the *prd* bands are based on those of the *ftz* bands, which may be off by one cell. Thus, although *prd* and *en* are initially under different controls, as apparent from their distribution of transcripts, such a spatial and temporal coincidence of the expression of these two genes during cellular blastoderm might indicate that their control becomes at least partly coordinated at this stage.

Two additional groups of cells begin to express the *prd* gene during late syncytial blastoderm. First, transcripts appear in a dorsal band of cells close to the anterior pole at a location similar to that of *h* expression[10]. As has been argued previously[10], these cells may represent the primordium for the labrum[32]. It remains to be shown, however, whether all of these cells express both *h* and *prd*. Second, a wide posterior band of *prd* transcripts that appears in the posterior region of A8 (and possibly in the primordia for A9, A10 and A11) migrates to the proctodeal invagination during germ-band extension. This band, together with the anterior dorsal band, are the last cells to exhibit *prd* expression during embryogenesis.

We thank Maya Burri for technical assistance, Christiane Nüsslein-Volhard for the *prd* mutant strains and discussions, Michael Levine for the *ftz* clone p523B, Hermann Steller for the cos-P-neo vector and Hans Noll for comments on the manuscript. This work was supported by Swiss NSF grants 3.180-0.82, 3.600-0.84 and 3.600-1.84 and by the Canton of Basel.

Measurements of the frequencies of various modes of trapped acoustic waves provide information about rotation and structure within the Sun. Previous work dealt with observations of wave modes confined near the solar equator, which provided some information about the depth variation of rotation without resolving a possible latitude variation[1,2]. Recent work extended measurements to modes covering various latitude ranges from which the variation with latitude of solar rotation can be studied[3–5]. Since these measurements were restricted to modes with spherical harmonic degrees less than 50, they provide averages of rotation over great depth ranges that do not resolve the convective envelope. We now present new results for degrees up to 98 which allow the convective envelope to be isolated. For degrees between 20 and 98 we find no evidence that internal rotation differs significantly with depth or latitude from the rotation of surface magnetic field patterns. Modes covering a wide latitude range have systematically lower frequencies than those confined near the equator, indicating the existence of a structural asymmetry within the Sun.

Modal patterns of trapped acoustic waves are described by the number of nodes of the wave pattern in the radial direction, n, the indices of the spherical harmonic function that characterizes the lateral wave pattern, l (degree) and m (azimuthal order) and cyclic oscillation frequency, ν. Slow rotation causes the frequency to depend on m approximately as[4]

$$\nu(n, l, m) - \nu(n, l, 0) = -m \frac{\int_{-1}^{1} \bar{\Omega}(\theta)[P_l^m(\cos\theta)]^2 \, \mathrm{d}\cos\theta}{\int_{-1}^{1}[P_l^m(\cos\theta)]^2 \mathrm{d}\cos\theta} \quad (1)$$

where θ is the colatitude, $\bar{\Omega}(\theta)$ is an appropriate average of the rotation frequency over the depth range sampled by the particular mode and P_l^m is the associated Legendre function. One may represent a general frequency variation with m as a series

$$\nu(n, l, m) - \bar{\nu}(n, l) = L \sum_{i=0}^{i=N} a_i P_i(-m/L) \quad (2)$$

where $\bar{\nu}$ is the frequency averaged over m, P_i are the Legendre polynomials of degree i and $L = \sqrt{l(l+1)}$. The argument m/L minimizes the innate l dependence of the coefficients. Unlike power series expansions in m used previously, equation (2) produces coefficients that are independent of each other and of the value of N. Expressed in terms of equation (2), the surface differential rotation measured by the motion of magnetic features[6] (or spectroscopically[7]) yields even-indexed coefficients equal to zero and odd-indexed coefficients (nHz sidereal) $a_1 =$ 442.8 (435), $a_3 = 21.7$ (21) and $a_5 = -2.5$ (−4) with negligible l dependences for $l > 20$.

We observed from the geographic South Pole in December 1981 and January 1982, in an effort to obtain sequences of sufficient length to resolve the oscillation spectrum freed from spurious features caused by diurnal interruptions. For the present investigation we used a set of observations started on 24 December 1981 having a duration of 50 h with one 4-h interruption. These data are the best 1/3 of the total collected. The instrument and observing programme have been discussed elsewhere[8,9]. Briefly, we recorded full-disk intensity images in a spectral band (±0.6 nm) centred on the Ca II line at 393.3 nm.

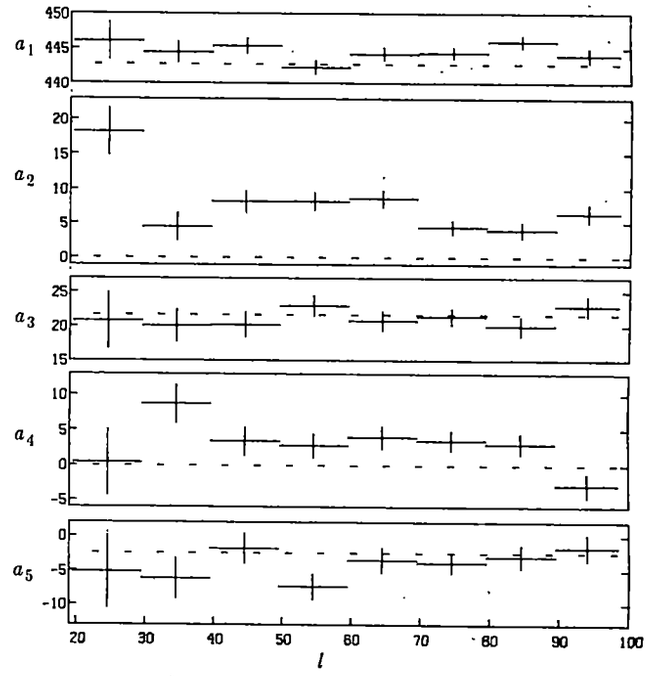

Fig. 1 Averaged coefficients from equation (2) and 1σ random errors as a function of l (nHz). The dashed lines are computed from measurements of the surface differential rotation based on observations of magnetic fields[6].

This spectral region shows intensity oscillations due to trapped acoustic modes which are several times stronger than adjacent continuum regions[10,11]. An advantage of intensity observations over the usual Doppler shift observations is a lack of signal weakening near the limb due to projection effects. A disadvantage of intensity observations is greater noise from solar and terrestrial sources[12]. Exposures were made with a telescope and a charge-injection-device camera which provided 226 pixels along the solar equator and 178 pixels along the solar rotation axis. Integrations were digitally recorded on magnetic tape cartridges every 90 seconds. After correction of the images for various characteristics of the camera, each image of the visible hemisphere was interpolated onto a longitude, sine latitude grid consisting of 512 by 421 elements. In the manner described by Brown[3,4], a Fourier transform in longitude was followed by a transformation by associated Legendre functions in sine latitude and then a Fourier transform in time to produce a spectrum of the solar oscillations with independent variables $l = 0(1)250$, $m = 0(2) \pm l$ and $\nu = 0(5.43)5556$ μHz. To save computation time and because higher resolution is not justified unless the entire surface of the Sun can be observed at once, the spectrum was computed only for even values of m.

The spectra show tens of thousands of modes. It has not yet been possible to assign the frequency of each mode in order to evaluate equation (2). Instead we used a cross-correlation procedure in a manner similar to Brown[3,4]. For each l, trial assumptions of $a_1 = 450$ nHz and $a_3 = 0$ were used for modes between

Table 1 Average rotation coefficients and standard deviations (nHz)

l range	a_1	a_2	a_3	a_4	a_5

2.4 and 4 mHz to produce a frequency spectrum averaged over m that estimated the spectrum for a non-rotating Sun. This estimate was cross-correlated with the spectrum for each value of m. The frequencies of the peaks of the cross-correlations were then used to improve estimates of $a_{1,3}$. The improved mean spectrum was then cross-correlated with each m-value spectrum to provide values for the solution of equation (2) with $N=5$. Results for $l<20$, $l>98$ were too noisy to be useful. The remaining results were averaged in groups of ten l values and are tabulated in Table 1. The uncertainties in the means are derived from the individual l uncertainties by normal error propagation rules. Individual uncertainties were based on the assumption that the frequency estimation error is independent of m at a given l. The values of a_0 were all less than 1 nHz and are not included in Table 1.

The results are shown in Fig. 1 together with values derived from the measured rotation of surface magnetic field patterns[6]. The odd-indexed coefficients carry information about rotation. There appears to be no significant variation of the rotation coefficients with changing l value. The slight difference between magnetic rotation coefficients and our results is within the range of variation of surface rotation during the solar activity cycle. Thus one may conclude from our results that the rotation averaged over the outer half of the Sun, probed by modes with $l>20$, is essentially identical with that of the surface. This conclusion requires verification by a formal inversion to deduce the range of possible rotation variations with latitude and depth admitted by the data. Pending such an inversion, we conjecture that differential rotation with latitude persists at least through most of the convection zone.

The even-indexed coefficients provide information about the latitude variation of sound speed versus depth. If the internal structure of the Sun were independent of latitude the even coefficients should be zero. Centrifugal distortion of the Sun would produce a negative value of a_2 (ref. 13). There appears to be a significant, positive difference from zero in the sense that apart from rotation, near-zonal modes have lower frequencies than near-sectoral modes of the same degree. Brown[3,4] also found a systematic, positive quadratic frequency dependence with m but attributed no significance to it. Transformed to the same basis, his values are about 1/3 of our values. We believe that the effect is genuine and indicates that the structure of the convection zone is different near the equator compared with higher latitudes.

The present measurements may be used to compute the frequency difference to be expected from prograde and retrograde sectoral modes. These calculated frequency differences agree with direct observations of sectoral mode frequencies[1]. Brown's[4] calculated sectoral mode frequency differences also agree with the present results. Unfortunately our results for the latitude dependence of rotation significantly disagree with those of Brown[3,4]. His values of a_3 for $l=20$–29, 30–39, 40–49 are 4.6 ± 1.2, 9.1 ± 1.4 and 4.1 ± 2.7 respectively, or roughly 1/3 of our values. Brown's rotation results indicate much less differential rotation with latitude than we find.

We have examined many possible sources of this discrepancy without identifying a satisfactory explanation. Some possibilities which have been examined and are now considered unlikely are: (1) simple numerical error, (2) different frequency ranges used in the analyses, (3) the different spatial responses of intensity and velocity, (4) the cross-correlation technique responding to (in the intensity observations) the solar background signal rotating at the surface rate and (5) the Sun changing with time. Some more likely possibilities which have been considered and which require additional evaluation include: (1) the different frequency resolution, (2) the different temporal sidelobe structure and (3) the surface pattern of intensity modulating the oscillations and changing the spatial response functions. Further observations should reveal the source of the systematic error. Although Libbrecht's observations[5] do not cover the degree range that we observed, his measurements substantially agree with those of Brown[3,4] at l values less than 20.

This work was done while T.L.D. was a visiting astronomer at the National Solar Observatory in Tucson. R. Aikens of Photometrics, Ltd and R. Pfeiffer of Bartol greatly assisted the success of our observations from the South Pole. R. Nagel of NOAO designed and assembled the data recording system. We appreciate discussions with T. Brown aimed at resolving the discrepancy between our separate results. P. Goode pointed out an error in the original version of equation (2). This work was supported in part by NSF grant DPP78-22267. The National Optical Astronomy Observatories are operated by the Association of Universities for Research in Astronomy, Inc. under contract with NSF.

Superparamagnetic component in the Orgueil meteorite and Mössbauer spectroscopy studies in applied magnetic fields

M. B. Madsen*, S. Mørup*, T. V. V. Costa†‡, J. M. Knudsen† & M. Olsen†

* Laboratory of Applied Physics II, Technical University of Denmark, DK-2800 Lyngby, Denmark
† Physics Laboratory I, H. C. Ørsted Institute, University of Copenhagen, DK-2100 Copenhagen Ø, Denmark

The Orgueil meteorite is a carbonaceous chondrite of group CI. Wdowiak and Agresti[1] have recently shown that very small magnetic particles, which exhibit superparamagnetic relaxation below 80 K, are present in this meteorite. They suggested that these small particles consist of magnetite. Using Mössbauer spectroscopy in external magnetic fields we have found that the Orgueil meteorite does not contain superparamagnetic magnetite in any appreciable amount. The meteorite contains another, as yet unidentified iron (III) compound which exhibits superparamagnetic behaviour below 80 K.

The sample of the carbonaceous chondrite Orgueil was ground into a powder and a Mössbauer absorber was prepared in a plexiglass absorber holder. Mössbauer spectra were obtained at various applied magnetic fields and temperatures.

Figure 1 shows a series of Mössbauer spectra of the meteorite recorded at various temperatures without applied magnetic fields. The spectra obtained at 298 and 125 K show the presence of magnetically split components due to iron in the tetrahedral (A) and octahedral (B) sites of magnetite[2]. The area ratio of

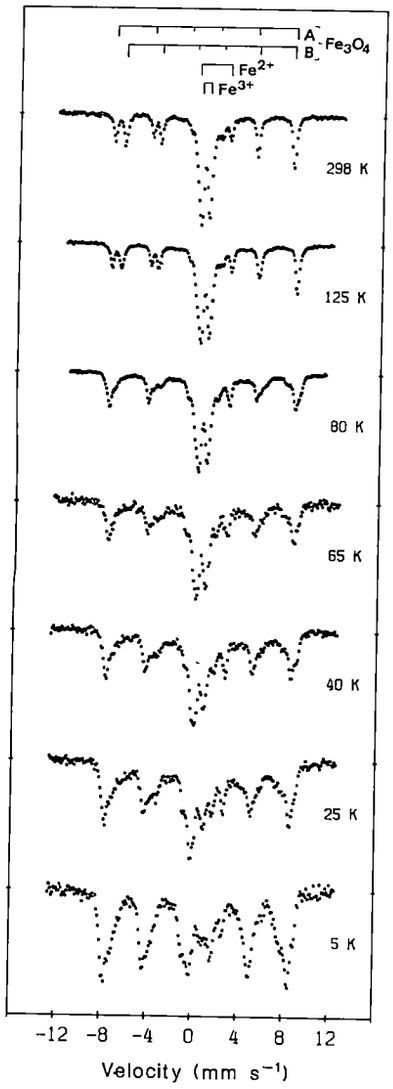

Fig. 1 Mössbauer spectra of the Orgueil meteorite obtained at different temperatures. The bar diagram indicates the tetrahedral (A) and octahedral (B) sites of the magnetite and the Fe^{2+} and Fe^{3+} doublets.

the A and B components indicates that the magnetite is slightly more oxidized than ideal stoichiometric magnetite, in which this area ratio is approximately 1:2. The spectra also contain quadrupole doublets due to paramagnetic Fe^{2+} and Fe^{3+}. At room temperature the Fe^{3+} doublet has a quadrupole splitting $\Delta E_Q = 0.73 \pm 0.03$ mm s^{-1} and an isomer shift relative to α-Fe, $\delta_{Fe} = 0.37 \pm 0.02$ mm s^{-1}. The line width is $\Gamma = 0.46 \pm 0.02$ mm s^{-1}. For the Fe^{2+} component we find $\Delta E_Q = 2.75 \pm 0.08$ mm s^{-1}, $\delta_{Fe} = 1.13 \pm 0.04$ mm s^{-1}, $\Gamma = 0.33 \pm 0.02$ mm s^{-1}. The Mössbauer parameters of the Fe^{2+} components are in accordance with Fe^{2+} ions in a hydrated silicate[3,4].

Below the Verwey transition temperature (~119 K)[5] the Mössbauer spectrum of magnetite is very complex and as many as six sextets may be required to fit the spectrum adequately[6]. The spectra of Fig. 1 reveal that the relative area of the iron (II) doublet remains nearly constant, at least down to 25 K. However, below 65 K, the relative area of the iron (III) doublet gradually decreases with decreasing temperature, whereas the total area of the magnetically split components increases. The observed behaviour is typical for a system containing superparamagnetic microcrystals with a distribution of particle sizes[7,8]. Thus the spectra indicate that Fe^{3+} ions are present in a compound which exhibits superparamagnetic relaxation in this temperature range. On the basis of similar spectra Wdowiak and

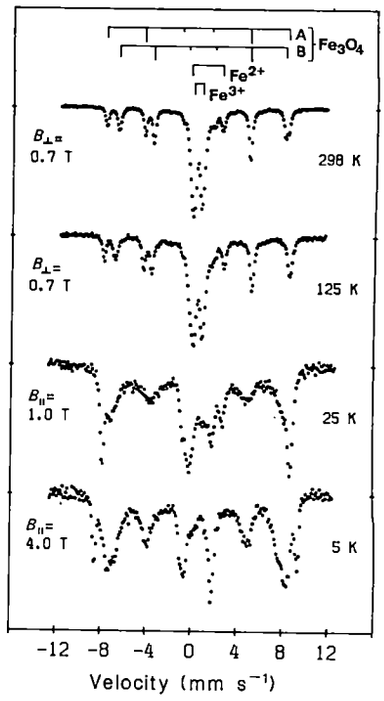

Fig. 2 Mössbauer spectra of the Orgueil meteorite obtained at different temperatures with the absorber in external magnetic fields. The intensity and direction of the external field, B, with respect to the γ-rays is indicated.

Agresti[1] concluded that the Orgueil meteorite contains superparamagnetic magnetite particles.

Because of the overlap of many different magnetically split components in the low-temperature spectra, it is difficult to determine the exact Mössbauer parameters of the six-line component which appears at low temperature at the expense of the Fe^{3+} doublet. Mössbauer studies in applied magnetic fields may, however, give supplementary information on superparamagnetic microcrystals and, in particular, such studies can give information on the magnetic moments of the microcrystals[7,8].

Therefore, to clarify whether the mineral that exhibits superparamagnetic relaxation above 5 K and contributes the Fe^{3+} doublet above 80 K has any net magnetic moment, Mössbauer spectra were obtained with external magnetic fields applied to the sample. The spectra are shown in Fig. 2. At 298 and 125 K a magnetic field of 0.7 T was applied perpendicular to the γ-ray direction. This leads to a change in the area ratios of the magnetite sextet lines from ~3:2:1:1:2:3 to 3:4:1:1:4:3, indicating alignment of the magnetization direction parallel to the applied field. The doublets are only slightly affected by the magnetic fields; that is, the width of their lines increases.

Comparing the parameters with those of the spectrum obtained in zero field, it was found that the relative areas of the doublets and the sextets do not change significantly on application of the external field. Previous studies[7,8] of samples of superparamagnetic magnetite particles with average particle diameters down to 4 nm have shown a substantial splitting of the spectra when similar magnetic fields were applied. This is due to the fact that the Zeeman energy is comparable with, or larger than, the thermal energy even at room temperature and, therefore, the particles are significantly magnetized by the external field. The present results, therefore, show that the quadrupole doublet is not due to superparamagnetic magnetite particles, as was suggested by Wdowiak and Agresti.

Further information about the nature of the superparamagnetic phase can be obtained from the spectra measured at 25 and 5 K with applied magnetic fields parallel to the γ-ray direction, shown in Fig. 2. From these spectra it is seen that the

magnetization direction of the magnetite aligns parallel to the applied magnetic field. This alignment leads to the disappearance of the $\Delta m = 0$ lines, that is, the lines 2 and 5 of the magnetite sextets. Some broad lines remain, however, at velocities where the magnetite should not give absorption lines. The broad lines at about -4 and $+5$ mm s^{-1} thus indicate the presence of an iron-containing compound with no significant net magnetization. This is the compound that gives rise to the iron(III) doublet at higher temperatures. The magnetic hyperfine fields of this compound are about 47 T at 25 K and 49 T at 5 K. The large line widths (>1 mm s^{-1}) of this compound suggest that it is a poorly crystallized or perhaps amorphous iron (III) compound. The low net magnetization of the compound could be due to antiferromagnetic ordering.

From our results we conclude that the superparamagnetic component in the Orgueil meteorite is not due to magnetite particles. The meteorite contains particles of another iron (III) compound that has a negligible net magnetization, but exhibits a superparamagnetic behaviour below 65 K.

The carbonaceous chondrites of group CI have an elemental composition closely resembling that of the Sun, if we disregard the most volatile elements. These meteorites are believed to have condensed in the very early phase of the formation of the Solar System. Even if the carbonaceous chondrites are partially altered, for example by aqueous activity, their chemical composition may still have some similarity to interstellar, and circumstellar, dust[9]. If this is so, the findings of Wdowiak and Agresti[1] and the results of the present work indicate that superparamagnetism is a much more common phenomenon in the Universe than hitherto believed.

The sample of the meteorite was supplied by the Mineralogical Museum of Copenhagen. The project is supported by the Danish Natural Science Research Council. T.V.V.C. is supported by the Brazilian Agency CAPES.

Gaseous ammonia and ammonium ions in the free troposphere

H. Ziereis & F. Arnold

Max-Planck-Institut für Kernphysik, Postfach 103980, D-6900 Heidelberg, FRG

Ammonia, the most important alkaline compound commonly found in the atmosphere, has a key role in aerosol chemistry. Gaseous ammonia is released at the Earth's surface primarily through the decomposition of organic material and, due to its extremely large solubility in water and reactivity with acid aerosol components, is efficiently removed by interaction with aqueous and acid aerosols. While the presence of ammonium ions (NH_4^+) in aerosols and rain water is well established, there have been few studies of gaseous ammonia and its abundance is not well established, particularly in the free troposphere[1]. This is probably due to the difficulty in developing sufficiently sensitive analytical methods, which are not affected by interference of ammonium-containing aerosols. Due to its large proton affinity or gas-phase basicity, ammonia vapour is expected to react also with atmospheric gaseous positive ions leading to gaseous NH_4^+ 'core ions'. Detection of the gaseous NH_4^+ core ions, which have not yet been observed in the free atmosphere, may provide sensitive means of detecting atmospheric ammonia vapour[2,3,4]. We report here on the first measurements of this ion in the free atmosphere at altitudes from 4,000 to 8,000 m. Ammonia vapour abundances inferred from these data are very low suggesting efficient heterogeneous ammonia removal and very low ammonia saturation pressures over aerosols.

Due to its large proton affinity (204.0 kcal mol^{-1}), ammonia vapour reacts with most atmospheric positive ion species[2]. This is particularly true for $H^+(H_2O)_n$ clusters, which are quickly formed from primary positive ions created in the troposphere by cosmic rays and radioactivity and react with ammonia vapour:

$$H^+(H_2O)_n + NH_3 \rightarrow NH_4^+(H_2O)_{n-1} + H_2O \qquad (1)$$

(rate coefficient: $k = 1.8 \times 10^{-9}$ cm^3 s^{-1} for $n = 3$; (ref. 5)).

Also $H^+CH_3CN(H_2O)_n$ clusters, which were recently found in the middle and lower stratosphere[6], undergo reactions analogous to (1) and the rate coefficients, as recently measured in our laboratory[7], are 1.8×10^{-9} cm^3 s^{-1} ($n = 0$), 1.8×10^{-9} cm^3 s^{-1} ($n = 1$) and 1.2×10^{-9} cm^3 s^{-1} ($n = 2$). Reactions (1) involving proton hydrate ions with n around 8 are also fast, having rate coefficients around 1×10^{-9} cm^3 s^{-1} as we have recently found by creating large $H^+(H_2O)_n$ clusters in ambient air and letting them react with ambient ammonia vapour. Using this active chemical ionization (ACIMS) method and taking the above $k = 1.8 \times 10^{-9}$ cm^3 s^{-1}, we obtained a ground-level ammonia vapour mixing ratio of 3.2 p.p.b.v. (parts per 10^9 by volume) which falls well inside the range of previous ammonia measurements employing denuder, chemical filter, and condensation collection techniques (0.5–10 p.p.b.v.; see refs 8, 9). Thus, it seems fairly well established that NH_4^+-containing clusters should be found in the Earth's atmosphere provided that ammonia vapour is sufficiently abundant.

We have used an improved aircraft-borne ion mass spectrometer with high mass resolution and sensitivity to search for NH_4^+-containing cluster ions. This instrument was similar to one used previously[10–14] and so will not be described here. It has three modifications: (1) A larger quadrupole mass spectrometer (rod diameter: 1.6 cm) providing higher mass resolution and sensitivity; (2) a larger cryopump (liquid neon-cooled) adding to the improved sensitivity; (3) an ECA (electric field-induced collisional activation) mode used for fragment ion studies facilitating ion identification and adding to an improved overall sensitivity.

Three flights of the modified ion mass spectrometer were carried out aboard a twin-jet research aircraft of the DFVLR (Deutsche Forschungs- und Versuchsanstalt für Luft- und Raumfahrt). The flights (F11, F12, F13), which took place on 11, 14, and 15 May 1985 over the FRG, covered a total altitude range from ~4,000 to 10,000 m.

When the ECA mode was used, the major positive ion mass peaks occurred within the mass range 12–25 AMU (atomic mass units). Therefore, this portion of the mass spectrum was preferably scanned to increase the effective sampling time and thereby increase the sensitivity for ion detection which is particularly helpful at high mass resolution. Figure 1*a*, *b*, and *c* show mass spectra as obtained in flight F12 at different altitudes. These mass spectra contain three major peaks at 19, 18, and 15 AMU which are due to H_3O^+, NH_4^+ and CH_3^+. To ensure that the two peaks of 18 and 19 AMU are due to two different ion species and not an artefact resulting from a bad peak shape (peak splitting), an in-flight calibration was carried out. Here, $H^+(H_2O)_n$ clusters were created using the ACIMS mode of the instrument employing a high-frequency glow discharge ion source[13].

A typical ACIMS spectrum as shown in Fig. 1*d* contains

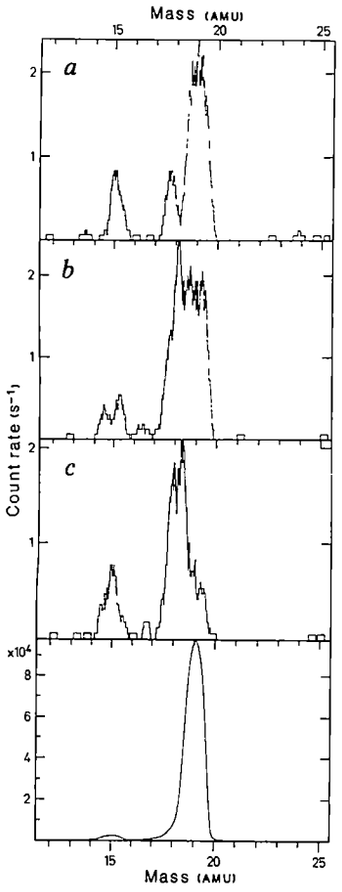

Fig. 1 Portions of positive ion mass spectra as obtained on flight F12 at altitudes of: *a*, 6,900 m; *b*, 6,000 m; *c*, 5,100 m. For comparison an ACIMS spectrum is also shown (*d*), obtained on the same flight at 8,000 m and serving as an in-flight calibration of the mass scale and the peak shape.

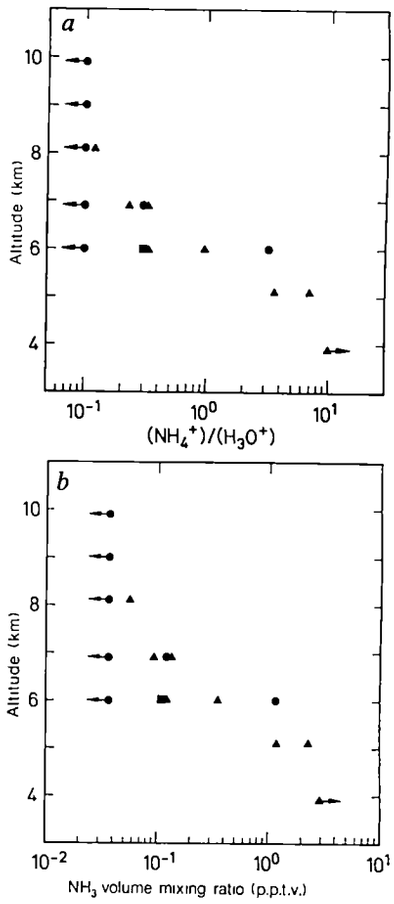

Fig. 2 *a*, Abundance ratios for NH_4^+ and H_3O^+ 'core' ions as measured in the aircraft flights given in the insert. Arrows denote upper or lower limits. *b*, Ammonia vapour volume mixing ratios as inferred from the data given in *a*. ●, F11, 11 May 1985; ▲, F12, 14 May 1985; ■, F13, 15 May 1985.

mainly a peak at mass 19 (H_3O^+). The peak shape of 19 is nominal with no peak splitting present. While H_3O^+ represents a core of ambient cluster ions, CH_3^+ is probably a fragment of core ions made up by a protonated molecule containing a methyl group as, for example, H^+CH_3CN (protonated acetonitrile), $H^+(CH_3)_2CO$ (protonated acetone) or $H^+(C_3H_6)$ (protonated propylene). The spectra shown in Fig. 1*a*–*c* also reveal a marked change of the abundance ratio for NH_4^+ and H_3O^+ taking place around 6,000 m. Figure 2*a* shows the height variation of this ion abundance ratio. It increases from 0.1 (lower limit of measurements) at 10,000 m to 10 (upper limit of measurements) at 4,000 m. At 6,000 m where most data were obtained, a marked variability was also found even during a single flight (F11). The time span between the two extreme F11 measurements at 6,000 m was only about 15 min corresponding to a horizontal distance of about 200 km. Weather conditions were characterized by clouds reaching up to about 3,000 m (F13) and no clouds present (F11, F12). Local tropopause levels were 9,800 m (F11), 11,570 m (F12), and 9,130 m (F13).

The ammonia vapour abundance can be roughly estimated from our ion composition data by assuming that NH_4^+-containing ions are formed from the other observed ions (mainly H_3O^+-containing ions) and lost by ion–ion recombination (typical[15] tropospheric ion–ion recombination lifetime: $t_R = 100$ s). A steady-state treatment yields the following continuity equation:

$$(H_3O^+)k(NH_3) = (NH_4^+)t_R^{-1} \quad (2)$$

(brackets denote number densities). H_3O^+ and NH_4^+ stand for clusters containing these 'cores'. Applying this passive chemical ionization mass spectrometry (PACIMS) method and taking $k = 2\times10^{-9}$ cm^3 s^{-1} (see above) and $t_R = 100$ s, one obtains ammonia vapour abundances as given in Fig. 2*b* ranging between ~0.043 and 3.5 p.p.t.v. (parts per 10^{12} by volume). The uncertainties for k, t_R, and the measured $(NH_4^+)/(H_3O^+)$ ratio are about ±50%, ±50%, and ±30%, respectively. Thus, the uncertainty for the inferred (NH_3) is about ±80%. An additional systematic error may arise if ECA-induced fragmentation of $NH_4^+(H_2O)_n$ clusters

$$(NH_4^+(H_2O)_n)^* \rightarrow NH_4^+(H_2O)_{n-m} + mH_2O \quad (3a)$$

$$\rightarrow H_3O^+(H_2O)_{n-k} + NH_3 + (k-1)H_2O \quad (3b)$$

(the asterisk denotes that the $NH_4^+(H_2O)_n$ cluster is internally highly excited) gives rise not only to H_3O^+ (equation (3*a*)) but also to NH_4^+ (3*b*). As can be judged from our above mentioned laboratory ACIMS measurements, process (3*b*) should be much less efficient than process (3*a*). However, even if there was only a minor side channel leading to H_3O^+ large errors could be induced for ratios of ambient $NH_4^+(H_2O)_n$ and $H^+(H_2O)_n$ ions being much larger than one. In such conditions, the PACIMS and ACIMS methods may underestimate ambient ammonia vapour abundances.

Compared with the two upper tropospheric ammonia vapour measurements of Hoell *et al.*[16], who used an infrared heterodyne radiometer technique (the only upper tropospheric ammonia vapour measurements previously reported) and obtained values between about 0.6 and 2 p.p.b.v., our present data are much

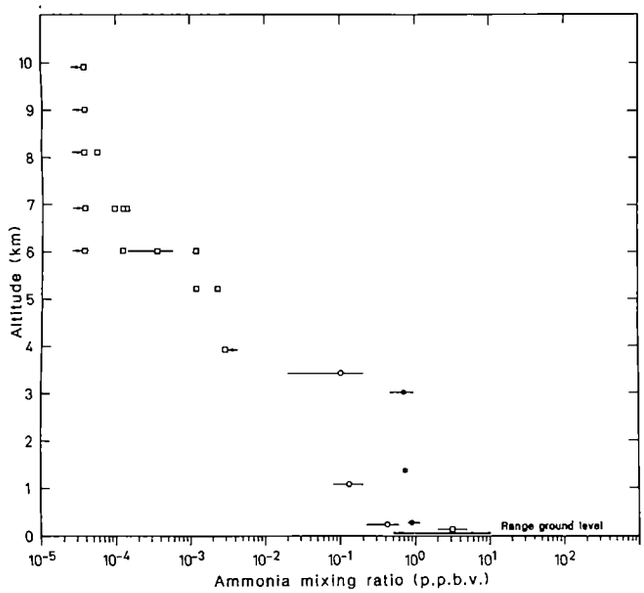

Fig. 3 Comparison of present ammonia vapour data (□) and previous denuder measurements by Lebel *et al.*[17]: ○, March 1983; ●, September, 1983. A typical range for previous ground level measurements at continental sites[8,9] is also given (△). Also shown is a typical ground level value obtained from active chemical ionization mass spectrometry during tests of the present method (see text).

lower. All other ammonia vapour measurements previously reported are restricted to heights below about 3,500 m and, therefore, a direct comparison with the present data is not possible. Recent aircraft-borne denuder measurements by Lebel *et al.*[17] (Fig. 3). extending up to 3,500-m range between about 0.1 and 1 p.p.b.v. Ground-level values, as mentioned before, typically fall into the range between about 0.5 and 10 p.p.b.v. (Fig. 3) being mostly much larger than free tropospheric values.

The observed decrease with height of the ammonia vapour volume mixing ratio suggests that an efficient sink for this gas must be operative throughout the troposphere. This sink can probably be identified as ammonia vapour interaction with aerosols of various sorts ultimately followed by washout and rainout of the aerosols. Even in fair weather conditions, the surface area densities of continental background aerosols are sufficiently large to make the lifetime t_c of a gaseous ammonia molecule against collision with aerosols much smaller than typical timescales t_{vT} for tropospheric vertical transport. Consequently, a very steep decrease with height of the ammonia vapour volume mixing ratio should be expected if ammonia reevaporation was negligible. On average, the aerosol content decreases with increasing height and therefore t_c increases. Considering typical aerosol abundances[1] and sizes, one estimates tropospheric t_c values to be much less than typical timescales for tropospheric vertical transport ($\sim 2\times10^4$–2×10^6 s km^{-1}). Thus, in many conditions, a local equilibrium between ammonia absorption by and re-evaporation from aerosols may be established depending sensitively on the aerosol composition. In reality, ambient aerosols are complex systems whose chemical and physical states are governed by atmospheric conditions and often vary with time and location. Depending on the extent of neutralization and atmospheric relative humidity, they may exist in a completely dissolved, partially dissolved or crystalline state as pure or mixed salts. For example, solid NH_4NO_3, a relatively simple aerosol, would have ammonia vapour equilibrium saturation volume mixing ratios[19] (ammonia equilibrium saturation pressures converted to volume mixing ratios) of about 0.37 p.p.b.v. (4,000 m), 0.15 p.p.b.v (5,200 m), 0.06 p.p.b.v (6,100 m), 0.03 p.p.b.v. (7,000 m), and 0.003 p.p.b.v. (8,200 m) if atmospheric temperatures as measured in F12 are considered. Compared with our measured ammonia abundances, these are generally larger by factors around 10–100. For NH_4HSO_4 and $(NH_4)_2SO_4$ aerosols the equilibrium saturation abundance for ammonia vapour may be much smaller than for NH_4NO_3 depending sensitively on the molar ratio NH_4^+/SO_4^{2-} and relative humidity[20]. At ground level (temperature of 25 °C and a relative humidity of 85%) for example, the equilibrium ammonia vapour pressure over ammonium sulphates (molar ratio $NH_4^+/SO_4^{2-}=1$) is about 50 times lower than over NH_4NO_3.

We conclude that it is at least conceivable that our measured ammonia vapour abundances represent equilibrium abundances over ambient aerosols. If so, they may contain valuable information on the chemical nature of aerosols. Future measurements should focus on variations of ambient ammonia vapour abundances with atmospheric temperature which should be very pronounced if ammonia reevaporation was in fact important. An attempt should be made to carry out combined measurements of ammonia vapour and other relevant parameters including H_2SO_4, HNO_3, and H_2O vapours as well as atmospheric temperatures.

We thank E. E. Ferguson and C. Brosset for helpful discussions, and the technical staffs of the Max-Planck-Institut für Kernphysik, particularly K. Oberfrank and W. Dann and of the Deutsche Forschungs- und Versuchsanstalt für Luft- und Raumfahrt (Flugbereitschaft), for their support. Part of this project was funded by the Bundesministerium für Forschung und Technologie through Gesellschaft für Strahlen- und Umweltforschung.

Acetone measurements in the upper troposphere and lower stratosphere—implications for hydroxyl radical abundances

F. Arnold, G. Knop & H. Ziereis

Max-Planck-Institut für Kernphysik, Postfach 103 980, D-6900 Heidelberg, FRG

Atmospheric acetone serves as a precursor of PAN (peroxyacetyl nitrate) which represents a temporary reservoir for reactive nitrogen and has a potential to form aerosols. Acetone has recently been detected in the atmosphere by Penkett[2], using ground-level flask sampling and gas chromatography/mass spectrometry (GC/MS) analysis in the laboratory finding an average volume mixing ratio of 470 p.p.t.v. (parts per 10^{12} by volume) in Atlantic

air. Very recently, acetone was for the first time detected in the free atmosphere, at heights around the tropopause, by Arnold and his colleagues[3,4] using aircraft-borne chemical ionization mass spectrometry (CIMS). We report here on the first measurements of atmospheric acetone abundances over an extended altitude range (5,900–11,300 m) covering the lowermost part of the stratosphere and the upper troposphere. The measured upper tropospheric abundances (average 120 p.p.t.v.) are substantially lower than the average values (470 p.p.t.v.) measured at ground level. Above the tropopause, a marked decrease of the acetone mixing ratio was observed. Our present data have interesting implications for the chemistry of non-methane hydrocarbons and possibly also hydroxyl radical abundances.

Aircraft-borne CIMS, used for the present measurements, is similar to the experimental method previously employed by our group[3–7] and will only briefly be reviewed here. It involves a flow reactor through which atmospheric air is passed and within which ions created in the air stream by a high-frequency glow discharge ion source undergo ion molecule reactions with atmospheric trace gases. Precursor and product ions are then mass analysed using a cryogenically-pumped quadrupole mass spectrometer. Abundances of reactant trace gases can be determined from measured ion abundance ratios and independently measured ion residence times.

The present CIMS-instrument has several modifications to the previous model including a larger quadrupole mass spectrometer (quadrupole rod diameter: 1.6 cm) and an ECA (electric field-induced collisional activation) mode. The larger quadrupole provides a larger sensitivity and mass resolution while the ECA mode is used for fragmented ion mass spectrometry studies, which greatly facilitates ion identification. A detailed description of the modified instrument will be given elsewhere.

Six flights (F6, F8, F9, F11, F12, F13) were carried out over the FRG using a twin-jet research aircraft (type: FALCON 20) of the Deutsche Forschungs- und Versuchsanstalt für Luft- und Raumfahrt. The flights, which all took place during daytime, covered a total altitude range from 5,900 to 11,300 m.

The acetone volume mixing ratios measured during these flights are shown in Fig. 1*a* along with the single data point of our first CIMS-flight (F5 (ref. 4)). Some of the data were obtained at altitudes above the local tropopause levels. Figure 1*b* shows the same data, but replotted as a function of the vertical separation from the local tropopause level. These data exhibit substantial scatter, but a trend also seems to exist towards lower values above the tropopause which is particularly pronounced for F6 and F8 where altitude profiles were obtained covering both the uppermost part of the troposphere and the lowermost part of the stratosphere. Our stratospheric data (obtained at heights at least 500 m above local tropopause levels) range between ~20 and 50 p.p.t.v. (average: 31 p.p.t.v.) whereas our tropospheric data range between ~50 and 250 p.p.t.v. (average: 120 p.p.t.v.).

Compared with the ground-level average of 470 p.p.t.v. our upper tropospheric average of 120 p.p.t.v. is substantially lower which, if both values were representative, would imply that efficient tropospheric acetone sinks must exist. Known sinks include photolysis and OH-attack of which the former process appears to be dominant. The photodissociation frequency J is about $1\text{–}2\times10^{-6}\ s^{-1}$ at the 10-km level[8] which implies an acetone lifetime of about 10 to 20 days (diurnal average). The reaction coefficient[1] for OH-attack is $2\times10^{-13}\ cm^3\ s^{-1}$ which implies a typical lifetime of about 53 days (diurnal average) in summer at middle latitudes (here a typical diurnal average OH-concentration of $1\times10^6\ cm^{-3}$ as given by the model of Crutzen[9] was taken). By comparison, the timescale for vertical mixing[10] between ground level and the 10 km level is about 10–100 days mostly exceeding the photochemical lifetime of acetone. Consequently, substantial upward mixing of acetone originating from the planetary boundary layer has to be expected. Taking a lower limit to the photochemical lifetime of acetone of 10 days, assuming a ground-level mixing ratio of 470 p.p.t.v., and neglecting photochemical acetone production above the ground, average winter and summer volume mixing ratio profiles as shown in Fig. 1 would be expected. Here, recent vertical eddy diffusion coefficients as given by Liu *et al*[10] were considered. Compared with our data (Fig. 1*a*), the model curves are gen-

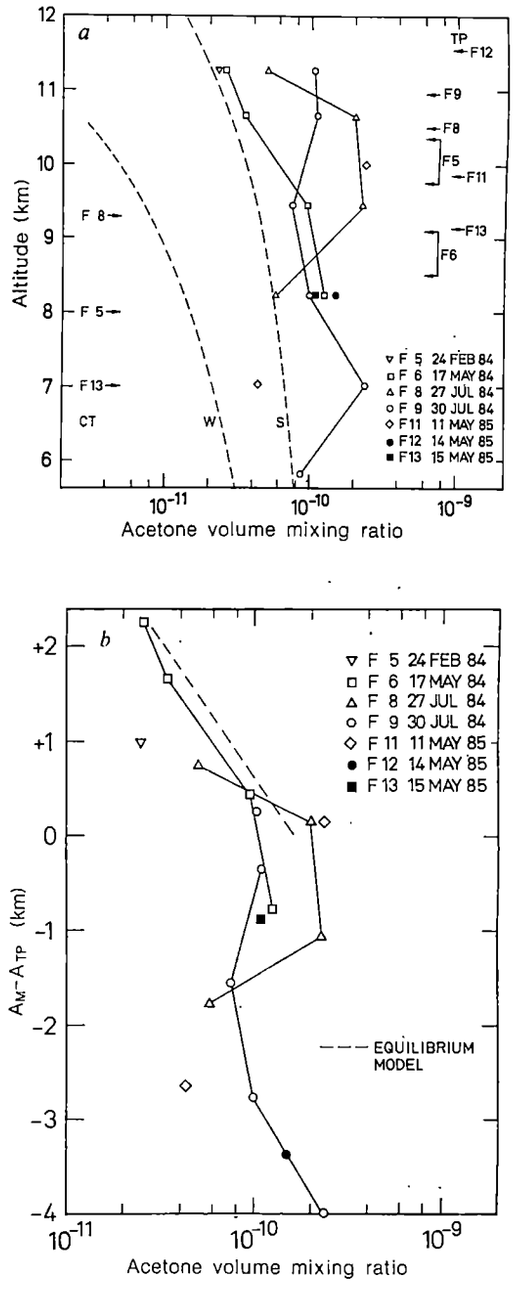

Fig. 1 *a*, Acetone volume mixing ratios as measured during the aircraft flights (F6, F8, F9, F11, F12, F13; see inset) along with the single data point of our previous flight (F5; ref. 4). Also given are local tropopause (TP) and cloud top (CT) levels. Model curves for a gas with a surface source, a 10-day lifetime and a ground-level mixing ratio of 470 p.p.t.v. are also shown for winter (W) and summer (S) conditions. *b*, As *a* with vertical separation from local tropopause level (A_M is the altitude of the measurement and A_{TP} the local tropopause level) instead of geometric altitude as the *y*-coordinate. A model curve assuming local photochemical equilibrium in the stratosphere between acetone formation by propane photooxidation and loss by photolysis is also shown (dashed curve).

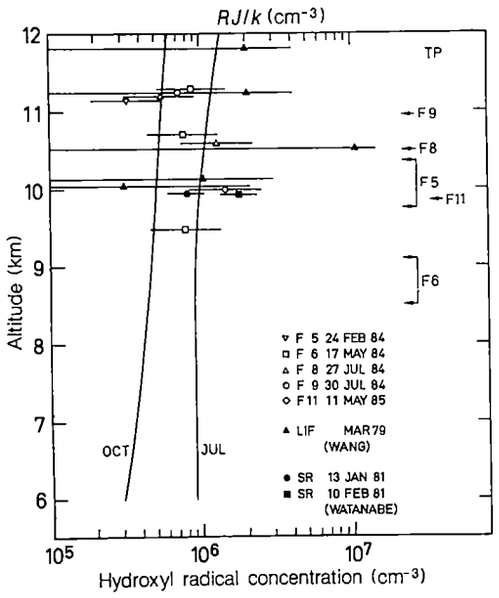

Fig. 2 Inferred stratospheric RJ/k values (see text), which would be equal to OH-concentrations (diurnal averages) for local photochemical equilibrium of acetone formation by C_3H_8+OH and acetone formation by C_3H_8+OH and acetone destruction by photolysis. For comparison, previous OH-measurements using laser-induced resonance fluorescence[15] (Wang) and spin trapping[16] (Watanabe), and the photochemical model calculations (diurnal averages for July and October at mid-altitudes) of Crutzen[9] are shown.

erally lower, particularly for the only winter data point (F5). This discrepancy may be due to a longer photochemical lifetime or faster vertical transport. The latter may occur during strong convective events of deep penetration like a mid-latitude storm when vertical transport may eventually occur within about 1–3 days[11]. However, it seems unlikely that all of our measurements were influenced by such events. An additional potential cause for the observed discrepancy is local photochemical production of acetone by photooxidation of hydrocarbons. It has been proposed by Singh and Hanst[1] that acetone may be formed by photooxidation of propane through the reaction chain:

$$C_3H_8 \xrightarrow{OH} CH_3CHCH_3 \xrightarrow{O_2} CH_3(O)CH_3 \longrightarrow$$
$$\xrightarrow{NO} CH_3CH(O)CH_3 \xrightarrow{O_2} CH_3COCH_3 \qquad (1)$$

which is initiated by the OH-radical and also involves nitric oxide as a reactant. Propane is emitted at ground level mainly as a result of natural gas losses and biomass burning[12] and reaches the upper troposphere and even the lower stratosphere since it has a photochemical lifetime of about 6–12 days which is mainly determined by OH-attack. Propane measurements[12,13] give free tropospheric volume mixing ratios at middle latitudes of about 50–1,000 p.p.t.v. (most values ranging between 100 and 300 p.p.t.v.) and rapidly decreasing values above the tropopause. At ground level[13], propane volume mixing ratios range between about 600–1,000 p.p.t.v. at middle latitudes being substantially higher than the upper tropospheric average of about 120 p.p.t.v.. It is conceivable that photooxidation of other, possibly even more reactive atmospheric hydrocarbons may contribute to the formation of acetone. In the stratosphere, the situation is different. Here vertical mixing becomes much slower having a typical timescale[10] of 100–200 days km^{-1} which is much longer than the photochemical lifetime of acetone. Therefore, the acetone concentration may be determined by local photochemical production and destruction by photolysis. However, here only relatively long-lived hydrocarbons like propane serve as potential precursors. Considering only photooxidation of propane one obtains the following continuity equation:

$$[C_3H_8]k[OH] = (CH_3)_2CO]\,J^{-1} \qquad (2)$$

Taking stratospheric propane volume mixing ratios as measured by Rudolph and Ehhalt[12], an OH-reaction coefficient k of $1.82\times10^{-11}\exp(-675/T)$ $cm^3\,s^{-1}$ as measured by Darnall and coworkers[14], and OH concentrations for summer conditions at middle latitudes as given by the theoretical model of Crutzen[9] (see Fig. 2, curve Jul), one obtains a photochemical equilibrium volume mixing ratio profile as shown in Fig. 1*b*. It is in reasonably good agreement with our stratospheric data. However, this agreement may be fortuitous since substantial temporal and spatial variations of lower stratospheric propane abundances may occur. Combined measurements of acetone and propane at the same time and location are required to investigate the local photochemical acetone production.

Finally, we consider the potential role of acetone as a tracer for hydroxyl radicals. In conditions where local photochemical equilibrium is established, which may be the case in the lower stratosphere, combined measurements of acetone and propane may allow to estimate the OH-concentration by applying the continuity equation (2). To illustrate the kind of information, which may be obtained, we have inferred the quantity RJ/k ($R=((CH_3)_2CO)/(C_3H_8)$), which should be equal to the OH-concentration (diurnal average) for local photochemical equilibrium conditions, from our data using propane volume mixing ratios as above (same as those taken for calculating the theoretical curve in Fig. 2). Resulting stratospheric RJ/k values are given in Fig. 3 along with published OH-measurements previously made in the tropopause region using laser-induced fluorescence[15] (only measurements with no O_3-interference are included) and spin trapping[16]. While our data represent diurnal averages, the above previous data were obtained during daytime, mostly at large solar elevations. As OH should be absent during the nightime, diurnal average values should be smaller than daytime values by about a factor of two to three. Considering this fact, our inferred values are roughly consistent with previous data. Theoretical model calculations (diurnal averages) by Crutzen[9] are also shown in Fig. 2.

We thank E. E. Ferguson, D. Ehhalt, P. Crutzen, and R. Chatfield for helpful discussions. Support by the technical staffs of the Max-Planck-Institut für Kernphysik, in particular K. Oberfrank and W. Dann, and of the Deutsche Forschungs- und Versuchsanstalt für Luft- und Raumfahrt (Flugbereitschaft) is gratefully appreciated. Part of this project was funded by the Bundesministerium für Forschung und Technologie through Gesellschaft für Strahlen- und Umweltforschung.

Precipitation scavenging of aerosol particles over remote marine regions

There is increasing evidence that the deposition of atmospheric particulate material has a significant influence on the chemistry of trace elements in many oceanic regions[1–4]. One significant but unknown parameter is the efficiency of in-cloud and below-cloud scavenging processes as a function of aerosol particle size. Studies in continental regions have indicated that the largest particles are scavenged most efficiently by rain[5]. We report here, for the first time, an evaluation of particle scavenging by tropical showers, based on data obtained at Eniwetok Atoll and American Samoa in the tropical Pacific Ocean. We find no clear evidence of a particle size dependence for scavenging in this remote marine region. This indicates that estimates of global atmospheric deposition over the ocean based on extrapolation of measurements made on land may be invalid.

Because of the regional variability of both the atmospheric and oceanic cycles of some trace elements, especially trace metals, an assessment of the impact on ocean chemistry of the deposition of atmospheric particulate material from natural or man-made sources must go beyond simple estimates of global mass balances. The need for accurate data on net air-to-sea particulate fluxes requires a precise assessment of the importance of both dry and wet deposition processes. Such data are extremely difficult to obtain, especially over remote marine regions.

Wet deposition appears to be the dominant removal process for particulate material from the remote marine atmosphere[3,6]: there is thus a need to understand how the concentrations of trace elements in rain are related to their concentrations in the atmosphere. The investigation of the relationship between particle size and scavenging efficiency over remote marine areas is of crucial importance, because the various sources contributing to the marine atmospheric burden of particulate trace elements generate aerosol particles with different mass-size functions.

The data reported here were obtained during the SEAREX Program experiments in 1979 at Eniwetok Atoll (11°20′ N, 162°20′ E) in the Marshall Islands, and in 1981 at American Samoa (14°15′ S, 170°34′ W). Both sites are >5,000 km from the nearest continent. Trade-wind rain-shower and atmospheric particulate samples were collected from the top of an 18-m-high tower on the windward shore of the islands. Samples were collected only during sustained on-shore winds, using ultra-clean procedures. Rain was collected on an event basis, whereas aerosol particle samples were generally collected over 2–5 days. Two different data sets are presented here which allow us to investigate the precipitation scavenging efficiency for aerosol particles as a function of particle size.

The first data set[4,7] consists of results of chemical analyses of 14 pairs of rain and air samples for trace elements at Eniwetok Atoll. These samples were analysed by neutron activation analysis and atomic absorption spectrometry. The air samples were obtained with high-volume cascade impactors, which separate aerosol particles into six different size ranges. Because the elements analysed are partitioned differently among particles of different size[7], we can examine the dependence of element concentrations in rain and air on aerosol particle size. Elements have been characterized by the mass median diameter (MMD) of the particles containing them. Although the aerosol samples were collected over intervals of several days, whereas the rain samples represent aerosol scavenging on a timescale of minutes to hours, the aerosol trace-metal size distributions were found to be quite consistent over a period of several months at Eniwetok. Comparison of rain and aerosol chemistry is thus justified.

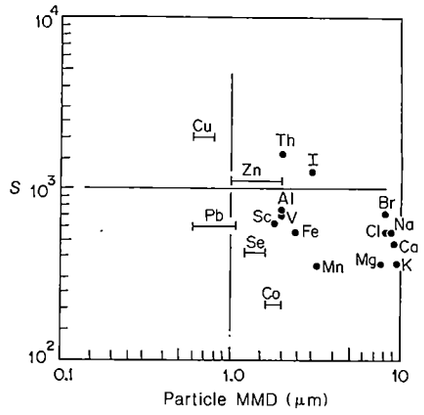

Fig. 1 Scavenging ratio, S, plotted against marine airborne particle size (mass median diameter) for various trace elements at Eniwetok Atoll.

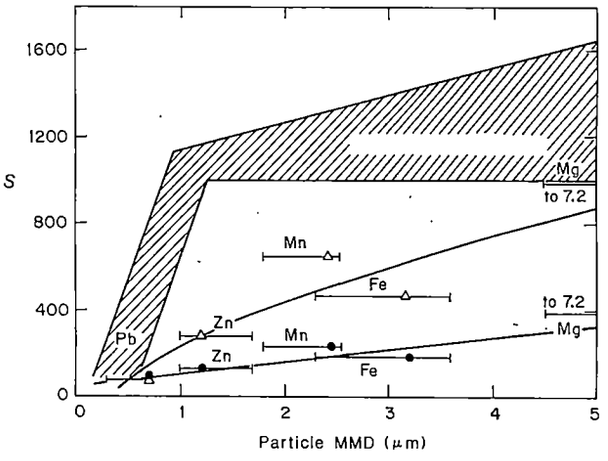

Fig. 2 Scavenging ratio, S, plotted against particle size for various trace elements in urban areas (adapted from ref. 5). The shaded area indicates the relationship observed in Chilton, UK[10]; the solid lines are for two sites near St Louis, USA[9].

The second data set[8] was obtained by means of scanning-electron-microscopic examinations of individual aluminosilicate dust particles in air and rain samples at Eniwetok and American Samoa. Such particles are nearly insoluble in rain water; therefore, these data should provide a direct estimate of wet removal efficiencies as a function of particle size.

The precipitation scavenging efficiency for a given substance is commonly expressed as a dimensionless number, the scavenging ratio (or washout factor) S, given by $S = C_{rain}\,\rho / C_{air}$, where C_{rain} is the concentration in rain in g kg^{-1}, C_{air} is the concentration in air in g m^{-3} and ρ is the density of air (1.2 kg m^{-3}) at standard conditions.

In Fig. 1, the mean scavenging ratios for elements in rain samples from trade-wind showers at Eniwetok Atoll are plotted against the mass median diameter of the aerosol particles containing them. There is no statistically significant correlation between scavenging ratio and particle size ($r = -0.39$, not significant at $P = 0.1$). This result is corroborated by the data

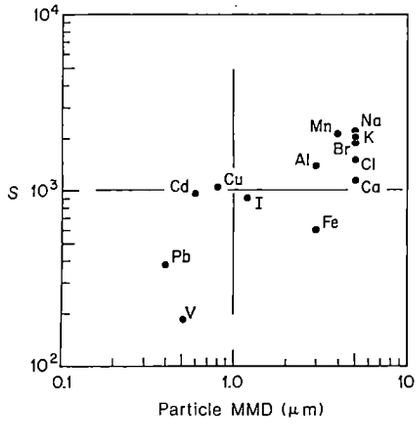

Fig. 3 Scavenging ratio, S, plotted against particle size for various trace elements in the Florida Keys (adapted from ref. 11).

Table 1 Scavenging ratios for mineral aerosols, Eniwetok and American Samoa

Particle diameter (μm)	S
0.1–0.5	940 ± 1,100
0.5–1	800 ± 620
1.0–1.5	500*
1.5–3	310 ± 250
3.0–6	270 ± 170
6–15	320 ± 120

Scavenging ratio S is given as arithmetic mean $\pm 1\sigma$, based on five air samples and three rain samples. Details of the particle counting statistics can be found in ref. 8. 100–400 particles were examined from each sample. The size distributions were found to be log-normal. Scavenging ratios were then calculated from the idealized log-normal distributions of the particles in air and rain samples. The stated uncertainties relate only to the variability of the particle size distribution from one sample to another.

* Assumed value (see text).

presented in Table 1 for aluminosilicate particles collected at Eniwetok and American Samoa, which show no statistical difference (at the 1σ level) among the values of S for the different size fractions. The data presented in this table indicate only the relative variation in S, because the data have been normalized to $S = 500$ for aerosol particles in the size range 1–1.5 μm.

If what we have observed is representative of the trade-wind regime, it can be inferred that over tropical marine areas the elemental concentration ratios in near-surface air and rain may be similar. This conclusion may also apply to the westerlies regime of the South Pacific, as indicated by recent analyses of individual aluminosilicate particles in air and rain samples collected during the SEAREX Program experiment in 1983 at Ninety-Mile Beach, New Zealand (P.B.-M., unpublished data).

The results presented here, which are to our knowledge the first of this type obtained over remote marine regions, contrast markedly with data obtained over continental and coastal areas. For example, Scott[5] has shown that S increases with MMD for metals collected in St Louis[9], USA, and Chilton, UK[10] (Fig. 2), and Duce *et al.*[11] have found similar results in the Florida Keys (Fig. 3) ($r = 0.76$, significant at $P = 0.01$). These results may be explained by the lower collection efficiency of raindrops for the smaller particles (down to perhaps a few tenths of a micrometre in radius) present over the continents[5,12]. These authors also note that differing chemical properties, particularly the solubility, of particles of different size may also play a role. Over remote marine regions, the absence of a particle size dependence of scavenging ratios is as yet unexplained. Slinn[12] has suggested that in truly remote marine regions, where there are relatively few cloud condensation nuclei (<200 cm^{-3}), essentially all particles are activated in clouds regardless of their size or chemical composition. This suggestion deserves further investigation, but there are other possible causes which might explain the results reported here.

Indeed, it can be argued that such a continental–marine comparison should result in differences, because for a given element the vertical distribution of its atmospheric concentration may be quite different over land from that over the sea. For example, elements (such as sodium) associated with atmospheric sea-salt particles exhibit a marked negative concentration gradient between the sea surface and the top of the marine boundary layer[13,14], whereas such a gradient is much less pronounced or non-existent over land. The reverse is generally observed for materials attached to aerosol particles over the ocean which are derived from land-surface sources[14,15]. Such differences in vertical distribution may generate large uncertainties in the calculation of S, because S values are estimated from near-surface air concentrations, which can be quite different from those at the altitude of cloud scavenging. However, such uncertainties should affect S values similarly for materials during their atmospheric transport from land to sea or from sea to land. That this is not observed is clear from Figs 1–3, which show that for elements derived from continental sources the shift of S values from continental or coastal regions to remote oceanic areas is not uniform for a given element, and seems to be related to the mass–size distribution of the element. Indeed, this shift is much more pronounced for elements (such as aluminium) attached to large aerosol particles than for those (such as lead) attached to smaller aerosol particles.

Another possible cause for the continental–marine difference is related to precipitation patterns over land and sea. Differences in the vertical and horizontal extent of cloud systems and in the duration, intensity and droplet size of the precipitation will certainly affect the precipitation scavenging efficiency of aerosol particles and the relationship between S and the mass–size distribution of the materials associated with these particles. As shown by Scott[5], large variations in S can be expected at different latitudes. For example, smaller scavenging ratios would be expected in 'cold clouds', where a much greater fraction of the precipitation occurs as a result of vapour-phase growth rather than droplet coalescence. The latter apparently dominates in 'warm' rains, that is, those not containing ice particles or supercooled droplets. This obviously implies that our limited data set may not apply to high-latitude oceanic areas.

The data presented here suggest strongly that the particle-size-dependent rain scavenging relationships observed in continental regions do not apply in tropical marine regions, where precipitation is often dominated by trade-wind showers. These apparent differences in scavenging processes must be evaluated more fully before accurate models can be made of the wet deposition of aerosol trace constituents into the ocean. Such modelling will become increasingly necessary in response to the growing interest in the use of new oceanic tracers[16,17], especially those (such as heavy metals) which are derived from aeolian inputs of anthropogenic origin.

Calcium-free pumpellyite, a new synthetic hydrous Mg–Al-silicate formed at high pressures

W. Schreyer, W. V. Maresch, O. Medenbach & T. Baller

Institut für Mineralogie, Ruhr-Universität Bochum, D-4630 Bochum, FRG

The mineral pumpellyite, $W_4X_2Y_4Z_6O_{(20+t)}(OH)_{(8-t)}$ where W = Ca, Mn; X = (Mg, Fe^{2+}, Mn)$_{2-t}$ (Fe^{3+}, Al)$_t$; Y = Fe^{3+}, Al; Z = Si (ref. 1) is a well-known constituent of very low-grade metamorphic rocks, especially of metabasic compositions. Schiffmann and Liou[2] have synthesized the ideal Fe-free endmember 'Mg–Al' pumpellyite', $Ca_4MgAl_5Si_6O_{21}(OH)_7$, and found its upper thermal stability to lie near 375–400 °C in the range of 5–8 kbar water pressure. Here we report the high-pressure synthesis of a pumpellyite-type phase in which the position W of the above formula is solely occupied by magnesium. This 'Mg–Mg–Al pumpellyite', which is chemically nearly equivalent to pyrope + H_2O, crystallizes at 40–55 kbar, 700–850 °C. Therefore, it qualifies as a potential hydrous mantle phase in a subduction zone regime.

During a recent high-pressure investigation of the system $MgO-Al_2O_3-SiO_2-H_2O$ (MASH) aimed at synthesizing a Ti-free ellenbergerite[3], reflections were encountered in the powder X-ray diffraction pattern that did not fit any of the known crystalline phases of the MASH system, nor could they be related to an ellenbergerite variety. In a run with a gel of the composition $4MgO \cdot 2Al_2O_3 \cdot 5SiO_2$ plus excess water at 700 °C, 50 kbar water pressure, for 5 days, these unknown peaks became dominant, while only small amounts of talc could be identified in addition. A comparison of the unknown peaks with those of potentially related silicate phases suggested a pumpellyite-type crystal structure. This was confirmed by successful indexing of more than 40 observed reflections below 70° 2θ CuKα, on the basis of a monoclinic cell. The refined cell dimensions, using an internal *F*-phlogopite standard, are given in Table 1. Observed diffraction data for the most prominent reflections of the new phase to a *d*-spacing of 2,000 are given in Table 2. Compared with the synthetic Ca-bearing 'Mg–Al pumpellyite' of Schiffmann and Liou[2], also listed in Table 1, the unit cell volume of the synthetic Ca-free phase is ~9% smaller. Under the microscope, the new phase forms small tabular crystals (4 × 10 × 40 μm) with negative elongation for all orientations. The refractive indices listed in Table 1 are appreciably higher than those of the synthetic Ca-bearing phase.

The crystal structure of pumpellyite[4,5] has Ca in sevenfold coordination with respect to oxygen and relatively short Ca—O distances of ~2.43 Å. Following the straightforward rule of increasing coordination number with pressure, it is most likely that, at the high pressure of synthesis, Mg is able to substitute for Ca in the sevenfold positions. Thus a general formula of the synthetic MASH pumpellyite can be expected to be

$$Mg_4(Mg_{2-t}Al_t)Al_4Si_6O_{20+t}(OH)_{8-t}$$

Since t can vary only between zero and 2, we can define the following theoretical compositions of Ca-free pumpellyites, which are here called 'Mg–Mg–Al pumpellyites':

Pu 1: $Mg_4Mg_2Al_4Si_6O_{20}(OH)_8$ (for $t = 0$)

Pu 2: $Mg_4(MgAl)Al_4Si_6O_{21}(OH)_7$ (for $t = 1$)

Pu 3: $Mg_4Al_2Al_4Si_6O_{22}(OH)_6$ (for $t = 2$)

In Fig. 1, these three compositions are plotted in the MAS compositional triangle and connected through the line of mutual theoretical substitution Mg + H = Al. Note that in this projection Pu 1 plots together with pyrope, $Mg_3Al_2Si_3O_{12}$. Pu 2 and 3 can be represented, for example, by the three-phase assemblage pyrope + SiO_2 + Al_2SiO_5.

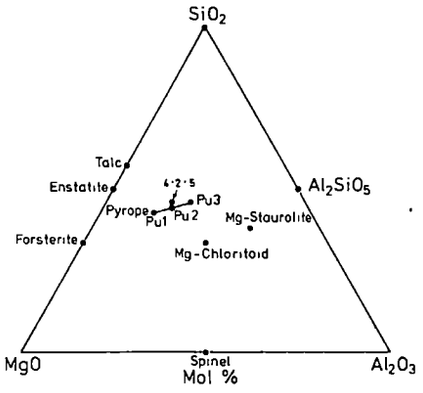

Fig. 1 Projection from H_2O of the $MgO-Al_2O_3-SiO_2-H_2O$ system, showing the possible extent of solid solution of the Ca-free pumpellyite phase (Pu 1 to Pu 3), as well as the bulk composition 4:2:5 of the critical run discussed in the text.

Figure 1 also shows the projection point of the gel composition 4:2:5 used as starting material for the successful synthesis. This composition lies very close to the theoretical 'Mg–Mg–Al pumpellyite' Pu 2. Indeed, the observed products of synthesis, 'Mg–Mg–Al pumpellyite' plus small amounts of talc, seem to indicate that this new pumpellyite phase has a composition close to that of Pu 2 and may even be identical to it. Note that in the system $CaO-MgO-Al_2O_3-SiO_2-H_2O$, 100% yield of Mg–Al pumpellyite could only be achieved with a bulk composition having $t = 1$ as in Pu 2 (ref. 2).

No reliable information is available as to the thermodynamic pressure/temperature (P/T) stability of the new pumpellyite-type phase. In other MASH synthesis runs at 40 kbar/700 °C, some of the characteristic X-ray powder diffraction lines were discerned as well. In addition, these reflections were observed, together with others, in chemically similar mixtures of the system $MgO-BeO-Al_2O_3-SiO_2-H_2O$ run in the P/T range 45–55 kbar, 700–850 °C (ref. 6). Nevertheless, all these products could be metastable. Seeded runs are required to resolve this problem.

The geoscientific importance of the high-pressure synthesis reported here lies in the fact that 'Mg–Mg–Al pumpellyite' is, as a first approximation, chemically equivalent to pyrope garnet + water. As this garnet is one of the minerals making up the Earth's mantle at depths ≥60–80 km, the question arises as to whether or not this garnet can be replaced in the mantle

material by the new pumpellyite phase, provided water is available and the temperatures are sufficiently low for hydration. If 'Mg-Ag-Al pumpellyite' were stable, for example, at 40 kbar and 800 °C, this phase could be a constituent of a mantle plate which is being subducted along a low geothermal gradient of ~7.5 °C km^{-1} to ~120 km. Such low geothermal gradients and subduction to at least 100 km were recently inferred even for crustal rocks[7]. The water required for the formation of the pumpellyite phase would be readily available in the serpentinized upper portions of an oceanic mantle. This model becomes even more attractive when one considers the possibility of solid solution in the pumpellyite phase, involving both Mg and Ca in the W-position of the structure, with concomitant stabilization towards lower water pressures. The new phase is also of interest in relation to a series of hydrous synthetic high-pressure phases in the system MgO-SiO_2-H_2O (refs 8, 9) which have largely unknown structures, and are also discussed as possible receptacles of water in the Earth's mantle.

The recent breakthrough in our ability to detect the radioactive isotope ^{36}Cl (half-life $T_{1/2} = 301{,}000$ yr) at natural levels by accelerator mass spectrometry[1] allows the processes of salination of water systems to be studied in a new way by distinguishing the chloride content originating in young rainwaters and their subsequent evaporation from that generated by the leaching of ancient rocks. Results for the Jordan River/Dead Sea system show that the amount of chloride leached from rocks ranges from ~70% in source springs to >90% in water bodies downstream. Furthermore, the amount of water left after evaporation decreases from ~50% in the source springs to 20% in the intermediate Lake Kinneret. In the terminal Dead Sea, 99% of the stable chloride originates from ancient rocks and evaporite formations while ~80% of its ^{36}Cl content is of meteoric origin. Using ^{36}Cl measurements, we estimate the accumulation time of the Dead Sea salt to be 19,000–25,000 yr.

Meteoric ^{36}Cl enters the hydrological cycle together with stable chloride from aerosols when they are both washed out of the atmosphere by precipitation. The evaporation and evapotranspiration (through vegetation) of surface and soil water, which follow soon after, are not expected to alter significantly the chlorine isotopic ratio, although they increase the chloride concentration. In contrast, the addition of chloride leached from rocks with a ^{36}Cl/Cl ratio generally much lower than that of precipitation, reduces this isotopic ratio. The chloride concentration is further increased by the evaporation which occurs in rivers and lakes after ground water emerges in springs.

It is extremely difficult to distinguish between the processes of evaporation (including evapotranspiration) and of rock leaching by means of standard hydrological methods, as both processes result in concentration increases. But independent measurement of ^{36}Cl/Cl ratios and of stable chloride concentrations permit the quantitative determination of the extent to which each of the two processes has occurred in a given system.

We denote the chloride concentration of a water body and of precipitation by C_W and C_P, respectively (in mg l^{-1}), their respective ^{36}Cl/Cl ratios as R_W and R_P, and the ^{36}Cl/Cl ratio in the rock leachate by R_L. The fraction of the total chloride in the water body which originated in the rock leachate is then given by:

$$f_L = (1 - R_W/R_P)/(1 - R_L/R_P) \quad (1)$$

The evaporation factor (EF), defined as the ratio of the volume of the water body to the volume of the precipitation from which it originated, may then be calculated from:

$$EF = (C_P/C_W)/(1 - f_L) \quad (2)$$

These equations demonstrate how the processes of evaporation and rock chloride addition may be distinguished by measuring the quantities C_P, C_W, R_P, R_W and R_L. If $R_L/R_P \ll 1$ (as expected in leachates of old rocks), equation (1) reduces to $f_L = 1 - R_W/R_P$.

¶ Rock salt core.

The physical meaning of the above equations is illustrated in Fig. 1. In the case of a closed system (no evaporation), all analytical results plotted in the $^{36}Cl/Cl$ versus (1/Cl) plane fall on a straight line PL. The value of the rock leachate fraction f_L determines the location of a given point on the line. Evaporation will shift a point horizontally to the left of the line PL by an amount related to the evaporation factor EF. Any additional source of ^{36}Cl (such as ^{36}Cl from the nuclear test pulse) will shift results of measurements in the vertical direction above the line PL.

The estimation of the salt accumulation age in a water body from ^{36}Cl measurements was first attempted by Bonner *et al.*[2]. This age t(yr) satisfies the equation:

$$N_{36} = \frac{I_{36}}{\lambda}(1 - e^{-\lambda t}) \qquad (3)$$

where λ(yr^{-1}) is the decay constant, N_{36} the total number of ^{36}Cl atoms present in the water body and I_{36} the annual input of this isotope. We assume that the amount of salt precipitated from the water is negligible. If the water body, as is often the case with saline lakes, receives in addition to the ordinary observable chloride input a significant sub-lacustrine input (from springs emerging below the lake surface and hence difficult to observe) of chloride originating from the leaching of old rocks, then the salt accumulation time of the water body may be determined by combining its ^{36}Cl balance with its stable chloride balance, even if the only information known about the sub-lacustrine source is its $^{36}Cl/Cl$ ratio. In this case, the annual ^{36}Cl input to the water can be shown to be the sum of two components: the annual ^{36}Cl input of meteoric origin and that of rock leachate origin. The accumulation age then satisfies the following equation:

$$N_{36} = C_W V_W R_W = \frac{Q_I C_I (R_I - R_L) + C_W V_W R_L / t}{\lambda}(1 - e^{-\lambda t}) \qquad (4)$$

where Q is the annual water discharge, V the water body volume, the subscript 'I' designates the input to the water body and the other symbols are as defined above.

To illustrate these applications of ^{36}Cl as a hydrological tracer, we consider the waters of the Jordan River/Dead Sea systems. This system (Fig. 2) is located in the northern part of the Syro-African rift and is composed primarily of the upper Jordan river,

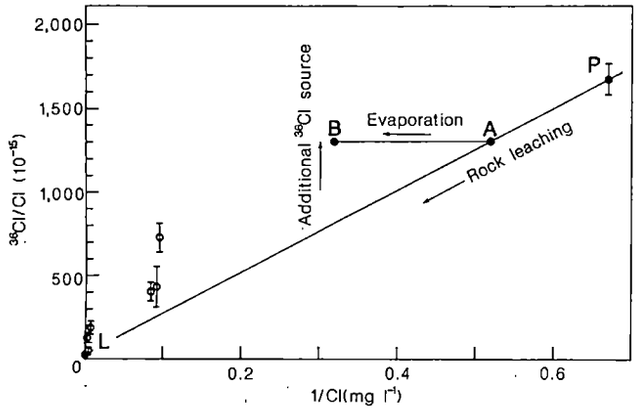

Fig. 1 Variation of the ^{36}Cl/Cl isotopic ratio versus the reciprocal (1/Cl) of the stable chloride concentration and schematic representation of different effects on the isotopic ratio. The straight line PL represents a hypothetical closed system (no evaporation) in which all samples are admixtures of precipitation (P) and rock leachate (L); as the latter contribution increases, the result moves down along line PL (A). Line AB reflects the effect of evaporation, which does not change the ^{36}Cl/Cl ratio. Results may lie above the line also due to an additional source of ^{36}Cl (for example, the ^{36}Cl nuclear test pulse). Also shown are results of measurements (open circles and vertical bars) for the Jordan River/Dead Sea system. The fact that all data points lie above the mixing line is mostly explained by evaporation processes (see text).

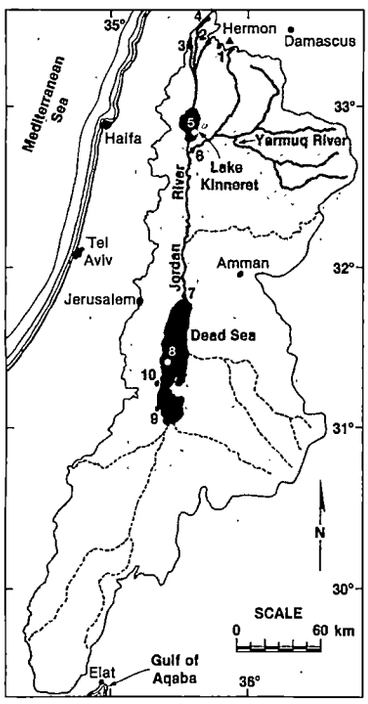

Fig. 2 Map showing the Jordan River/Dead Sea catchment basin (light shading) and the localities (numbered 1-10) sampled for ^{36}Cl measurements. The sample locations and their numbers are listed in Table 1.

Lake Kinneret, the Yarmuq river, the lower Jordan river and the Dead Sea terminal lake. The three important tributaries of the upper Jordan river—the Dan, Snir and Banias rivers—arise as springs which derive their waters from precipitation on Mount Hermon, with an underground residence time of a few years[3]. These waters collect large quantities of salt from the many saline springs that enter the system during their flow to the Dead Sea. This extremely saline lake acquired its present shape about 15,000 yr ago[4] as a result of the shrinking of its less saline predecessor, Lake Lisan. This 15,000 yr age is distinct from the

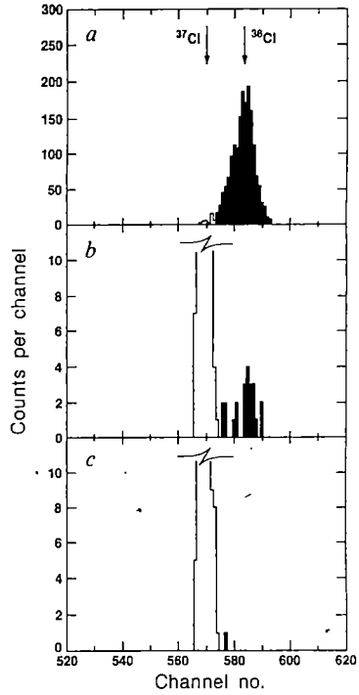

Fig. 3 Identification spectra of chlorine ions for: *a*, reference sample with ^{36}Cl/Cl = 3.5×10^{-12}; *b*, Dead Sea water; *c*, rock salt from Mount Sedom. The spectra were obtained after a software filtering of events to reject background (^{36}S isobaric and contaminant) ions. ^{37}Cl ions shown result from a tail of ^{37}Cl$^-$ injected into the accelerator. They are further discriminated from ^{36}Cl ions by time-of-flight measurements. See ref. 5 for details of the identification scheme.

age of the salt, discussed below. The high salinity of the Dead Sea results partly from intense evaporation and accumulation of the salt discharged by the Jordan River and smaller rivers, and partly from extremely saline springs which emerge at the lake shore and at its bottom.

The water samples on which the present study is based were collected from the localities indicated in Fig. 2. After removing SO_4^{2-} ions with Ba^{2+}, Cl^- was precipitated with Ag^+ and purified by dissolution in NH_3 before the final reprecipitation as AgCl. The ^{36}Cl/Cl ratio was measured using the accelerator mass spectrometry system set up at the Rehovot 14UD Pelletron tandem laboratory[5]. Figure 3 shows examples of ^{36}Cl spectra. The stable chloride concentrations in the same water samples were determined by titration with $AgNO_3$.

The results of our measurements are shown in Table 1 and Fig. 4. The consistent downstream decrease in ^{36}Cl/Cl in Fig. 4*a* reflects the progressive dilution of the meteoric ^{36}Cl input, represented by the Mount Hermon snow sample, with the chloride leached from rocks. Samples representing essentially pure rock chloride, whose meteoric ^{36}Cl component is expected to be extinct, were obtained from materials near the Dead Sea: rock salt from an old formation (Mount Sedom) and brine from a hypersaline spring. These samples yielded the two lowest ^{36}Cl/Cl values in our measurements. These values are, however, higher than ratios determined in some old salt deposits[6]; they may result from natural radioactivity[6], but at such low levels, experimental effects such as cross-contamination during sample preparation or ion source operation cannot be excluded. The downstream increase in the ^{36}Cl concentration (Fig. 4*b*), is attributed to evaporation processes. This is also illustrated in Fig. 1 where, in agreement with important evaporation effects, all data points lie above the rock leachate-precipitation mixing line. Extensive evaporation and accumulation are believed to

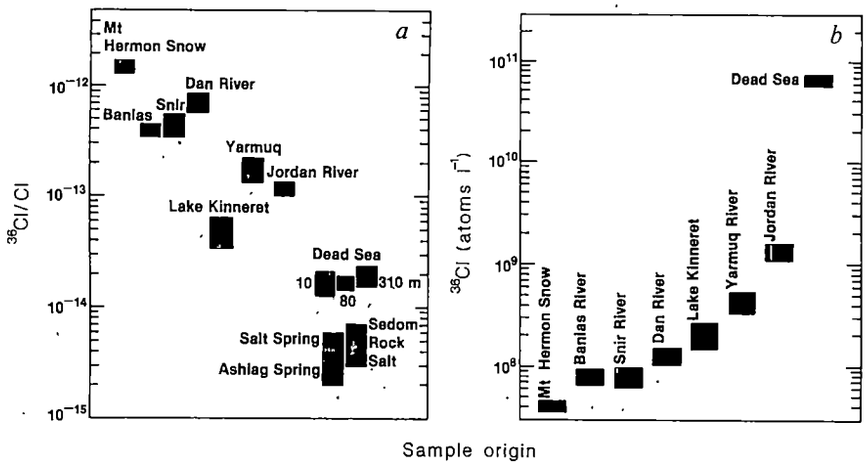

Fig. 4 Systematic variation of ^{36}Cl levels in waters from the Jordan River/Dead Sea system, arranged in downstream order. The distances along the horizontal axis are arbitrary. Also shown are a rock salt sample from a 2,000-m-deep core in the Mount Sedom area and a brine sample from the hypersaline Ashlag spring which is believed to be representative of the sub-lacustrine saline springs: *a*, ^{36}Cl/Cl isotopic ratios measured by accelerator mass spectrometry; *b*, ^{36}Cl concentrations in waters obtained from the ^{36}Cl/Cl ratios and measurements of the stable chloride concentrations. The monotonous downstream enrichment is attributed mainly to evaporation.

be responsible for the particularly high ^{36}Cl concentration in the terminal lake.

The rock leachate fraction f_L and the evaporation factor EF relative to Mount Hermon snow, calculated using equations (1) and (2), are shown for the various waters of the Jordan River/Dead Sea system in Table 1. The last column in Table 1 shows, for comparison, the available EF values obtained by hydrological methods[7]. Except for the Jordan River, the agreement between the two sets of estimates is surprisingly good. The agreement with independent measurements of the evaporation factors indicates that the additional ^{36}Cl source from the nuclear test pulse, known to have been important around 1960 (ref. 8), does not significantly affect our results. Substituting for example the hydrological estimates (EF(hydro.), Table 1) for Lake Kinneret and the Yarmuq River in equation (2), we derive expected values for the ^{36}Cl/Cl ratio of 38×10^{-15} and 108×10^{-15} respectively, only marginally different from the measured values, considering the uncertainties in the ^{36}Cl/Cl and EF(hydro.) values. The discrepancy for the case of the Jordan River may be due in part to such a contribution but is most probably caused also by an increase of evaporation following the great reduction in the flow of the Jordan river (presently <10% of the 1964 flow)which has resulted from the diversion of both Lake Kinneret and Yarmuq River waters for irrigation purposes.

The considerable amount of chloride contributed by rocks, even in the very dilute Jordan river tributaries, could not have been determined previously because it was not possible to distinguish between the effects of evaporation and of rock chloride addition. The relatively high evaporation factors for these tributaries are almost entirely caused by evapotranspiration, whereas the much lower values for the Yarmuq River must result from the intense evaporation which occurs along the long desert route between its source and the sampling point. Finally, the high rock leachate fraction for both Lake Kinneret and the Dead Sea undoubtedly reflect the well-known salt contributions by sub-lacustrine springs[9]. Note that an added advantage of the present method of determining the rock leachate fraction and the evaporation factor over the standard hydrological methods is that the former can be applied to any element of a river system and related directly to precipitation without making any measurements on other water bodies in the system.

Turning now to the determination of the salt accumulation age of the Dead Sea, we first use equation (3). But, as explained above, because of man-made changes in the hydrological system, the ^{36}Cl input of the natural system before 1964 cannot be directly measured. The annual ^{36}Cl input ($I_{36}=3.9\times10^{20}$ ^{36}Cl atoms yr^{-1}) may be estimated using the annual rainfall over the entire Dead Sea basin (9.8×10^{12} l yr^{-1}, ref. 7) and the ^{36}Cl concentration measured in the Mount Hermon snow (Table 1), assuming that it is representative of the whole basin. The number of ^{36}Cl atoms in the Dead Sea, as calculated by the expression $N_{36}=V_W C_W R_W$, is 9.4×10^{24} ^{36}Cl atoms, using both the Dead Sea volume ($V_W=1.43\times10^{14}$ l, ref. 10) and our measured Cl concentration and ^{36}Cl/Cl ratio (Table 1). The accumulation time of ^{36}Cl in the Dead Sea thus obtained is 25,000 yr. A value of 20,000 yr is obtained if one uses actual measured contributions of the two main inputs, Lake Kinneret and the Yarmuq River (0.5×10^{12} and 0.44×10^{12} l yr^{-1}, respectively, ref. 7) to estimate the annual ^{36}Cl input; to these contributions we added the annual ^{36}Cl input from precipitations over the rest of the basin (5.1×10^{12} l yr^{-1}, ref. 7), estimated as was done above for the entire basin.

The above calculations assume that the sub-Dead Sea saline springs derive their salt from very old deposits ($R_L=0$). If we assume that the measured ^{36}Cl/Cl value of 4.5×10^{-15} in Ashlag Spring and Mount Sedom (Table 1) is a representative value of the rock leachate fraction, we obtain, solving equation (4) by iteration, a range of slightly lower accumulation ages, 19,000–21,000 yr. For this calculation, an effective value of the ^{36}Cl/Cl ratio of the input waters from the various sources ($R_I=35$–44×10^{-15}) was derived by dividing the annual ^{36}Cl input, estimated above, by the Cl discharge (using $Q_I=1.4\times10^{12}$ l yr^{-1}, ref. 7 and $C_I=474$ mg l^{-1}, ref. 10). This range of R_I values, lower than the ^{36}Cl/Cl values measured in Lake Kinneret and the Yarmuq River, shows the effect of the known important salt addition in the lower Jordan River basin. The ratio of the ^{36}Cl contributions from meteoric input to that of rock leachate in the total ^{36}Cl content of the Dead Sea water can be estimated to be ~4:1 by using equation (4) and the calculated accumulation age. The contribution of the increase in the ^{36}Cl content of the atmosphere during the nuclear test period[8] is quite small compared with the amount of ^{36}Cl accumulated in the Dead Sea. The correction to the above accumulation times can be estimated by using the measured integral ^{36}Cl bomb pulse[8] to be ~500 yr. Furthermore, the contribution of ^{36}Cl produced by the capture of cosmic-ray neutrons by ^{35}Cl in the Dead Sea can be shown to be negligible.

Note that the present ages, although not very much higher than the 12,100 yr geochemical age derived by Bentor[10], were obtained without making any assumptions as to the detailed chemical nature of the saline springs. A comparison of these age estimates with the ~15,000 yr age of the present Dead Sea basin[4] may indicate that some of the salt now in the Dead Sea was inherited from its predecessor Lake Lisan.

Phosphate pumps and shuttles in the Black Sea

Gary Shaffer

Oceanographic Institute, University of Gothenburg, Box 4038, 400 40 Gothenburg, Sweden

Phosphate distributions in oxic–anoxic ocean basins are related to distributions of total oxygen consumed (mainly from free oxygen, nitrate and sulphate) in the decomposition of organic matter[1,2]. Data from the Black Sea show, however, that phosphate concentrations immediately above and below the redox front are considerably lower and higher, respectively, than would be predicted from such stoichiometric models. This implies extra sinks and/or sources of phosphate and/or total oxygen not associated with organic decomposition. Here, I present two physical–biogeochemical interactions that result in phosphate sinks and sources with the structure needed to explain the observed phosphate anomalies. A phosphate pump based on iron can account for up to 40% of the required sink–source strength. The rest may be caused by a phosphate shuttle based on manganese.

The salinity, temperature, PO_4^{3-}, NO_3^-, O_2, H_2S, Fe^{2+} and Mn^{2+} data analysed here originated from cruise 49 of RV *Atlantis II* in March and April 1969 (refs 3, 4). I chose 18 stations which had a good coverage of the Black Sea and good sampling depth and salinity data. All PO_4^{3-} and sample depth data from these stations have been plotted as functions of salinity (Fig. 1) and fitted with least-mean-square B-splines[5]. The splines, plotted against each other, yield a pseudo-mean distribution with depth ($\overline{PO_4}$, Fig. 2). This procedure is superior to conventional depth averaging[6] or depth averaging relative to an oxygen zero boundary[4,7]. It averages over isopycnal surfaces, where the salinity determines the density below the Black Sea surface layer, and thus should retain maximum information on mean 'vertical' structure[8]. Indeed, the $\overline{PO_4}$ minimum/maximum pair (Fig. 2) reflects a similar structure from detailed, individual PO_4^{3-} profiles from this data set[6,9].

Phosphate distribution can be calculated from organic decomposition, $(PO_4)_{exp}$ (Fig. 2) and be expressed as

$$(PO_4)_{exp} = a\Delta O_2 + b\Delta NO_3 + c\Delta SO_4 + (PO_4)_p \qquad (1)$$

where $\Delta O_2 = O_2(\text{saturation}) - \overline{O_2}$, $\Delta NO_3 = d\Delta O_2 + (NO_3)_p - \overline{NO_3}$, and $\Delta SO_4 = \overline{H_2S}$. The subscript 'p' refers to preformed substances[1,2]. Here the concentrations of $(NO_3)_p$ and $(PO_4)_p$ are 0 and 0.15 μmol l^{-1} respectively. Pseudo-mean distributions are determined as above and a–d are $(138)^{-1}$, $(85)^{-1}$, $(53)^{-1}$ and $(8.6)^{-1}$, respectively[2]. $(PO_4)_{exp}$ over-estimates $(PO_4)_{ox}$ (a 'true' PO_4^{3-} distribution from organic decomposition) above L, the O_2–H_2S boundary (Fig. 2) and under-estimates it below this boundary. In the present-day Black Sea nearly all H_2S-S produced during sulphate reduction below L should reappear, after advection, diffusion and a series of intermediate oxidation steps, as SO_4^{2-}-S above L. This implies extra O_2 and H_2S consumption, above and below L, respectively, without concurrent PO_4^{3-} release. A $(PO_4)_{ox}$ distribution (Fig. 2) based on estimates of this extra O_2 consumption and $(PO_4)_{ox} \rightarrow \overline{PO_4}$ away from L, underlines some inherent weaknesses in using only chemical data. With a knowledge of diapycnal advection and diffusion, rates could be calculated and a stoichiometric model applied directly to them[8]. The large phosphate anomaly dipole pivoted near the O_2–H_2S boundary in the Black Sea, however, needs extra sinks and sources of PO_4^{3-} to be explained.

Iron-oxyhydroxo-phosphates (FeOP) form in oxidizing conditions ($Eh > \sim 200$ mV) and dissolve in reducing conditions ($Eh < \sim 200$ mV)[10,11]. Any combination of physical processes which lead to a net transport of such particles down through the redox front and Fe^{2+} and PO_4^{3-} ions back up through it, would produce an extra sink–source pair for PO_4^{3-} of the type needed to explain the observed anomaly dipole. Two possible cycles containing such combinations are the phosphate pump and the phosphate shuttle (Fig. 3). In the pump, vertical isopycnal displacements sweep the redox front back and forth across a sea-bottom segment B. During the release phase (shallow redoxocline) PO_4^{3-} and Fe^{2+} leave B as FeOP dissolves. Some Fe^{2+} reprecipitates as iron sulphide (FeS). During the retention phase (deep redoxocline) FeS dissolves and FeOP forms on B. PO_4^{3-} is adsorbed from the water column and the pore water. Increased upward diffusion of PO_4^{3-} (caused by its enhanced vertical gradients) closes the cycle. Thus, baroclinic motions near the coast pump PO_4^{3-} down through the O_2–H_2S boundary in oxic–anoxic basins. In the shuttle, Fe^{2+} is advected and diffused up through the redox front to form FeOP, thereby adsorbing PO_4^{3-}. FeOP particles sink through the front, dissolve, and release PO_4^{3-}. Again increased diffusion closes the cycle.

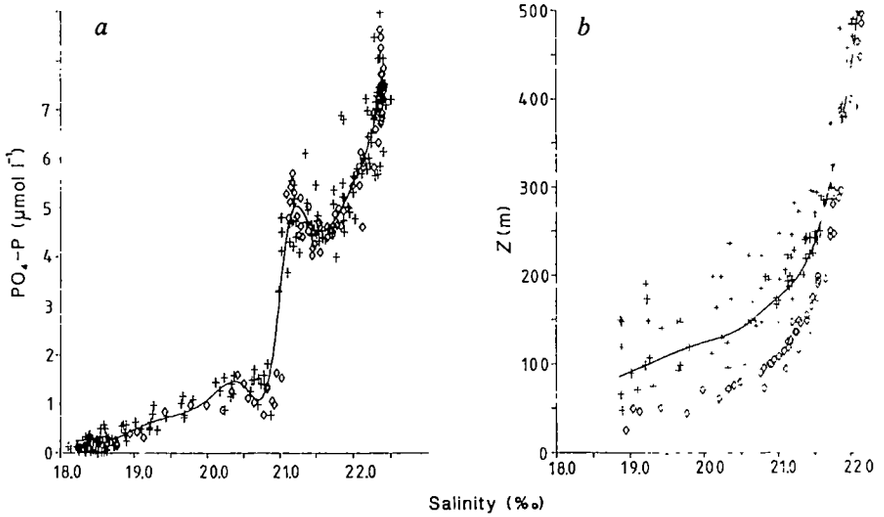

Fig. 1 Phosphate-phosphorus (a) and water sample depth (b) plotted against salinity for 18 stations of the *Atlantic II* cruise 49 to the Black Sea, March–April 1969 (ref. 3). The open sea stations (◇) are numbers 1445, 1446, 1447, 1466, and 1468. The shelf stations (+, water depth <1,800 m) are numbers 1435, 1437, 1439, 1441, 1443, 1447, 1450, 1452, 1454, 1461, 1470, 1473 and 1476. Least mean square B-spline fits[5] are shown for data from all 18 stations. For the water sample depths linear interpolation in salinity space[8] was applied to individual stations before B-spline fitting.

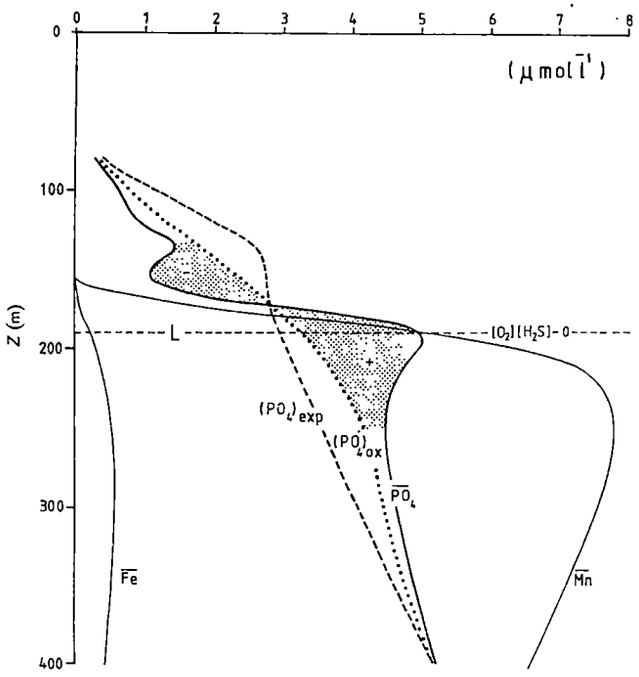

Fig. 2 Pseudo-mean distribution of phosphate-phosphorus with depth, $\overline{PO_4}$, formed by plotting the B-splines in Fig. 1 against each other. This procedure should retain a maximum of 'real' mean vertical structure and gradients. Analogous distributions are shown for dissolved manganese, $\overline{Mn}$, and iron, $\overline{Fe}$, from data of stations 1435, 1439, 1445, 1446, 1452, 1461, 1464 and 1466 (ref. 4). The zero oxygen and hydrogen sulphide concentration level, L, is indicated (taken from $\overline{O_2}$ and $\overline{H_2S}$ distributions calculated as $\overline{PO_4}$ above). Also presented is the phosphate-phosphorus distribution expected from organic decomposition alone, $(PO_4)_{exp}$, as calculated from equation (2). $(PO_4)_{ox}$ is $(PO_4)_{exp}$ 'corrected' for extra O_2 consumption as described in the text. The phosphate anomaly dipole, shaded, is defined by $(PO_4)_{ox}$-$\overline{PO_4}$.

The strength of the extra PO_4^{3-} sinks and sources, $|Q_{PO_4}|$, can be estimated from

$$Q_{PO_4} \approx Ak\mathrm{d}(PO_4)_{anom}/\mathrm{d}z \qquad (2)$$

where A, the cross-sectional area, k, the vertical turbulent diffusion coefficient and the vertical gradient of $(PO_4)_{anom}$ $[=(PO_4)_{ox}-\overline{PO_4}]$; all are evaluated at the $(PO_4)_{ox}$, $\overline{PO_4}$) intersection near level L (Fig. 2). There, $A \approx 3.0\times10^{11}$ m^2 (ref. 12) and $\mathrm{d}(PO_4)_{anom}/\mathrm{d}z \approx 9\times10^{-2}$ mmol m^{-4} (Fig. 2). Previous estimates[4,7] of k of 1.4×10^{-6} m^2 s^{-1} in the Black Sea halocline are probably in error. Salt conservation requires that the vertical velocity, w, be much greater than the w used to obtain this estimate: A salty (35‰) inflow of 190 km^3 yr^{-1} (refs 4, 13) must entrain much 18.5-22.0‰ ambient water before becoming 22.0-22.4‰ deep water; a six to ninefold increase in volume transport (and in the w and k estimates) is implied. Although a constant w and k, one-dimensional model[4,7] is probably not a good one for a system like the Black Sea, for example, entrainment and decreasing cross-section with depth imply a large increase in w with depth, a k from a salt space method can be estimated[14,15] which agrees with the new k above and thus the value $k=1\times10^{-5}$ m^2 s^{-1} is adopted here; then $|Q_{PO_4}| \approx 2.3\times10^{10}$ mmol PO_4^{3-} day^{-1}. A mean cycling time, τ, for PO_4^{3-} ions around the anomaly dipole may be estimated by $|RQ^{-1}_{PO_4}|$ where R is the mean total PO_4^{3-} anomaly. From Fig. 2, $R \approx 1.5\times10^{13}$ mmol and thus, $\tau \approx$ 2 yr. A τ of ~500 yr results for the cycle PO_4^{3-} uptake by phytoplankton followed by PO_4^{3-} regeneration in the deep water.

Isopycnal displacements near the Black Sea coast may be caused by upwelling/downwelling[14], coastal-trapped waves[16] and seasonal changes of the mean circulation[17]. The r.m.s. displacement near level L from these processes may be ~30 m, which implies a typical bottom area swept by the phosphate pump of $\sim1.5\times10^{10}$ m^2 (Fig. 3 and ref. 12) and mean retention-release rates for PO_4^{3-} bound with Fe oxyhydroxides of ~1.5 mmol m^{-2} day^{-1} to explain the anomaly dipole by the pump. Retention-release rates of 0.7-1.5 mmol m^{-2} day^{-1} have been obtained in benthic chamber experiments meant to simulate redox turnovers[18,19]. Such high retention rates, however,

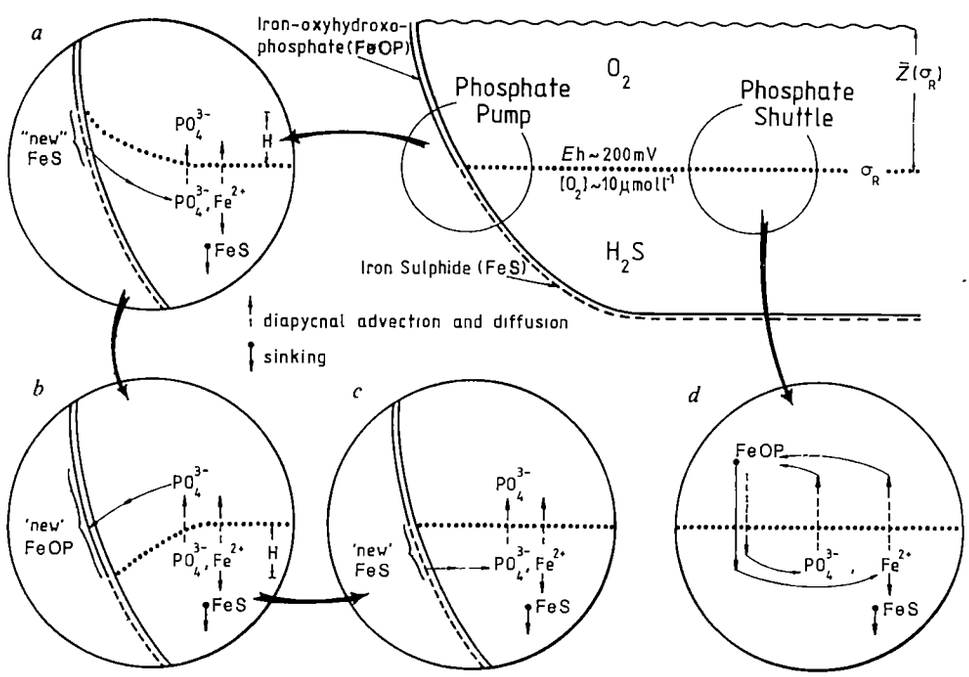

Fig. 3 The basic situation shown in the upper right hand corner is a basin with oxygen in the surface water and hydrogen sulphide in the deep water. The redox front between these two layers is represented by an isopycnal surface σ_R with mean depth $\bar{Z}$, chosen to coincide with $Eh\sim$ 200 mV, the approximate potential of the Fe^{2+}-Fe^{3+} redox pair. Iron-oxyhydroxo-phosphate (FeOP) and iron sulphide (FeS) are found at the sediment surface in contact with the upper and lower layer respectively. In the phosphate pump, isopycnal displacements sweep back and forth across a segment of sea bottom between depths $\bar{Z} \pm H$. The release and retention phases for PO_4^{3-} are illustrated by insets *a*, *c* and *b*, respectively. The + and − anomalies for PO_4^{3-} should have comparable vertical scales, ~2*H*. In the text, it is argued that the efficiency of the pump is limited by its retention phase, also, since some Fe^{2+} is continually lost to the deep anoxic bottoms with FeS, new Fe from runoff is needed to keep the pump primed. In the phosphate shuttle (*d*), the vertical scales of the + and − anomalies depend on the balance between diapycnal advection and mixing and speeds of sedimentation and chemical reactions. Thus, these scales should differ.

were observed at water column $PO_4^{3-} \sim 10$ times greater than the Black Sea ones and in artificial flow conditions. Some PO_4^{3-} retention in the sediment is caused by adsorption from the water column. A likely maximum rate for this would be $D\,[PO_4^{3-}]\,\delta^{-1}$ where D is a molecular diffusion coefficient, $[PO_4^{3-}]$ is the water column PO_4^{3-} and δ is the thickness of the diffusive sublayer at the sediment/water interface. With $D \sim 6\times10^{10}$ m^2 s^{-1} (ref. 20, $T \sim 8$ °C), $[PO_4^{3-}] \sim 2$ μmol l^{-1} and $\delta \sim 2\times10^{-4}$ m (ref. 21, large flow velocities), this rate is ~ 0.5 mmol m^2 day^{-1}. The rest of PO_4^{3-} retention is caused by direct adsorption of PO_4^{3-} released in the sediment during organic decomposition. An estimate of the sedimentation rate of organic P is $[w(PO_4)_{ox} + k\,d(PO_4)_{ox}/dz]_L$ from a physical transport-production balance. With k as before, $[(PO_4)_{ox}, d(PO_4)_{ox}/dz]_L$ from Fig. 2 and $w = 1.2\times10^{-7}$ m s^{-1} in accordance with the discussion earlier, this rate is ~ 0.06 mmol m^{-2} day^{-1}. Thus the efficiency of the phosphate pump seems to be limited by its retention phase and the pump can only explain up to 40% of the Black Sea PO_4^{3-} anomaly dipole.

The strength of the Fe^{2+} sink resulting from precipitation above level L may be estimated from

$$Q_{Fe} \approx A[w\overline{Fe} + k\,d(\overline{Fe})/dz]_L \qquad (3)$$

With A, w, k as above and $[\overline{Fe}]_L$ from Fig. 2, $Q_{Fe} \approx 2\times10^9$ mmol Fe day^{-1}. Thus $Q_{Fe}|Q_{PO_4}|^{-1} < 0.1$ and a phosphate shuttle based on iron probably makes no significant contribution to the observed PO_4^{3-} anomalies. Concentrations of dissolved manganese are ~ 10 times greater than those of iron in the Black Sea (Fig. 2) caused by the greater solubility of Mn salts in reducing conditions[4]. From a calculation like equation (3), $Q_{Mn} \approx 5.2\times10^{10}$ mmol Mn day^{-1} and $Q_{Mn}|Q_{PO_4}|^{-1} \approx 2.3$. Note that, from equations (2) and (3), $\overline{Fe}$ and $\overline{Mn}$, the Q ratios above are insensitive to choices of w and k.

I suggest that manganese, like iron, forms oxyhydroxophosphate and that a shuttle based on Mn explains the rest of the PO_4^{3-} anomaly dipole. This would require a P/Mn ratio of at least 0.3 in the Mn precipitate observed above level L in the Black Sea[22]. The hypothesis is supported by the $\overline{Mn}$, $\overline{Po_4}$ and $(PO_4)_{ox}$ distributions (Fig. 2) which indicate good spatial correlations between Mn^{2+} and extra PO_4^{3-} sinks and sources. For both ions, the scale of the source layer is apparently greater than that of the sink layer. This is consistent with the shuttle scenario (Fig. 3). Also, the PO_4^{3-} anomalies appear more pronounced for open Black Sea stations (Fig. 1), and may indicate an open sea process. The $\overline{PO_4}$ distribution (Fig. 2) and our w and k imply an order of magnitude weaker PO_4^{3-} sink directly below the PO_4 maximum. This has been attributed to bacterial chemosynthesis[7].

Similar large PO_4^{3-} anomalies near the O_2–H_2S zone have been observed elsewhere, for example, in Lake Nitinat[2]. The processes presented here probably also explain these observations, and detailed sampling should reveal similar PO_4^{3-} anomaly dipoles in most other oxic–anoxic basins. Finally, observational and theoretical searches for other possible important effects should be carried out, for instance, on denitrification and sulphate reduction rates, of redox front bottom sweeping due to coastal dynamics. After all, such physical processes not only expose the sediment surface to cyclic changes of O_2 and H_2S concentrations but also may alter the diffusive sublayer thickness in a systematic way through associated currents.

I thank David Dyrssen for help with the data and literature search and for discussions. This research was supported by grants from the geoscience division of the Swedish Natural Science Research Council.

Mechanosensitivity of mammalian auditory hair cells *in vitro*

I. J. Russell, G. P. Richardson & A. R. Cody

MRC Neurophysiology Group, School of Biology, University of Sussex, Falmer, Brighton BN1 9QG, UK

Intracellular responses recorded *in vitro* from the cochleas of anaesthetized mammals have shown that the mechanoreceptive inner and outer hair cells are sharply tuned, accounting for many of the properties of the afferent fibres in the auditory nerve[1–4]. However, *in vivo* it has not been possible to measure directly the excitatory mechanical input to these cells (the displacement of their mechanosensitive stereocilia)[5,6] and thus to determine the relationship between the receptor potentials and displacement of their stereocilia. As a means of circumventing this technical difficulty, we have developed an organ culture of the mouse cochlea and here we describe the receptor potentials generated by the hair cells in response to direct displacement of their stereocilia.

Cochleas were dissected from mice at days 1–3 postnatal. The capsules surrounding the cochleas, stria vascularis and Reissner's membranes were removed and the organs of Corti, together with the spiral ganglia, were cultured for 2–7 days at 37 °C on collagen-coated coverslips in Maximow slide assemblies using a method similar to that described by Sobkowitz *et al.*[7]. Figure 1*a*, *b* shows the morphology of the hair cells in these *in vitro* preparations. Figure 2 shows the arrangement for making intracellular recordings from the hair cells while displacing their stereocilia. The resting membrane potentials of inner hair cells, outer hair cells and supporting cells measured *in vitro* in HEPES-buffered HBSS (Hanks' balanced salt solution) are very similar to those found *in vivo* for the cells of the guinea pig cochlea: −30 to −70 mV for inner hair cells, −40 to −70 mV for outer hair cells and −60 to −75 mV for supporting cells. In contrast to the situation *in vivo*, there is no endocochlear potential in these cultures and the abneural surfaces of the hair cells are exposed to an ionic environment whose dominant cation is sodium rather than potassium.

In the absence of mechanical stimulation, the resting membrane potentials of the hair cells were remarkably constant and did not exhibit the oscillatory behaviour characteristic of hair cells in the turtle cochlea and frog sacculus[8,9]. The voltage responses of inner and outer hair cells from the same region of the mouse cochlea to sinusoidal displacement of their stereocilia (Fig. 3*a*, *b*) were very similar in shape to those recorded from hair cells in isolated preparations from other species (for example, bullfrog sacculus[5]). The transfer functions in Fig. 3*c*, *d* show that in response to depolarizing displacements of their stereocilia towards the kinocilium, the responses of the inner

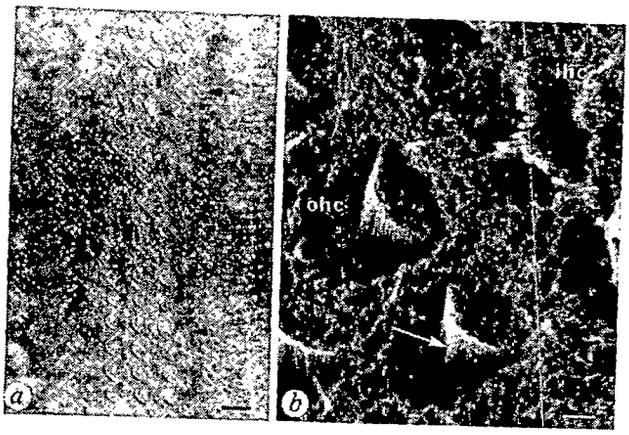

Fig. 1 *a*, Surface view of a 4-day-old culture of a mouse cochlea viewed using Nomarski optics. The stereocilia of the three rows of outer hair cells are clearly visible. The position of the single row of inner hair cells is marked by the arrowheads. The stereocilia of the inner hair cells are positioned slightly higher than those of the outer hair cells and are out of focus in this photomicrograph. The stereocilia of the inner hair cells form palisades while those of the outer hair cells form V-shapes whose internal angles become increasingly acute towards the basal high-frequency turn of the organ of Corti. Scale bar, 10 μm. *b*, Scanning electron micrograph of a 2-day-old organ culture of the mouse organ of Corti, showing the arrangement of the mechanically sensitive stereocilia of the inner (ihc) and outer (ohc) hair cells. The cells still possess a vestigial kinocilium (arrow) which is lost later in development. In scanning electron micrographs the bundles of stereocilia have the appearance of bundles of organ pipes as each row decreases in height with distance from the kinocilium. In these immature hair cells the stereocilia are more numerous than those found in the adult, and the microvilli on the apical surfaces of the intercalated supporting cells are more extensive. Scale bar, 1 μm.

Methods. Cultures were prepared from the cochleas of mice at days 1–3 postnatal. The cartilaginous capsule, stria vascularis, Reissner's membrane and the immature mesenchymal internal spiral lamina were removed by dissection in HEPES-buffered HBSS, leaving the organ of Corti, greater epithelial ridge and attached spiral ganglion as one unit. These tissue pieces were then explanted onto collagen-coated round glass coverslips, fed with ~50 μl of complete medium (8 parts Eagle's minimum essential medium with Earle's salts, 1 part heat-inactivated horse serum, 1 part mouse embryo extract buffered with 10 mM HEPES *p*H 7.2) and maintained in Maximow slide assemblies in the lying drop position at 37 °C for up to 7 days. For scanning electron microscopy the cultures were fixed in 5% glutaraldehyde in 0.1 M sodium phosphate, *p*H 7.2, for 2 h at room temperature, post-fixed in 1% OsO_4, dehydrated in acetone, dried to the critical point from liquid CO_2, sputter-coated with gold and viewed with a Jeol 100C scanning transmission electron microscope.

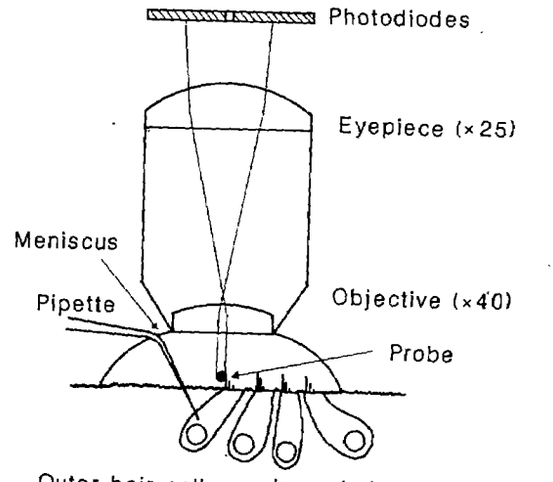

Fig. 2 For the electrophysiological experiments hair cells were maintained at room temperature (20 °C) and observed with the aid of a microscope equipped with a fixed stage, Nomarski optics and a ×40 water immersion lens. The stereocilia of the hair cells were displaced with the tip of a fine glass probe (0.5–1.5 μm diameter) along their axis of greatest sensitivity, that is, towards and away from the kinocilium in a plane parallel to the cuticular plate[17]. The probe was attached to a piezoelectric driver constructed from a short length of Vernitron bimorph (type PZT-5B). The displacement of the tip of the probe was monitored according to a method described elsewhere[18]. With the preparation illuminated in bright field from a battery-driven light source, the secondary image of the microscope was projected onto a screen by a ×25 eyepiece fitted to a trinocular head stage. The focused image of the tip of the probe was adjusted until it was ~0.5 mm wide and thus filled about half the width of a double photodiode array (2×0.5 mm; Centronics Ltd 2–5) mounted at the centre of the screen. The differences between the photocurrents of the two photodiodes was proportional to the displacement of the probe tip over the range 1–500 nm. The absolute displacement of the tip was determined as described by Art *et al.*[19]. The position of the photodiode array (which was mounted on a micropositioner) was adjusted until the difference in photocurrents was zero; the photodiode array was then displaced by a known amount (1–10 μm) and the photocurrent measured. The same photocurrent would have been measured if the tip had been displaced by this amount divided by the magnification of the optical system (~×1,000). Glass micropipettes (resistance 120–300 MΩ) were bent at right angles 200–250 μm from their tips, filled with 4 M potassium acetate, and inserted into the hair cells close to the nucleus. When stable recording conditions were achieved, the vibrating probe was placed against the stereocilia and the static position of the probe adjusted until a maximum response was obtained for a displacement of ~50 nm.

and outer hair cells are about three times greater than the hyperpolarizing and strongly saturating responses to displacements in the opposite direction. In this respect, the receptor potentials of hair cells in the mouse cochlea *in vitro* are similar to the receptor potentials recorded *in vivo* for hair cells from the apical, low-frequency turns of the guinea pig cochlea in response to tones close to their most sensitive frequencies; they are also similar to receptor potentials recorded for inner hair cells from the basal turn in response to low-frequency tones[2,10,11]. They differ from the responses of outer hair cells, however, in the basal high-frequency turn of the guinea pig cochlea to very-low-frequency tones, where the receptor potentials are predominantly hyperpolarizing, except at high intensities when they become depolarizing[12]. We propose that the different transfer functions of outer hair cells in the basal turn of the guinea pig cochlea may result from their mechanical interaction with the tectorial membrane. In the *in vitro* preparations the tectorial membrane does not cover the hair cells because it has not grown over them by the stage at which the organs are explanted. Thus, in the *in vitro* preparation, the outer hair cells do not interact with the tectorial membrane.

Figure 3 shows that the receptor potentials of the outer hair cell saturate at a lower voltage than those of the inner hair cell. Results from a further five outer hair cells showed that the receptor potentials saturate in the depolarizing direction at a mean of 6.5 mV (s.d. = 1.4 mV) above resting membrane potential, while the responses of the inner hair cells studied always saturated at higher levels. Further experiments are needed to determine whether the lower saturating voltage levels in outer hair cells reflect smaller receptor currents. The transfer functions of the hair cells shown in Fig. 3 show that the inner hair cells are most sensitive to stereocilia displacements in the depolarizing direction over the 0–60-nm range whereas the outer hair cells are most sensitive over the 0–30-nm range. This measure of sensitivity and dynamic range is largely dependent on the coupling between the stimulus probe and the stereocilia and is

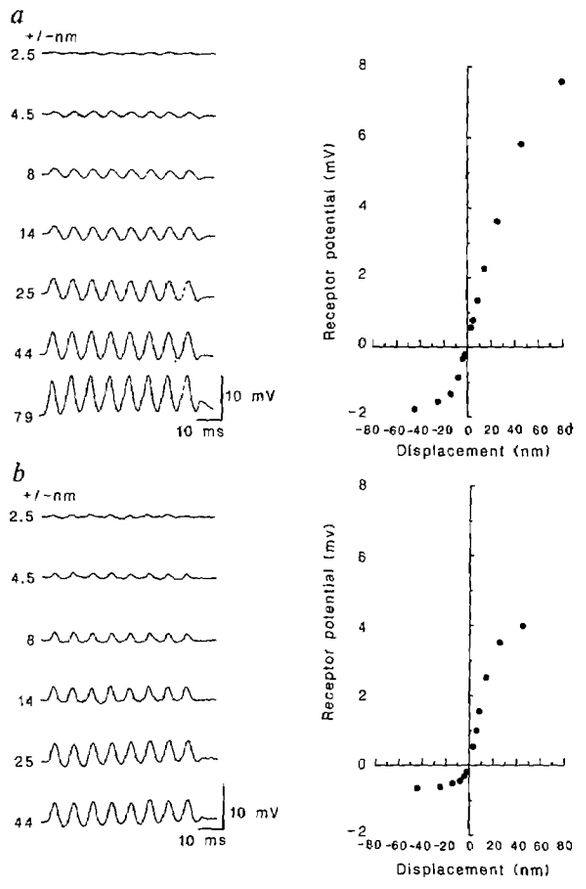

Fig. 3 Intracellular receptor potentials recorded from an inner hair cell (*a*) and an outer hair cell (*b*) from the apical low-frequency turn of the mouse cochlea *in vitro*, in response to sinusoidal displacements of their stereocilia. The peak amplitudes of the displacements are indicated alongside each trace. *c*, *d*, The relationship between peak displacement of the stereocilia and receptor potential for the inner hair cell and the outer hair cell, respectively.

not necessarily an indication that outer hair cells are more sensitive than inner hair cells. The stereocilia are at most 4 μm long, and it is difficult to determine the exact point of contact of the probe along the length of the stereocilia. Obviously, the angular rotation of the stereocilia will be greatest for a given displacement the closer it is to their points of attachment on the abneural surface of the hair cells.

The most sensitive cells recorded from the mouse cochlea *in vitro* are depolarized by ~0.8 mV (mean = 0.53, s.d. = 0.17, n = 18) when their stereocilia are displaced by 2 nm (Fig. 3*c*,*d*). The tallest hair-cell stereocilia in the *in vitro* preparations are 3–4 μm long. Thus the sensitivity of these hair cells is ~30 mV per degree of angular rotation of their stereocilia, or 0.4 mV per nm of displacement. This estimate of hair-cell sensitivity is considerably greater than that of hair cells in the frog sacculus (5–7 mV per μm), based on their responses to displacements of their stereocilia[5,9], but similar to estimates of hair-cell sensitivity reported for the turtle cochlea when the influence of the membrane resonance is disregarded (0.2 mV per nm)[13].

We have compared the mechanosensitivities of hair cells recorded *in vivo* in the basal turn of the guinea pig cochlea with those recorded from the mouse cochlea *in vitro*. Inner hair cells in the basal turn of the guinea pig cochlea are depolarized by 0.8–2 mV in response to tones close to their best frequencies at neural threshold[1]. At this sound level the basilar membrane displacement has been estimated to be ~0.1 nm[14]. In the intact cochlea the tips of the sterocilia are in contact with, or embedded in, the tectorial membrane and they are free to pivot about their bases[15]. This mechanical arrangement amplifies the rotational displacement of the stereocilium caused by the displacement of the basilar membrane by the ratio of the thickness of the organ of Corti to the stereocilium height which, in the basal turn of the guinea pig cochlea, is ~10 (ref. 16). Thus, at neural threshold the displacement of the stereocilia is probably ~1 nm. In comparing the mechanosensitivities of hair cells in the two preparations, it should be remembered that the driving voltage for the receptor current in hair cells recorded *in vivo* is about 2–3 times that of the hair cells *in vitro*, because the driving voltage is provided by the hair-cell membrane potential (−40 to −80 mV; refs 1, 11) and the endocochlear potential (+80 to +90 mV), producing a total of 120–170 mV in the guinea pig cochlea *in vivo*. In the mouse cochlea *in vitro*, the driving voltage is produced solely by the hair-cell membrane potential (−30 to −70 mV). Thus, the measurements of the sensitivity of inner hair cells in the mouse cochlea *in vitro* (0.4 mV per nm displacement of their stereocilia) are similar to the estimates of the mechanosensitivity of inner hair cells in the guinea pig cochlea *in vivo*, if the increased driving voltage due to the endocochlear potential is taken into account. In view of this finding, the *in vitro* preparation offers the opportunity for direct measurements of the electrical and mechanical properties of mammalian cochlear hair cells and for elucidation of the mechanisms of mechano-electrical transduction.

We thank Mrs E. M. Cowley, Mr D. Bowell and Dr J. Thorpe for technical assistance, and the MRC for support.

NMDA-receptor activation increases cytoplasmic calcium concentration in cultured spinal cord neurones

Amy B. MacDermott*§, Mark L. Mayer†, Gary L. Westbrook†, Stephen J. Smith‡ & Jeffery L. Barker†

Excitatory amino acids act via receptor subtypes in the mammalian central nervous system (CNS)[1–3]. The receptor selectively activated by *N*-methyl-D-aspartic acid (NMDA) has been best characterized using voltage-clamp and single-channel recording; the results suggest that NMDA receptors gate channels that are permeable to Na^+, K^+ and other monovalent cations[4–7]. Various experiments suggest that Ca^{2+} flux is also associated with the activation of excitatory amino-acid receptors on vertebrate neurones[8–11]. Whether Ca^{2+} enters through voltage-dependent Ca^{2+} channels or

§ Present address: Howard Hughes Medical Institute, Columbia University, CPS, 722 West 168th Street, New York, New York 10032, USA.

through excitatory amino-acid-activated channels of one or more subtype is unclear. Mg^{2+} can be used to distinguish NMDA-receptor-activated channels from voltage-dependent Ca^{2+} channels, because at micromolar concentrations Mg^{2+} has little effect on voltage-dependent Ca^{2+} channels[12] while it enters and blocks NMDA receptor channels[4,5,7,13,14]. Marked differences in the potency of other divalent cations acting as Ca^{2+} channel blockers compared with their action as NMDA antagonists also distinguish the NMDA channel from voltage-sensitive Ca^{2+} channels[5,7]. However, we now directly demonstrate that excitatory amino acids acting at NMDA receptors on spinal cord neurones increase the intracellular Ca^{2+} activity, measured using the indicator dye arsenazo III, and that this is the result of Ca^{2+} influx through NMDA receptor channels. Kainic acid (KA), which acts at another subtype of excitatory amino-acid receptor, was much less effective in triggering increases in intracellular free Ca^{2+}.

Experiments were performed using spinal cord neurones in dissociated cultures prepared from 13–14-day-old mouse embryos as described previously[5–7]. After 1–4 weeks in culture, whole-cell recording was performed using the patch-clamp technique[15] with a high-speed discontinuous voltage-clamp amplifier. The intracellular solution contained 0.8–1.5 mM arsenazo III dissolved in a conventional electrolyte solution for whole-cell recording (see Fig. 1 legend for details). The application of NMDA to spinal cord neurones voltage-clamped at −50 to −60 mV evoked an inward current accompanied by an increase in the intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) signalled by wavelength-specific changes in the absorbance of arsenazo III (Fig. 1). The inward current activated by NMDA was accompanied by an increase in variance (Fig. 1), and fluctuation analysis (not shown) had the properties characteristic of the 50-pS channel of mean open time 5–6 ms linked to NMDA receptors on mesencephalic, striatal and cerebellar cultured neurones[4,16]. Under the conditions of our experiments, NMDA-evoked increases in $[Ca^{2+}]_i$ similar to that shown in Fig. 1, were recorded in almost all neurones examined ($n = 29$).

In each neurone a depolarizing voltage jump, usually a step from −60 to 0 mV for 0.5–2 s, was used to induce Ca^{2+} influx through conventional voltage-regulated Ca^{2+} channels to check on the adequacy of the optical recording system before application of excitatory amino acids. Voltage-sensitive Ca^{2+} entry in spinal cord neurones, measured using arsenazo III, could be detected with command voltages as negative as −40 mV, depending on the duration of the step. The increase in $[Ca^{2+}]_i$ peaked near +10 mV, and declined in amplitude on further depolarization; at membrane potentials more positive than +80 mV Ca^{2+} entry was too small to measure. The similarity of the arsenazo III voltage–absorbance curve to the current–voltage relationship of neuronal Ca^{2+} currents[17] suggests good voltage-clamp control of the membrane area through which Ca^{2+} influx was measured. Such results are similar to those obtained in larger cells[18,19] and show that arsenazo III can be used to measure Ca^{2+} entry in mammalian spinal cord neurones.

Increases of $[Ca^{2+}]_i$ evoked by excitatory amino acids could be caused by either transmembrane influx of Ca^{2+} or release of Ca^{2+} from intracellular stores. For example, production of inositol trisphosphate ($InsP_3$), one of the second messengers known to stimulate intracellular Ca^{2+} mobilization[20], may increase in response to excitatory amino acids[21]. The fact that ion channels activated by excitatory amino acids allow influx of Na^+ provides another indirect mechanism for the increase in $[Ca^{2+}]_i$ induced by NMDA (that is, Na^+-stimulated Ca^{2+} release from mitochondria[22]). We used two procedures (Fig. 2) to demonstrate that transmembrane ion flux is necessary for the appearance of the arsenazo III signal evoked by NMDA, thus eliminating a major contribution by $InsP_3$ production to the elevation in $[Ca^{2+}]_i$ described here. Figure 2*a* shows the blockade by Mg^{2+} of both the inward current and the increase in $[Ca^{2+}]_i$ evoked by NMDA; as Mg^{2+} ions interfere with ion flux through the NMDA-receptor-activated channel[4,5,7,13,14], without

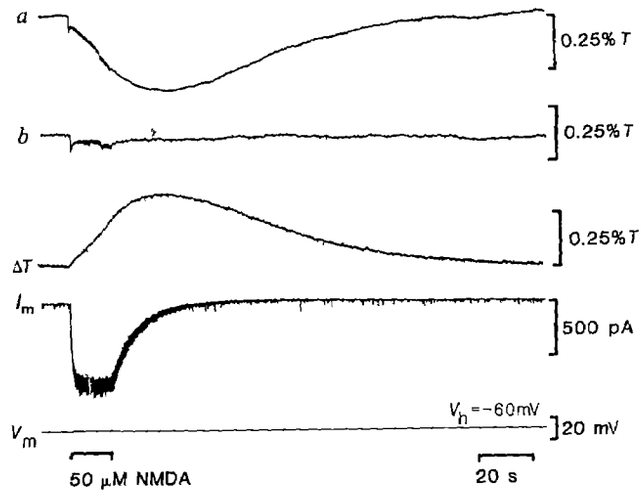

Fig. 1 NMDA increases $[Ca^{2+}]_i$, as measured with the metallochrome indicator dye arsenazo III in mouse spinal cord neurones under voltage clamp. Traces *a* and *b* show optical absorbance signals recorded simultaneously at wavelengths of: *a*, 660 nm (the wavelength at which changes in $[Ca^{2+}]$ evoke maximal increases in absorbance) and *b*, 570 nm (the isosbestic wavelength of arsenazo III, used to control for movement-related artefacts). Application of 50 μM NMDA reduced the transmittance at 660 nm but not at 570 nm, indicating an increase in $[Ca^{2+}]_i$. The trace labelled ΔT shows a differential record, obtained by subtracting the transmittance at 660 nm from that at 570 nm, and detects optical absorbance changes due to arsenazo III binding of Ca^{2+}; an upward deflection reflects an increase in $[Ca^{2+}]_i$. Small deflections in traces *a* and *b* are movement-related artefacts caused by pressure application (90 ms, ≤1 p.s.i., 3.6 Hz) of NMDA; these are subtracted in the third trace, the difference record. I_m, Membrane current; application of 50 μM NMDA evoked an inward current associated with a large increase in variance as described previously[4]. V_m, Membrane potential, voltage-clamped at −60 mV to prevent Ca^{2+} entry through voltage-gated calcium channels. The slow decay of the optical traces probably reflects sequestration and extrusion of calcium ions[19] and is typical of responses recorded using arsenazo III.

Methods. Experiments were performed on the stage of an inverted microscope. Light from a quartz halogen source was focused onto the cell body and an iris diaphragm used to select a field 50 μm in diameter; spinal cord neurones 15–20 μm in diameter were centred in this field for whole-cell recording using patch pipettes containing 0.8–1.5 mM arsenazo III. Light from the microscope objective was focused onto a diffraction grating and photodiodes used to measure the intensity at 570, 610, 660 and 700 nm. $[Ca^{2+}]_i$ signals were recorded differentially as 570–660 nm or 700–660 nm. The change in absorbance at 660 nm was greater than that at 610 nm, as expected for changes in $[Ca^{2+}]_i$ rather than intracellular *p*H. Records are calibrated as changes in transmittance (T) from the pre-stimulus baseline. Calibration of optical signals in terms of the underlying free calcium change was not attempted here, because of uncertainties as to dye behaviour in the cytoplasm, and difficulties in estimating the path length and stray light under our experimental conditions. The intracellular solution contained (in mM): 140 K-gluconate, 2 $MgCl_2$ and 10 HEPES titrated to *p*H 7.2 with KOH; sucrose was added to adjust the osmolarity to 310 mosM. In some experiments CsCl or $CsMeSO_3$ was substituted for K-gluconate. In addition, the intracellular solution usually contained 1.1 mM EGTA without or with 0.1 mM $CaCl_2$, but similar results were obtained with either no EGTA and no $CaCl_2$ (in this solution arsenazo III chelates residual free Ca^{2+} normally present in patch solutions) or with 5 mM EGTA plus 0.5 mM $CaCl_2$. The extracellular solution contained (in mM): 145 NaCl, 2.5 KCl, 2.5 $CaCl_2$, no added Mg^{2+}, 10 glucose, and 10 HEPES titrated to *p*H 7.3 with NaOH; sucrose was added to adjust the osmolarity to 325 mosM. Spontaneous activity and synaptic transmission were reduced by adding 1 μM tetrodotoxin. NMDA, KA and L-glutamic acid were applied to individual spinal cord neurones by miniperfusion using extracellular patch pipettes.

Experiments were performed at room temperature (25 °C).

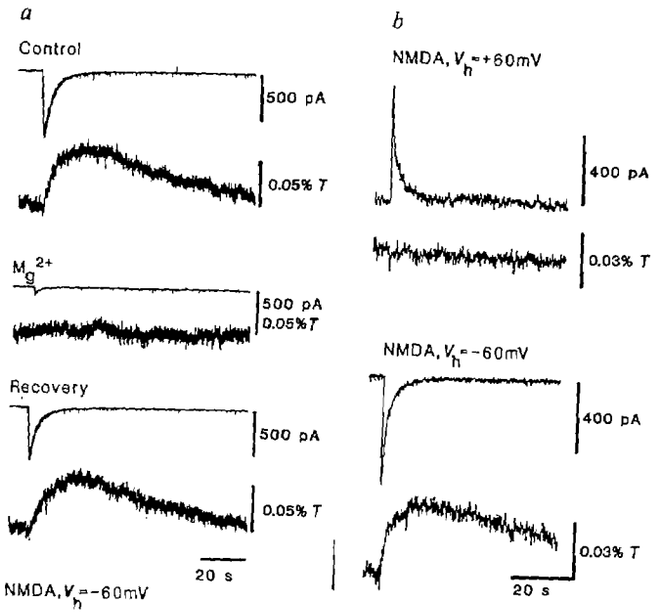

Fig. 2 Increases of $[Ca^{2+}]_i$ result from inward current flow through ion channels activated by NMDA. *a*, Reversible block by pressure application of Mg^{2+} of both the inward current and the increase in $[Ca^{2+}]_i$ evoked by brief application of NMDA (350 ms, 1 mM) to a spinal cord neurone voltage-clamped at −60 mV; an upward deflection represents an increase in $[Ca^{2+}]_i$. The fact that Mg^{2+} ions block the channels activated by NMDA, but do not interfere with agonist binding to the receptor, suggests that ion flux through the NMDA-receptor-activated channel is necessary for the increase in $[Ca^{2+}]_i$. $MgCl_2$ (10 mM) was dissolved in the bathing medium and applied from a patch pipette similar to that used to evoke NMDA responses; the actual concentration of Mg^{2+} at the membrane surface was unknown but dilution by the Mg^{2+}-free bathing medium is expected to have decreased the concentration below that in the pipette. *b*, Responses to pressure application of NMDA (110 ms, 1 mM) recorded at holding potentials of +60 mV and −60 mV (the NMDA reversal potential is ~0 mV); at +60 mV NMDA evokes outward current flow, with no change in $[Ca^{2+}]_i$, whereas at −60 mV NMDA evokes inward current flow associated with an increase in $[Ca^{2+}]_i$. NMDA evokes current flow of similar amplitude at both membrane potentials, suggesting that inward current flow through ion channels activated by NMDA is the source of the increase in $[Ca^{2+}]_i$.

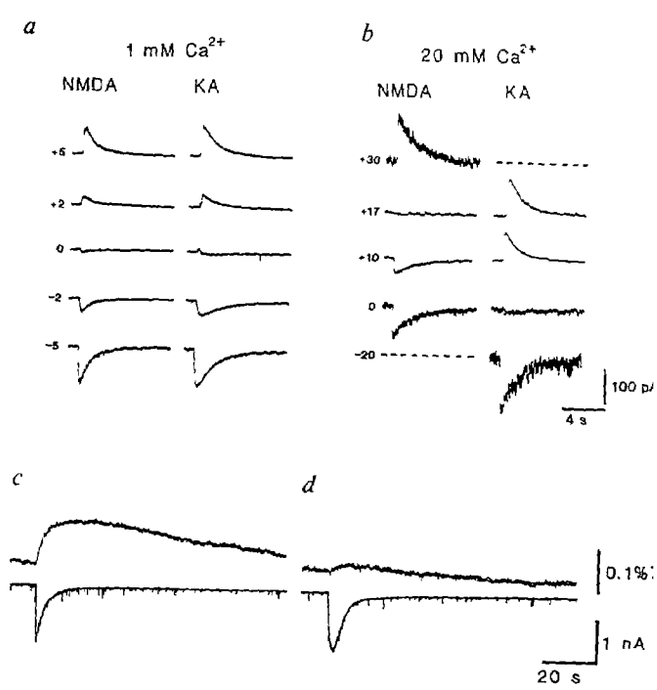

Fig. 3 Measurements of reversal potential suggest that NMDA channels are more permeable to Ca^{2+} than are KA channels. *a*, Current responses of one spinal cord neurone bathed in medium containing 1 mM Ca^{2+}, to pressure application of NMDA (60 ms, 1 mM) and KA (200 ms, 300 μM) as the membrane potential (under voltage clamp) was varied over the range −5 to +5 mV; the reversal potential of the response to both excitatory amino acids is close to 0 mV. *b*, Current responses of a second spinal cord neurone, bathed in medium containing 20 mM Ca^{2+}, to application of NMDA (90 ms, 1 mM) and KA (120 ms, 300 μM) as the membrane potential was varied over the range −20 to +30 mV. The reversal potential to NMDA is shifted to +17 mV, whereas reversal of the response to KA occurs at 0 mV. Assuming equal permeability (P) of monovalent cations through NMDA receptor channels, this result suggests that P_{Ca}/P_{Na} is ~5, which compares with a value of 0.22 for nicotinic acetylcholine receptor channels[33,34]. *c*, *d*, Optical measurements of $[Ca^{2+}]_i$ transients recorded from one spinal cord neurone bathed in medium containing 2.5 mM Ca^{2+} evoked by pressure application of NMDA (*c*: 200 ms, 1 mM) and KA (*d*: 70 ms, 100 μM); the responses were matched for similar peak inward current activation by each of the excitatory amino acids at a holding potential of −60 mV. Note that the increase in $[Ca^{2+}]_i$ evoked by NMDA is much greater than that evoked by KA, a result compatible with the interpretation of the measurements of reversal potential shown in *a* and *b*.

preventing agonist binding[23], this result suggests that $[Ca^{2+}]_i$ is increased by transmembrane ion flux through the NMDA-receptor-activated ion channels. L-Glutamate, a mixed agonist acting at NMDA receptors[2,6,7], also evoked Mg^{2+}-sensitive increases in $[Ca^{2+}]_i$. Figure 2*b* shows the responses to a constant dose of NMDA recorded at two membrane potentials; the inward current activated by NMDA at −60 mV was associated with an increase in $[Ca^{2+}]_i$, whereas the outward current activated by NMDA at +60 mV did not increase $[Ca^{2+}]_i$. In Mg^{2+}-free medium the NMDA current–voltage relationship was linear at membrane potentials more positive than −60 mV[4,5,7], and in the present experiments the increase in $[Ca^{2+}]_i$ evoked by constant doses of NMDA varied with the driving force for inward current over the membrane potential range 0 to −60 mV, suggesting that inward flux of Na^+ or Ca^{2+} through the ion channels opened by NMDA causes the increase in $[Ca^{2+}]_i$. At membrane potentials positive to +10 mV, NMDA did not induce increases in $[Ca^{2+}]_i$ detectable with arsenazo III. These experiments indicate that receptor activation *per se* is insufficient to account for the increase in $[Ca^{2+}]_i$ described here, and suggest that under our experimental conditions the production of $InsP_3$ does not play a major part in the response to excitatory amino acids. Our results do not by themselves exclude the possibility that Ca^{2+} or Na^+ influx through ion channels activated by NMDA triggers the intracellular release of Ca^{2+}, but the results presented below suggest that NMDA channels are indeed permeable to Ca^{2+}.

There is good evidence that the unitary properties of the ion channels linked to NMDA receptors are different from those linked to other excitatory amino-acid receptors in the vertebrate CNS[16,24]. To determine whether these ion channels show differences in their permeability to Ca^{2+}, we measured the reversal potential of responses to NMDA and KA with extracellular calcium concentrations ($[Ca^{2+}]_o$) of 1 and 20 mM (Fig. 3*a*, *b*). A depolarizing shift of the NMDA reversal potential on increasing the $[Ca^{2+}]_o$ provides direct evidence that NMDA channels have a measurable calcium permeability. In contrast, the reversal potential of responses evoked by KA showed little Ca^{2+} dependence. Recently, Ca^{2+} dependence of the NMDA reversal potential[25] has been confirmed using single-channel recording experiments[26]. Arsenazo III measurements also

differed between NMDA and KA (Fig. 3c, *d*), and in individual spinal cord neurones KA-evoked increases in $[Ca^{2+}]_i$ were always much smaller than those evoked by NMDA. These experiments suggest that Na^+ is a poor trigger for inducing an increase in $[Ca^{2+}]_i$, since in several neurones the inward (Na^+) current activated by KA produced no detectable arsenazo III signal. However, our results do not exclude the possibility that Ca^{2+} influx through ion channels activated by NMDA triggers release of Ca^{2+} from intracellular stores[27], contributing further to the NMDA-evoked arsenazo III signals reported here. Although the present results suggest a high Ca^{2+} permeability of NMDA-receptor-activated channels (Fig. 3), the net flux of monovalent cations (that is, conductance) decreases in the presence of Ca^{2+}. This reflects interactions between permeant ions within the channel with Ca^{2+} acting as both a permeant ion and as a blocker of monovalent cation flux[25,26,28].

The experiments reported here provide evidence for an agonist-triggered increase in $[Ca^{2+}]_i$ in mammalian spinal cord neurones. Previously, ion-sensitive microelectrodes were used to measure changes in intracellular ionic activity triggered by excitatory amino acids in frog motoneurones[9]. The latter experiments suggested an increase in both $[Na^+]_i$ and $[Ca^{2+}]_i$ during perfusion with L-glutamate but the results were difficult to interpret clearly as (1) neurones were not voltage-clamped and thus it is difficult to separate the relative contributions of Ca^{2+} influx via voltage-dependent calcium channels and agonist-activated channels, and (2) L-glutamate is a mixed agonist that acts at multiple subtypes of excitatory amino-acid receptor[2,6,7].

The response to NMDA-receptor activation thus provides a second source of calcium flux, distinct from that resulting from conventional voltage-dependent calcium channels, which may have important long-term effects on excitability. Our finding that the ion channels linked to the NMDA receptor subtype are more permeable to Ca^{2+} than those linked to KA receptors, has implications for the role of excitatory amino-acid receptors in CNS function. It is possible that Ca^{2+} influx activated by NMDA receptors underlies the synaptic plasticity generating long-term potentiation, as the latter is prevented by intracellular injection of EGTA to chelate Ca^{2+} (ref. 29), or by blocking NMDA receptors with selective antagonists[30]. For example, Ca^{2+} influx localized at transmitter-operated ion channels could have a role in organizing and regulating postsynaptic structures in an appropriate spatial relation to transmitter-releasing presynaptic terminal boutons, and it is important to consider that Ca^{2+} influx occurring at NMDA receptors located on dendritic spines might produce an especially large but localized elevation in intracellular Ca^{2+} concentration, due to restriction of Ca^{2+} diffusion along the narrow shaft of the spine. In addition, our results have some bearing on the mechanisms of desensitization of NMDA receptors, as the link that has been demonstrated between $[Ca^{2+}]_i$ and desensitization of nicotinic receptors at the neuromuscular junction[31,32] may occur also for other receptor-ionophore complexes. Thus our results may help to explain the similar desensitization evoked by either large doses of NMDA or depolarizing voltage jumps[7], which trigger Ca^{2+} entry through NMDA channels and voltage-dependent calcium channels, respectively.

Replacing the complementarity-determining regions in a human antibody with those from a mouse

Peter T. Jones, Paul H. Dear, Jefferson Foote, Michael S. Neuberger & Greg Winter

Laboratory of Molecular Biology, Medical Research Council, Hills Road, Cambridge CB2 2QH, UK

The variable domains of an antibody consist of a β-sheet framework with hypervariable regions (or complementarity-determining regions—CDRs) which fashion the antigen-binding site. Here we attempted to determine whether the antigen-binding site could be transplanted from one framework to another by grafting the CDRs. We substituted the CDRs from the heavy-chain variable region of mouse antibody B1–8, which binds the hapten NP-cap (4-hydroxy-3-nitrophenacetyl caproic acid; $K_{NP\text{-}cap} = 1.2\ \mu M$), for the corresponding CDRs of a human myeloma protein. We report that in combination with the B1–8 mouse light chain, the new antibody has acquired the hapten affinity of the B1–8 antibody ($K_{NP\text{-}cap} = 1.9\ \mu M$). Such 'CDR replacement' may offer a means of constructing human monoclonal antibodies from the corresponding mouse monoclonal antibodies.

The three-dimensional structures of several immunoglobulins show that the variable domains consist of two β-sheets pinned together by a disulphide bridge, with their hydrophobic faces packed together[1–3]. The individual β-strands are linked by loops which at one tip of the β-sheet may fashion a binding pocket for small haptens[1,2]. Sequence comparisons among heavy- and light-chain variable domains (V_H and V_L respectively) reveal that each domain has three CDRs flanked by four relatively conserved regions (framework regions—FRs)[4]. As seen in the structure of the human myeloma protein NEWM (Fig. 1), the CDRs include each of the three main loops. Often the CDRs also include the ends of the β-strands, suggesting that side chains at the ends of the β-strands may help to fix the conformation or orientation of the loops. The framework regions form the bulk of the β-sheet, although for example in the V_H domain of NEWM, FR1 includes part of the loop between the two β-sheets and CDR2 not only forms a loop but a complete β-strand (Fig. 1). The structure of the β-sheet framework is similar in different antibodies, as the packing of different side chains is accommodated by slight shifts between the two β-strands[5]. Furthermore, the packing together of V_L and V_H FRs is conserved[6], therefore the orientation of V_L with respect to V_H is fixed. We wondered whether the FRs represent a simple β-sheet scaffold on which new binding sites may be built, and

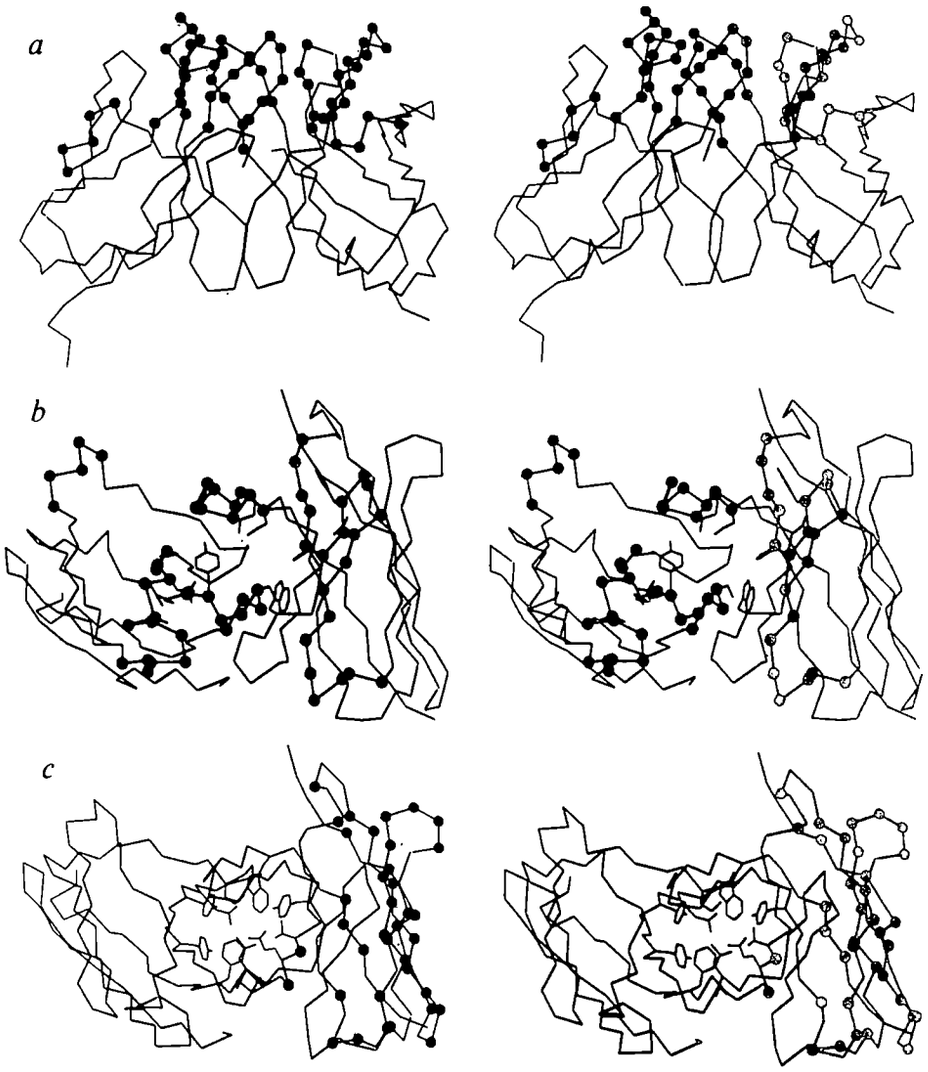

Fig. 1 Stereo pairs of the V_H (right) and V_L (left) domains of the human myeloma protein NEWM[1,8] generated using the computer graphics program FRODO[25]. The tracings indicate the backbone of C^α atoms for the framework regions. *a*, The C^α atoms of the CDRs (●) cluster at the tip of the variable domain. *b*, A view into the hapten binding pocket with the CDRs in the order (clockwise from noon): V_H CDR3, CDR1 and CDR2, and V_L CDR3, CDR1 and CDR2. The side chains lining the binding pocket (V_L A 28, N 30, Y 90, S 93, R 95; V_H W 47, Y 50, F 52, I 100, A 101) lie almost entirely in the CDRs. *c*, The C^α atoms in the NEWM V_H domain are marked (●) where side chains in the mouse B1-8 V_H domain are different. The side chains (V_L Y 35, Q 37, A 42, P 43, Y 86, F 99; V_H V 37, Q 39, L 45, Y 94, W 107) involved in packing V_H and V_L framework regions are traced. In the V_H domain all these side chains are conserved in mouse B1-8.

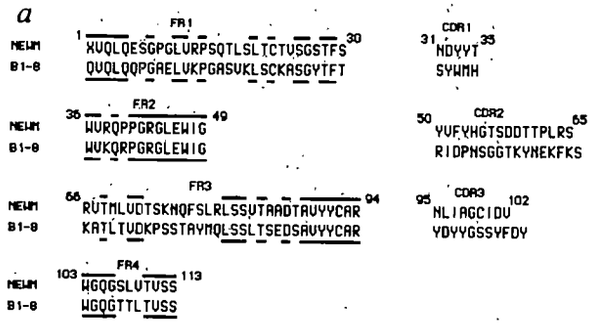

whether the structure of the CDRs (and antigen binding) is therefore independent of the FR context. To answer these questions experimentally, we have grafted the CDRs from one antibody to another, to determine whether antigen binding transfers with the CDRs.

We grafted the CDRs from the V_H domain of the mouse monoclonal antibody B1-8 (ref. 7) into the V_H domain of the human myeloma protein NEWM, whose crystallographic structure is known[1,8]. The V_H domain of the CDR donor (B1-8) is attached to a μ constant region and associated with a mouse λ1 light chain, and the antibody is directed against the hapten NP-cap. Both the V_H and V_L domains seem to have a role in determining the affinity of the antibody for NP-cap as the substitution of either domain by other, often highly related variable domains can destroy hapten binding (refs 7, 9 and M.S.N., unpublished results). In the V_H domain, each of the CDRs has been implicated in NP-cap binding[10], but the class of constant domains attached to V_H does not seem to affect binding of hapten[11,12]. The CDRs from the V_H domain of antibody B1-8 (ref. 13) are longer than the CDRs which they replace in NEWM[4] and this may give rise to a deeper binding pocket.

Most of the residues conserved between the V_H domains of B1-8 and NEWM are located in FR2, FR4 and the carboxy-terminal third of FR3 (Fig. 2*a*) and largely form the region of β-sheet which is packed against the light chain. Therefore, it might be expected that the V_H domain of B1-8 (hereafter abbreviated to MV_{NP}) and the hybrid B1-8/NEWM domain (HuV_{NP}) would dock in a similar manner with the mouse V_L domain to form the antigen-combining site[6]. The more variable FR1 and N-terminal two-thirds of FR3 form the other β-sheet which is exposed to solvent (Fig. 1*c*).

The gene encoding the HuV_{NP} domain was constructed by gene synthesis (Fig. 2*b*). We then constructed a plasmid, pSV-$HuV_{NP}H\varepsilon$, in which the HuV_{NP} domain is linked to a human ε constant region, and cloned into a pSV2gpt-derived vector[14]. The plasmid DNA was introduced into cells of the J558L mouse myeloma by spheroplast fusion. J558L secretes λ1 light chains which have been shown to associate with heavy chains containing a MV_{NP} variable domain, to create a binding site for NP-cap or the related hapten NIP-cap (3-iodo-4-hydroxy-5-nitrophenylacetyl caproic acid)[7]. As the plasmid pSV-$HuV_{NP}H\varepsilon$ contains the *gpt* marker (encoding guanine phosphoribosyltransferase), stably transfected myeloma cells could be selected in medium containing mycophenolic acid[14]; transfectants would be expected to secrete an antibody (HuV_{NP}-IgE) with a heavy chain composed of a HuV_{NP} variable domain and human ε constant regions, and the λ1 light chain of the J558L myeloma. The culture supernatants of several gpt^+ clones were assayed by radioimmunoassay and found to contain NIP-cap-binding antibody. The antibody secreted by one such clone was purified from the culture supernatant by affinity chromatography on NIP-cap–Sepharose, and by SDS-polyacrylamide gel electrophoresis the protein was indistinguishable from the mouse chimaeric MV_{NP}-IgE (ref. 12) (results not shown). The HuV_{NP}-IgE antibody competes effectively with MV_{NP}-IgE for binding to both anti-human ε (Fig. 3*a*) and NIP-cap coupled to bovine serum albumin (NIP-BSA) (Fig. 3*b*).

The affinities of HuV_{NP}-IgE for NP-cap and NIP-cap were

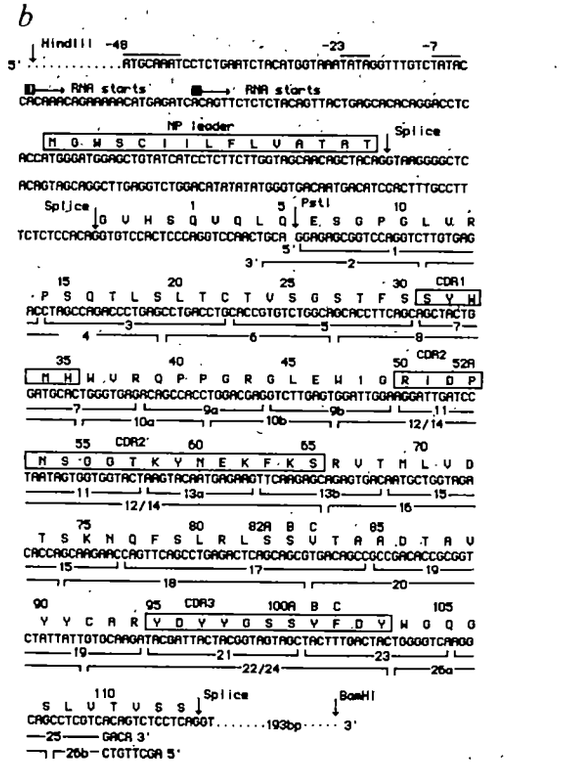

Fig. 2 *a*, Amino-acid sequence of the V_H domain of the human myeloma protein NEWM compared with that of the mouse B1-8 (anti-NP) antibody, and divided into FRs and CDRs according to Kabat *et al.*[4]. Conserved residues are marked with a line above and below the residue. *b*, Amino-acid and nucleotide sequence of the HuV_{NP} gene, in which the CDRs from the V_H domain of the mouse B1-8 antibody alternate with the FRs of human NEWM protein. The gene was constructed by replacing a section of the MV_{NP} gene in the vector pSV-V_{NP} (ref. 12) with a synthetic fragment encoding the HuV_{NP} domain. Thus the 5′ and 3′ noncoding sequences, the leader sequence, the leader–variable region intron, five N-terminal and four C-terminal amino acids are derived from the MV_{NP} gene; the rest of the coding sequence is derived from the synthetic HuV_{NP} fragment. The oligonucleotides are aligned with the corresponding portions of the HuV_{NP} gene. For convenience in cloning, the ends of oligonucleotides 25 and 26b form a *Hin*dII site followed by a *Hin*dIII site, and the sequences of the 25/26b oligonucleotides therefore differ from the HuV_{NP} gene.

Methods. The synthetic gene for HuV_{NP} was constructed as a *Pst*I–*Hin*dIII fragment. The nucleotide sequence was derived from the protein sequence using the computer program ANALYSEQ[26] with optimal codon usage taken from the sequences of mouse constant-region genes. The oligonucleotides used in synthesis (1–26b, 28 in total) vary in size from 14 to 59 bases and were made on a Biosearch SAM or an Applied Biosystems machine, and purified on 8 M urea/polyacrylamide gels[27]. The oligonucleotides were assembled in eight single-stranded blocks (A–D and A′–D′) containing oligonucleotides 1, 3, 5 and 7 (block A); 2, 4, 6 and 8 (block A′), 9, 11, 13a and 13b (block B), 10a, 10b and 12/14 (block B′), 15 and 17 (block C), 16 and 18 (block C′), 19, 21, 23 and 25 (block D); and 20, 22/24, 26a and 26b (block D′). In a typical assembly, for example of block A, 50 pmol of oligonucleotides 1, 3, 5 and 7 were phosphorylated at the 5′ end with T_4 polynucleotide kinase and mixed with 5 pmol of the terminal oligonucleotide which had been phosphorylated with 5 μCi of [γ-^{32}P]ATP (Amersham; 3,000 Ci mmol^{-1}). These oligonucleotides were annealed by heating to 80 °C and cooling to room temperature over 30 min with unkinased oligonucleotides 2, 4 and 6 as splints in 150 μl of 50 mM Tris-HCl *p*H 7.5, 10 mM $MgCl_2$. For the ligation, ATP (1 mM) and dithiothreitol (10 mM) were added, together with 50 units of T_4 DNA ligase (Anglian Biotechnology Ltd), and the mixture was incubated for 30 min at room temperature. EDTA was added to 10 mM, the sample extracted with phenol, precipitated from ethanol, dissolved in 20 μl of water and boiled for 1 min with an equal volume of formamide dyes. Then the sample was loaded onto a thin (0.3 mm) 8 M urea/10% polyacrylamide gel[27] and a band of the expected size detected by autoradiography and eluted by soaking. The two full-length single strands were assembled from A–D and A′–D′ using splint oligonucleotides; thus, A–D were annealed and ligated in 30 μl as above with 100 pmol each of oligonucleotides 10a, 16 and 20 as splints, then incubated overnight (A′–D′ were constructed with oligonucleotides 7, 13b and 17 as splints). After phenol/ether extraction blocks A–D were annealed with blocks A′–D′, small amounts were cloned in the vector M13 mp18 (ref. 28) then cut with *Pst*I and *Hin*dIII, and the gene sequenced by the dideoxy technique[29]. The MV_{NP} gene was transferred as a *Hin*dIII–*Bam*HI fragment from the vector pSV-V_{NP} (ref. 12) to the vector M13mp8 (ref. 30). To facilitate the replacement of MV_{NP} coding sequences by the synthetic HuV_{NP} fragment, three *Hin*dII sites were removed from the 5′ noncoding sequence by site-directed mutagenesis, and a new *Hin*dII site subsequently introduced near the end of FR4. By cutting the vector with *Pst*I and *Hin*dII, most of the V_{NP} coding sequence falls out and the synthetic fragment could be introduced as a *Pst*I–*Hin*dII fragment. The sequence at the *Hin*dII site was corrected to give NEWM FR4 by site-directed mutagenesis. The *Hin*dIII–*Bam*HI fragment, now carrying the HuV_{NP} gene, was excised from M13 and cloned back into pSV-V_{NP} to replace the MV_{NP} gene (and yield the vector pSV-HuV_{NP}). Finally, the heavy-chain constant domains of human IgE (ref. 31) were introduced as a *Bam*HI fragment to yield the vector pSV-$HuV_{NP}H_\varepsilon$, which was transfected into the myeloma line J558L by spheroplast fusion. The sequence of the HuV_{NP} gene in pSV-$HuV_{NP}H_\varepsilon$ was checked by re-cloning the *Hin*dIII–*Bam*HI fragment back into M13mp8 (ref. 30).

Table 1 Affinity of HuV_{NP}-IgE and MV_{NP}-IgE for the haptens NP-cap and NIP-cap

	$K_{NP\text{-}cap}$ (μM)	$K_{NIP\text{-}cap}$ (μM)
MV_{NP}-IgE	1.2 ± 0.1	0.02 ± 0.01
HuV_{NP}-IgE	1.9 ± 0.2	0.07 ± 0.02

The affinity of HuV_{NP}-IgE and MV_{NP}-IgE for NP-cap was determined by fluorescence quenching with excitation at 295 nm and emission observed at 340 nm (ref. 22). Antibody solutions were diluted to 100 nM in phosphate-buffered saline, filtered (0.45 μm-pore cellulose acetate) and titrated with NP-cap in the range 0.2–20 μM. As a control, the mouse D1-3 antibody[23], which does not bind hapten, was titrated in parallel. A decrease in the ratio of the fluorescence of HuV_{NP}-IgE or MV_{NP}-IgE (as appropriate) to that of the D1-3 antibody was taken as being proportional to NP-cap occupancy of the antigen-binding sites. The maximum quench was ~40% for both HuV_{NP}-IgE and MV_{NP}-IgE, and hapten dissociation constants were determined from least-squares fits of triplicate data sets to a hyperbola. The concentration of NIP-cap was varied from 10 to 300 nM, and ~50% quenching of fluorescence was observed at saturation. As the antibody concentrations were comparable to the values of the dissociation constants, data were fitted by least-squares to an equation[24] describing tight binding inhibition.

then measured directly using the fluorescence quench technique, and compared with those of MV_{NP}-IgE (Table 1). The antibodies HuV_{NP}-IgE and MV_{NP}-IgE have similar affinities for either hapten (NP-cap or NIP-cap), and although the affinity of HuV_{NP}-IgE for both haptens is slightly lower than that of MV_{NP}-IgE (2–3-fold, 0.3–0.6 kcal mol^{-1}), the difference in affinity is less than expected for loss of either a hydrogen bond or van der Waals' contact from the active site of an enzyme[15,16]. Thus, it seems that binding affinity and specificity for hapten can be conferred on a human antibody by grafting in the CDRs from an appropriate mouse antibody.

Is this result likely to be general? This would assume (1) that antigen usually binds to the CDRs, and any contacts to the FRs are made to the polypeptide backbone or to conserved side chains, and (2) that substitutions in the FRs do not usually affect the conformation of the CDR loops. These assumptions seem reasonable: thus, in the structure of a complex of the D1-3 antibody with lysozyme (R. A. Mariuzza, S. Phillips and R. J. Poljak, personal communication) most contacts to the lysozyme are made by the CDRs, but there is also a hydrogen bond in FR1 of the V_H domain from the β-OH of Thr 30 (often conserved or replaced by Ser). Similarly, the conformation of CDR loops

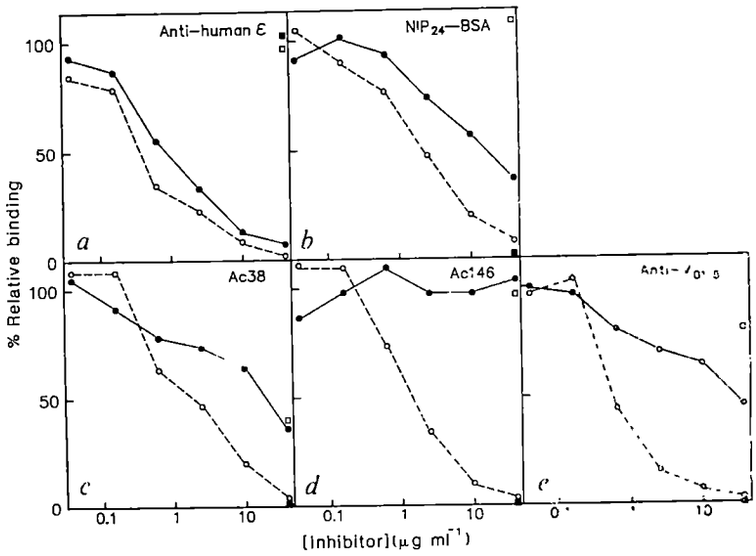

Fig. 3 Comparison of HuV_{NP} and MV_{NP} IgEs in binding inhibition assays. Various concentrations of HuV_{NP}-IgE (●) and MV_{NP}-IgE (○) were used to compete the binding of radiolabelled MV_{NP}-IgE to polyvinyl microtitre plates that had been coated with *a*, sheep anti-human ε antiserum (Seward Laboratory); *b*, $(NIP\text{-}cap)_{24}$-BSA; *c*, Ac38 anti-idiotypic antibody; *d*, Ac146 anti-idiotypic antibody; *e*, rabbit anti-MV_{NP} antiserum. Binding was also carried out in the presence of MV_{NP}-IgM antibody JW1/2/2 (ref. 32) (■) as well as in the presence of JW5/1/2 (□), which is an IgM antibody that differs from JW1/2/2 at 13 residues mainly located in V_H CDR2 (M.S.N., unpublished results). Values of binding are relative to the binding in the absence of inhibitor.

between β-strands depends on loop size and specific interactions of the loop back to the β-sheet. However, in the same class of variable domains (V_H, V_κ or V_λ) these interactions are usually conserved (ref. 5 and A. M. Lesk and C. Chothia, personal communication).

While human monoclonal antibodies have therapeutic potential in human disease, they can be difficult to prepare[17] and treatment of patients with mouse monoclonal antibodies often increases the titre of circulating antibody against the mouse immunoglobulin[18]. As chimaeric antibodies containing human constant domains[12,19,20] and variable domains made by grafting mouse CDRs into human FRs, could have therapeutic potential, we wondered whether the HuV_{NP}-IgE antibody loses antigenic determinants associated with the MV_{NP} variable region (idiotopes). The binding of HuV_{NP}-IgE and MV_{NP}-IgE to both monoclonal and polyclonal anti-idiotypic antibodies directed against the MV_{NP} domain was examined by using inhibition assays. As shown in Fig. 3*d*, the HuV_{NP}-IgE antibody has lost the MV_{NP} idiotypic determinant recognized by antibody Ac146 (ref. 21). Furthermore, HuV_{NP}-IgE also binds the antibody Ac38 (ref. 21) less well (Fig. 3*c*), therefore it is not surprising that HuV_{NP}-IgE has lost many of the determinants recognized by a polyclonal rabbit anti-idiotypic antiserum (Fig. 3*e*). While the loss of idiotypic determinants that accompanies 'humanizing' of the V_H region is reassuring in view of potential therapeutic applications, it does suggest that the recognition of the hapten and of anti-idiotypic antibodies is not equivalent. Thus the HuV_{NP}-IgE antibody retains hapten binding but has lost idiotypic determinants, indicating that the immunoglobulin uses different sites to bind hapten and anti-idiotypic antibodies. It appears, therefore, that both FR and CDR side chains form the binding site for these anti-idiotopes, but mainly CDR side chains interact with hapten.

We thank C. Milstein for suggesting this project, K. Rajewsky and M. Reth for the anti-idiotypic antibodies Ac38 and Ac146, and A. M. Lesk, C. Chothia, R. J. Leatherbarrow and C. Milstein for helpful discussions. J.F. is a Fellow of the Jane Coffin Childs Memorial Fund for Medical Research.

Regulation of human insulin gene expression in transgenic mice

Richard F Selden*, Marek J. Skośkiewicz†, Kathleen Burke Howie*, Paul S. Russell† & Howard M. Goodman*

Insulin is a polypeptide hormone of major physiological importance in the regulation of fuel homeostasis in animals (reviewed in refs 1, 2). It is synthesized by the β-cells of pancreatic islets, and circulating insulin levels are regulated by several small molecules, notably glucose, amino acids, fatty acids and certain pharmacological agents. Insulin consists of two polypeptide chains (A and B, linked by disulphide bonds) that are derived from the proteolytic cleavage of proinsulin, generating equimolar amounts of the mature insulin and a connecting peptide (C-peptide). Humans, like most vertebrates, contain one proinsulin gene[3,4], although several species, including mice[5] and rats[6,7], have two highly homologous insulin genes. We have studied the regulation of serum insulin

levels and of insulin gene expression by generating a series of transgenic mice containing the human insulin gene. We report here that the human insulin gene is expressed in a tissue-specific manner in the islets of these transgenic mice, and that serum human insulin levels are properly regulated by glucose, amino acids and tolbutamide, an oral hypoglycaemic agent.

The human insulin gene that we have used to generate transgenic mice is contained within a 12.5-kilobase (kb) *Eco*RI fragment that was isolated from a genomic library[4]. Of 46 mice born after one series of single-cell embryo microinjections, three contained human insulin gene sequences as detected by Southern hybridization analysis (Fig. 1*a*). A human C-peptide radioimmunoassay (Behringwerke) was used to monitor expression of the human insulin gene in the transgenic mice and their offspring. Several hundred transgenic and control mice have been analysed under a variety of physiological circumstances (see below), and the transgenic mice show variable levels of human C-peptide in their sera, whereas control mice show no such expression.

The tissue specificity of human insulin gene expression in these transgenic mice was examined by both RNA analyses and pancreatic islet function studies. Northern hybridizations using a human insulin complementary DNA probe demonstrated that total pancreatic RNA from both transgenic (Fig. 1*b*, lane 11) and control (lane 1) mice hybridized to the human insulin cDNA probe, whereas RNAs from transgenic spleen, kidney, brain, lung, liver, salivary gland, intestine, heart and muscle (lanes 2–10, respectively) showed no hybridization. Because no transgenic tissues other than pancreas were found to express detectable levels of insulin RNA, insulin expression in both transgenic and control pancreas was studied to determine whether the transgenic pancreas is a site of human insulin expression. Pancreatic islets from six transgenic and six control mice were isolated by collagenase digestion as described previously[8,9] and cultured in groups of 80–100 islets per tissue culture well. The following day, aliquots of media were taken and human C-peptide levels measured. The samples from the transgenic islet wells contained 250–650 ng ml^{-1} of human C-peptide, but the control islet wells contained no detectable human C-peptide. The cultured transgenic islets continued to express human C-peptide for several days. From these experiments, we conclude that the major site of human insulin expression in these transgenic mice is the endocrine pancreas.

Transgenic and control pancreas were stained with immunoperoxidase using a guinea pig anti-porcine insulin antibody and a goat anti-human C-peptide antibody (Fig. 2). The anti-porcine insulin antibody cross-reacted with both human and mouse insulin, and islets from both transgenic (Fig. 2*a*) and control (Fig. 2*b*) mice were stained. The size, distribution and number of islets were essentially the same in transgenic and control mice. The anti-human C-peptide antibody showed little or no cross-reactivity with mouse C-peptide, however, and the transgenic islets (Fig. 2*c*) were stained using this antibody whereas the control islets (Fig. 2*d*) were not. These immunohistochemistry data are consistent with the Northern analysis and islet function studies presented above, and demonstrate that the transgenic islets were specifically expressing human insulin.

Glucose and human C-peptide levels in the transgenic mice were studied under a variety of physiological conditions to determine whether normal glucose homeostasis was being preserved and whether expression of the human insulin gene was being regulated appropriately in these mice. Blood glucose regulation was studied by glucose tolerance tests. Transgenic offspring of mouse 16 and non-transgenic siblings were fasted overnight, given an intraperitoneal (i.p.) injection of glucose, and bled at various times after injection to determine serum glucose levels. The glucose tolerance curve from the transgenic mice was similar to that from the control mice (Fig. 3*a*). Of particular importance is the finding that the fasting and maximally stimulated glucose levels as well as the kinetics of

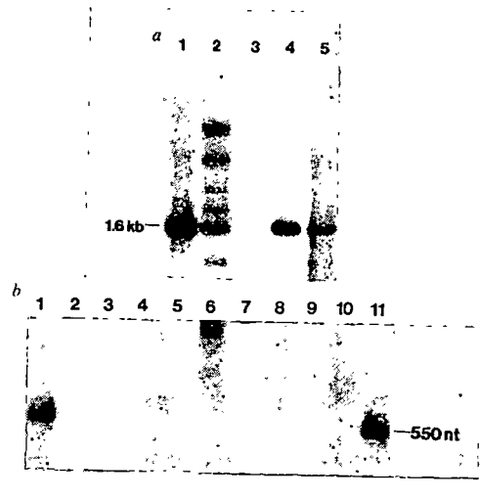

Fig. 1 Characterization of microinjected mice. *a*, Detection of human insulin sequences in total genomic DNA of microinjected mice. DNA samples digested with *Pvu*II are from the following microinjected mice: lane 1, mouse 16, containing 5–10 copies of the human insulin gene fragment per haploid genome; lane 2, mouse 20, also containing 5–10 copies of the human insulin gene fragment per haploid genome; lane 3, mouse 21, negative for human insulin sequences, demonstrating that the endogenous mouse insulin genes do not hybridize significantly to the human insulin genomic probe; lane 4, human control, containing 1 copy of the human insulin gene per haploid genome; lane 5, mouse 38, containing 1–2 copies of the human insulin gene fragment per haploid genome (this DNA sample was analysed in a separate experiment in which the hybridizing band was of comparable intensity to the human control). DNA samples from each transgenic mouse contain a hybridizing band of ~1,600 bp which corresponds to a 1,594-bp *Pvu*II fragment contained within the 12.5-kb human insulin DNA fragment[4] used for microinjection. This result suggests that at least one structurally intact human insulin gene was incorporated into the genome of each transgenic animal, although the presence of multiple hybridizing bands in lane 2 indicates that other integration events are likely to have occurred during the embryogenesis of mouse 20. Mouse 16, a male, was bred to generate a colony of several hundred offspring, and the human insulin gene was transmitted in mendelian fashion, with ~50% of both the F_1 and F_2 offspring inheriting the injected DNA fragment. *b*, Detection of human and mouse insulin messenger RNAs in tissues of transgenic and control mice. Total cellular RNA samples are from transgenic and non-transgenic offspring of mouse 16 as follows: lane 1, non-transgenic pancreas; lane 2, transgenic spleen; lane 3, transgenic kidney; lane 4, transgenic brain; lane 5, transgenic lung; lane 6, transgenic liver; lane 7, transgenic salivary gland; lane 8, transgenic intestine; lane 9, transgenic heart; lane 10, transgenic muscle; lane 11, transgenic pancreas. Neither the mouse insulin cDNA nor gene sequences have been determined, but since the coding regions of the human and rat insulin mRNAs share 81% sequence homology[15], it was expected that both transgenic and control pancreatic RNAs would hybridize to the human insulin cDNA probe.

Methods. A 12.5-kb *Eco*RI fragment containing the human insulin gene[4] was isolated from pBR322 sequences by preparative gel electrophoresis and electroelution[16]. Fertilized mouse eggs for microinjection were recovered *in cumulus* from the oviducts of $(C57\times C3H)F_1$ females that had mated with F_1 males several hours earlier. Approximately 1,000 copies of the human insulin gene fragment were microinjected into the male pronucleus of each fertilized egg. Microinjected eggs were implanted into the oviducts of 1-day pseudopregnant ICR foster mothers and carried to term[17]. Several weeks after the birth of animals that developed from microinjected eggs, total genomic DNA was prepared[18] from mouse tails. For the Southern blot analysis in *a*, 8 μg of total genomic DNA for each mouse were digested with *Pvu*II, subjected to electrophoresis on a 0.9% agarose gel and transferred to nitrocellulose[19]. The filter was then prehybridized overnight, hybridized to a ^{32}P-labelled genomic human insulin probe, washed and exposed to X-ray film. The genomic human insulin probe is a fragment that extends from a *Bgl*II site at −169 with respect to the transcriptional start site of the human insulin gene to an *Ava*I site at +644 (ref. 4). In addition to promoter sequences, this fragment contains the first intervening sequence, the first exon (including sequences encoding the signal peptide, B-peptide and a portion of C-peptide), and a portion of the second intervening sequence. Approximately 75% of the genomic human insulin probe consists of noncoding sequences that are not highly conserved between species, which explains its limited cross-hybridization with the endogenous mouse insulin genes (which can be detected only after long exposures). Total cellular RNA was isolated from tissue samples by the guanidinium isothiocyanate/caesium chloride technique[20]. For Northern blot analysis, 4 μg of total RNA from each sample was subjected to electrophoresis on a 1.2% agarose–formaldehyde denaturing gel and transferred to nitrocellulose filters[16]. The filter was then prehybridized, hybridized to a ^{32}P-labelled human insulin cDNA[15] probe, washed and exposed to X-ray film.

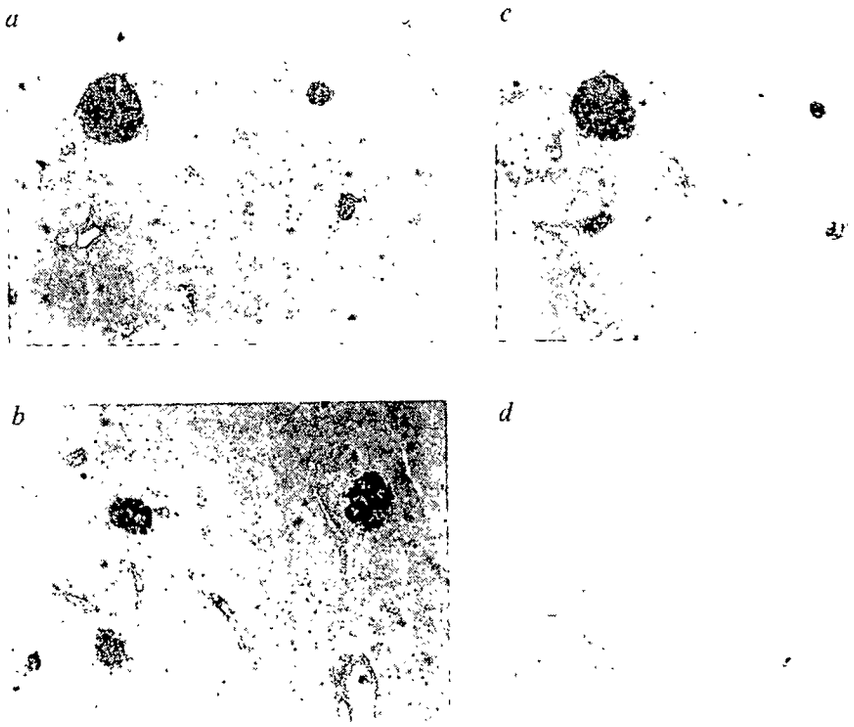

Fig. 2 Immunoperoxidase staining of transgenic and control pancreas. Pancreas samples were immersed in liquid nitrogen and 4-μm tissue sections were prepared using a cryostat. Immunoperoxidase staining of serial sections was performed as described previously[21], using either guinea pig anti-porcine insulin antibody (*a* and *b*) or goat anti-human C-peptide antibody (*c* and *d*). *a*, Transgenic pancreas stained with anti-insulin antibody (Arnel Products). *b*, Control pancreas stained with anti-insulin antibody. *c*, Transgenic pancreas stained with anti-human C-peptide antibody (Behringwerke). *d*, Control pancreas stained with anti-human C-peptide antibody (photographically enhanced to allow visualization of islets). Other transgenic tissues, including liver, adrenal and thyroid, are not stained using the guinea pig anti-porcine insulin antibody (not shown).

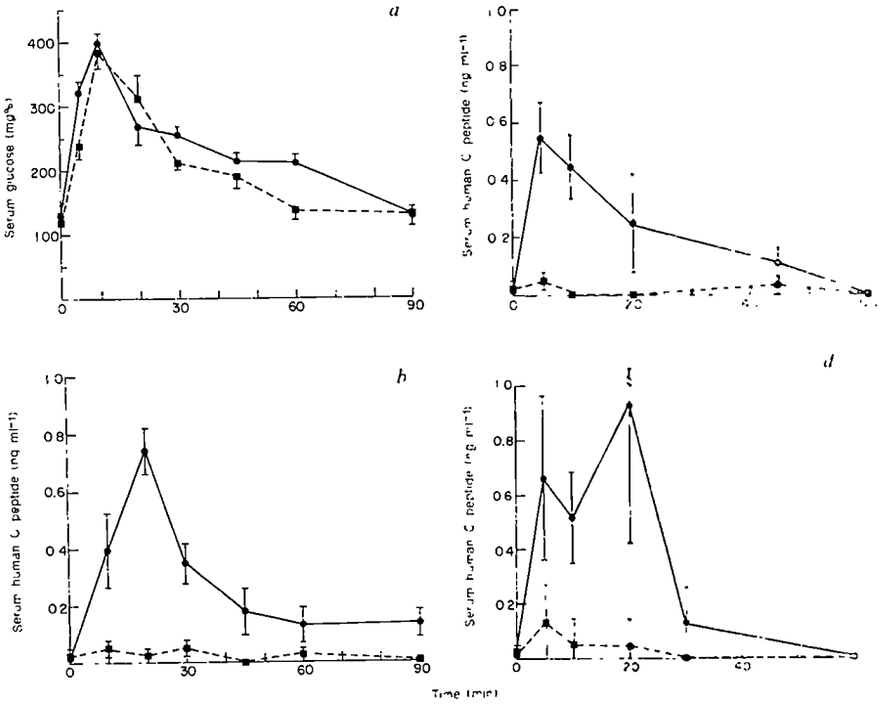

Fig. 3 *a*, Intraperitoneal glucose tolerance test. Transgenic offspring of mouse 16 and non-transgenic siblings were fasted overnight, then given an i.p. injection of glucose (1 mg glucose per g body weight). Each mouse was then arbitrarily assigned to a group of four for serum sampling at 5, 10, 20, 30, 45, 60 or 90 min post-injection. Four mice did not receive glucose and were bled to determine fasting serum glucose levels. Each time point therefore represents an average of values from four animals, and standard deviation half-bars are indicated. Solid line, transgenic mice; dashed line, control mice. Serum glucose determinations were performed using a commercially available kit (Worthington) under the conditions recommended by the manufacturer. Intravenous and oral glucose tolerance tests performed as described above showed no statistically significant difference between the transgenic and control mice (data not shown). *b*, Human C-peptide levels during an i.p. glucose tolerance test. The experiment was performed as described in *a*, with each transgenic point representing an average of values from six animals (i.p. injection of 2 mg glucose per g body weight). Serum human C-peptide levels were measured using a commercially available kit (Behringwerke) under the conditions recommended by the manufacturer. Solid line, transgenic mice; dashed line, control mice. These data are similar to glucose tolerance results previously reported for both mice[22] and humans[2]. Preliminary experiments suggest that mouse 20 also expresses human C-peptide and responds to a glucose tolerance test, and more extensive studies will be performed when mouse 20 and mouse 38 have generated large colonies. An assay specific for mouse C-peptide is not available, and we were unable to compare levels of endogenous mouse C-peptide with levels of human C-peptide. *c*, Human C-peptide levels during an i.v. amino-acid tolerance test. Transgenic and control mice were fasted overnight, infused with a solution containing 0.5 mg arginine and 0.5 mg leucine, and bled at the indicated times for human C-peptide determination. Each time point represents the average of values from four animals. Solid line, transgenic mice, dashed line, control mice. *d*, Human C-peptide levels during an i.v. tolbutamide infusion test. Transgenic and control mice were fasted overnight, infused with a solution containing 0.5 mg of tolbutamide (Upjohn) and bled at the indicated times for human C-peptide determination. Each time point represents the average of values from two animals. Solid line, transgenic mice; dashed line, control mice.

the return to basal glucose levels were similar for the transgenic and control animals. In addition, intravenous (i.v.) administration of glucagon increased serum glucose levels by ~50% within 15 min in both transgenic and control mice. Taken together, these results strongly suggest that serum glucose levels were appropriately modulated in the transgenic mice. The weights of the transgenic mice, growth rates, feeding behaviour, reproductive capability and longevity appeared normal.

The role of human insulin in the regulation of blood glucose levels in transgenic mice was investigated by performing a glucose tolerance test on transgenic and control mice (Fig. 3*b*). No human C-peptide was detected in the sera of fasting transgenic mice, but within 10 min of i.p. administration of glucose, human C-peptide appeared in the serum, and peak levels were attained within ~20 min. By 45 min post-glucose, human C-peptide levels fell to values approaching the pre-stimulation or basal level. This pattern of human C-peptide expression correlates closely with the glucose tolerance curves presented above, and suggests that serum human insulin levels were being appropriately regulated by glucose. The control mice did not express any detectable human C-peptide, indicating that the human gene must have been the source of the human C-peptide in the transgenic animals.

Insulin is regulated by several other factors, including amino acids and certain pharmacological agents. An i.v. amino-acid infusion test was performed on fasting transgenic and control mice and human C-peptide levels in the serum were determined. Peak human C-peptide levels were seen within 5 min of amino-acid infusion and declined gradually over the next 40 min (Fig. 3*c*). Similarly, serum human C-peptide levels responded to tolbutamide, a sulphonylurea derivative known to promote insulin release[10] (Fig. 3*d*). Within 20 min of i.v. tolbutamide administration, serum human C-peptide levels peaked, then decreased rapidly over the next 10 min. Tolbutamide has been used clinically to diagnose insulinomas[11] because in normal subjects serum insulin (or C-peptide) levels rapidly return to normal from their tolbutamide-induced peak, but in insulinoma patients elevated insulin levels persist. That the transgenic mice quickly regained basal serum human C-peptide levels supports the conclusion that their insulin expression was tightly regulated.

We have demonstrated that the human insulin gene is expressed in the pancreas of transgenic mice. Cell-type- and tissue-specific expression of human[12] and rat[12–14] insulin genes has been documented in two other laboratories. A 230-base-pair (bp) region (from −103 bp to −333 bp with respect to the transcriptional start site) of the rat insulin I promoter was reported to be sufficient to allow tissue-specific expression of insulin/chloramphenicol acetyltransferase fusion genes in a hamster pancreatic cell line[12,13]. Similarly, a rat insulin II/simian virus 40 large-T antigen fusion gene has been reported to cause the development of islet cell tumours in transgenic mice[14]. As both of these studies used fusion genes, the regulation of circulating human insulin could not be studied.

Serum insulin levels are regulated by glucose, amino acids, proteins and drugs such as the sulphonylurea derivatives. The human insulin gene in these transgenic mice is regulated appropriately by all of these agents, and serum glucose homeostasis is normal. These transgenic animals can therefore now be used to study several critical aspects of the physiological regulation of insulin gene expression, including the mechanisms controlling serum insulin and total β-cell insulin levels. Because at least one additional insulin gene is being expressed in the transgenic mice and total insulin RNA and protein levels are approximately the same as in control mice, the question of dosage compensation can be investigated. Moreover, our tolbutamide results indicate that drugs thought to affect human insulin metabolism can now be tested in an *in vivo* animal system. In a more general sense, the *in vivo* effects of various pharmacological agents on human gene expression and protein function can therefore be evaluated in a non-human setting.

Finally, it is noteworthy that a 12.5-kb DNA fragment contains sufficient information for the appropriate physiological regulation of insulin levels in these transgenic mice. The organism's ability to modulate foreign DNA sequences and proteins on a minute to minute basis clearly has important implications for both molecular biology and gene therapy.

We thank Dr Tom Wagner for instruction in microinjection, Victoria Roman for technical assistance and Patrick Mattoon for animal care. The human C-peptide assay was the gift of Dr H. H. Schoene and Behringwerke, AG. This work was supported by grants from Hoechst AG and the NIH (AM-07055).

Genetic recombination between RNA components of a multipartite plant virus

Jozef J. Bujarski & Paul Kaesberg

Biophysics Laboratory and Department of Biochemistry, University of Wisconsin-Madison, Madison, Wisconsin 53705, USA

Genetic recombination of DNA is one of the fundamental mechanisms underlying the evolution of DNA-based organisms and results in their diversity and adaptability. The importance of the role of recombination is far less evident for the RNA-based genomes that occur in most plant viruses and in many animal viruses. RNA recombination has been shown to promote the evolutionary variation of picornaviruses[1–4], it is involved in the creation of defective interfering (DI) RNAs of positive- and negative-strand viruses[5–9] and is implicated in the synthesis of the messenger RNAs of influenza virus[10] and coronavirus[11]. However, RNA recombination has not been found to date in viruses that infect plants. In fact, the lack of DI RNAs and the inability to demonstrate recombination in mixedly infected plants has been regarded as evidence that plants do not support recombination of viral RNAs. Here we provide the first molecular evidence for recombination of plant viral RNA. For brome mosaic virus (BMV), a plus-stranded, tripartite-genome virus of monocots, we show that a deletion in the 3′ end region of a single BMV RNA genomic component can be repaired during the development of infection by recombination with the homologous region of either of the two remaining wild-type BMV RNA components. This result clearly shows that plant viruses have available powerful recombinatory mechanisms that previously were thought to exist only in animal hosts, thus they are able to adapt and diversify in a manner comparable to animal viruses. Moreover, our observation suggests an increased versatility of viruses for use as vectors in introducing new genes into plants.

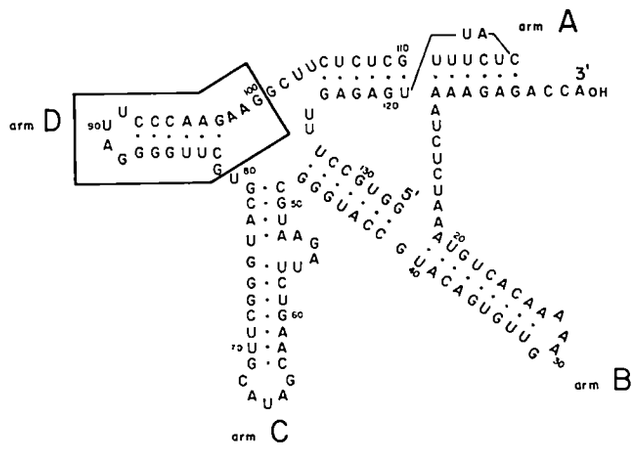

Fig. 1 Schematic representation of the postulated conformation of the tRNA-like structure at the 3′ end of BMV RNA3 (after Rietveld *et al.*[14]). The open box indicates the location of the 20-nucleotide deletion (deletion m4) so that the entire D arm is absent from the resulting structure. This deletion, located between nucleotides 81 and 100, was originally introduced into a cDNA clone comprising the last 200 bases of BMV RNA3 as described in ref. 19 and subsequently transferred into the full-length cDNA clone of BMV RNA3 as described in ref. 21.

To study recombination between the individual BMV RNAs, we used wild-type RNA1 and RNA2 together with an engineered BMV RNA3 in which a sequence located in its 3′-proximal noncoding region had been deleted. The 3′-noncoding region for each of the three BMV RNAs extends for ~300 nucleotides, the last 200 of which are similar in sequence but not identical in the three RNAs[12]. Their 3′-proximal 134 nucleotides are folded into a transfer RNA-like conformation[13,14], which is involved in initiation of BMV RNA replication[15,16], aminoacylation[17] and adenylation[18]. The RNA3 mutant, designated m4, had been constructed previously by S_1 nuclease deletion of a 20-base long, stem-and-loop hairpin corresponding to arm D in its tRNA-like structure[19] (bases 81–100; see Fig. 1).

RNAs 1 and 2, transcribed from cDNA clones of wild type (Madison M1 strain)[20], together with transcribed m4-type RNA3, are infectious to barley plants and progeny virus initially has the m4-type 3′ region in both RNA3 and RNA4 (ref. 21). RNA4 is a subgenomic RNA derived during virus infection from the 5′-proximal one-third of negative-strand RNA3 (ref. 22). However, m4 RNA3 and RNA4 accumulated less well than their wild-type counterparts, probably because of modified activity of the m4-type 3′ region, as determined *in vitro*[19,21]. We therefore decided to test the possibility that, after a prolonged infection, the original m4 RNA3 might be outcompeted by a revertant form of RNA3 which had regained the deleted stem-and-loop region as a result of recombination with wild-type RNA1 or RNA2.

Time-course analysis of progeny viral RNA3 species from successively appearing leaves of plants inoculated with transcribed wild-type RNAs 1 and 2 and m4 RNA3 revealed a stepwise decrease of the m4 RNA3 over days 3–16 after inoculation (Fig. 2). The presence of the m4 deletion near the 3′ end in RNAs 3 and 4 was determined by observation of a readily identifiable, 3′-terminal fragment released by partial digestion with ribonuclease T_1 (ref. 23). The disappearance with time of the 141-base-long m4-type fragment expected for m4 RNA3, and the parallel appearance of a 161-base fragment characteristic of wild-type RNA3 (compare lanes 2 and 4 of Fig. 2) indicated a gradual increase of an RNA3 variant that was more similar to wild-type RNA3.

To delineate the emergent RNA more precisely, we examined progeny RNA3 and RNA4 isolated from three individual barley plants on day 15 post-inoculation. In plant I we found that the variant RNA3 and RNA4 each migrated more slowly on agarose

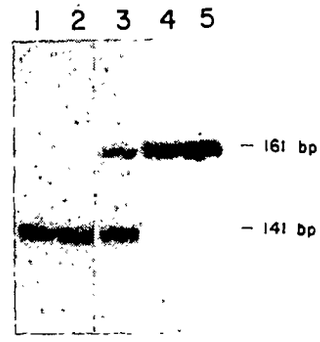

Fig. 2 Analysis by polyacrylamide gel electrophoresis for the presence of the m4 deletion in a 3′-terminal fragment released from progeny BMV RNA3 by limited digestion with RNase T_1. Lanes 5 and 1, standard T_1 fragments obtained from wild-type (161 base pairs (bp) long[23]) or m4-type (141 bp) transcript RNA3, respectively. Lanes 2, 3 and 4, T_1 fragments from progeny BMV RNA3 isolated from the virus at 3, 10 and 16 days post-inoculation, respectively.
Methods. Barley seedlings were inoculated with a mixture of transcribed wild-type BMV RNAs 1 and 2 and the m4 RNA3 following the procedure described in ref. 20. Progeny viral RNA was isolated from virus extracted from 0.1 g of leaves of a single infected plant, as described elsewhere[27]. The BMV RNA3 component was separated by electrophoresis on a low-melting point 1% agarose gel and a 3′-terminal fragment was released from the purified RNA3 by limited digestion with RNase T_1 as described elsewhere[21]. To generate standard 161- and 141-bp T_1 fragments, both wild-type and m4 RNA3 were synthesized by transcription *in vitro* as described in ref. 28, and the fragments were released from transcripts with RNase T_1. After labelling of the 3′ ends with ^{32}P-pCp and T_4 RNA ligase[29], the released RNA fragments were analysed on a 6% polyacrylamide/7 M urea sequencing gel and their positions were determined by autoradiography.

gel electrophoresis than m4-type and also wild-type RNAs 3 and 4 (see Fig. 3, lanes 1 and 2), indicating that they are larger than both m4-type and wild-type RNAs 3 and 4. There was no evidence of m4-type or wild-type RNA3 or RNA4. This pattern was unaltered after two passages of the virus through other barley plants. Sequence analysis of RNA3 from the emergent virus (designated mutant A; see Fig. 4 legend) indicated that the region corresponding to the last 267 bases of wild-type RNA3 had been replaced with the last 307 bases of wild-type RNA2. Thus, mutant A RNA3 had the deleted stem-and-loop region restored plus 39 more bases than wild-type RNA3 and 59 more bases than its m4 RNA3 progenitor.

In plant II, viral RNA3 and RNA4 co-migrated with wild-type BMV RNA3 (Fig. 3, lanes 4 and 5). Electrophoresis on a higher-resolution gel showed that the RNA3 was composed of at least two bands, the lower band containing most of the material (Fig. 3, lane 6, bands 3a and 3b). In plant III, gel electrophoresis revealed two bands each in the regions of RNA3 and RNA4 (compare lanes 7 and 10 of Fig. 3); a similar pattern was present after the first passage of the virus (lane 8), whereas after the second passage the upper band was absent (lane 9). Analysis on a higher resolution gel indicated that the lower band in the region of RNA3, present as a single band in lane 9, in fact consisted of at least two closely migrating bands (lane 11, bands 3c and 3d).

To identify the species present in RNA3 preparations obtained from plants II and III, a complementary DNA library was created and individual clones were sequenced in their 3′-noncoding regions, as described in Fig. 4 legend. Three sequences, corresponding to mutants designated B, C and D, were found in both libraries. In addition, a fourth sequence, corresponding to mutant E, was identified in the library of plant III. While four clones of mutant B, three clones of mutant C, eight of mutant D and one of mutant E were identified, cDNA clones corresponding to neither m4-type RNA3 nor the strictly wild-

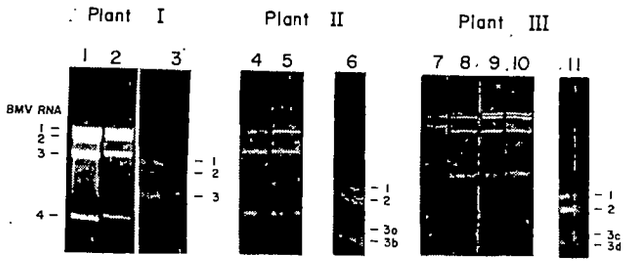

Fig. 3 Electrophoretic analysis of progeny BMV RNA extracted from three independently inoculated barley plants. Barley leaves were infected with transcribed wild-type RNAs 1 and 2 and m4 RNA3. Plants I and II: BMV RNA was extracted from leaves showing symptoms of infection, on day 15 after inoculation, and was analysed on 1.2% agarose gels (either 10 cm long, lanes 2 and 5; or 30 cm long, lanes 3 and 6). Plant III: viral RNA was obtained from leaves 15 days after inoculation with transcribed BMV RNAs (lane 7) as well as on day 15 after the first and second passages through barley (lanes 8 and 9, respectively; 10-cm gels). Lane 11, RNA from lane 9 analysed on a 30-cm gel. Lanes 1, 4 and 10, wild-type BMV RNA.

type 3′ end sequence of BMV RNA3 were found. This last observation tends to exclude the possibility that a causal infection with wild-type BMV RNA3 contaminated the experiments.

The sequences of RNA3 in mutants B, C and D revealed recombination between RNA3 and RNA1 or RNA2 at a site in their homologous 3′ end region. As these RNAs differ in only a small number of bases in this region (see Fig. 4 legend), the exact site of putative recombination could not be specified. We can conclude, however, that mutant B is a combination of RNA3 and RNA1 somewhere between bases 130 and 101, mutant C combines the RNA3 and RNA1 sequences somewhere between bases 175 and 131, and mutant D combines RNA3 and RNA2 somewhere between bases 205 and 101. Similar to mutant A, mutant E had its deleted stem-and-loop region restored and was larger than wild-type RNA3. Sequence analysis showed that the region corresponding to the last 206 bases of the wild-type RNA3 had been replaced by 215 3′-terminal nucleotides from wild-type RNA2 (see Fig. 4).

The structure of these five mutants suggests strongly that one or more recombination events have occurred between the 3′-noncoding regions (within or outside the homologous sequences) of individual BMV RNAs, resulting in the restoration of the deleted hairpin in progeny RNA3. Clearly, that stem-and-loop region is not essential for infectivity but its presence nevertheless confers a selective advantage. In mutants A and E recombination outside the closely homologous region resulted in emergent noncoding regions larger than wild-type RNA3, indicating that a degree of structural variability is permissible there. In mutants B, C and D the recombination event(s) occurred within the homologous region and resulted in sequences of wild-type lengths only.

The results described here demonstrate that recombination between viral RNAs occurs in plant cells at a relatively high frequency and at various positions on the RNA. As with animal RNA viruses, the mechanism of recombination between the BMV sequences is unknown. Two diverse mechanisms have been suggested for RNA genomes: (1) Enzymatic cutting and re-ligation. (2) A 'copy-choice', during replication, between adventitiously proximal templates. The latter mechanism has been favoured for recombination in picornaviruses[24], negative-strand viruses[5,10] and alpha viruses[7].

The recent discoveries of remarkable sequence similarities among encoded proteins of diverse plant RNA viruses[25,26] suggest that recombination may be a common phenomenon during synthesis of plant viruses. Like other processes of natural mutagenesis, recombination between plant viruses may render the progeny more adaptable to new environments or hosts.

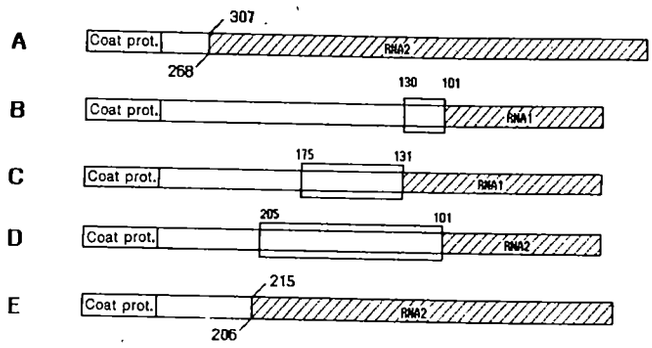

Fig. 4 Schematic representation of BMV RNA3 recombinants identified by sequence analysis of BMV RNA3 preparations obtained from plants I–III. Mutant A was obtained from plant I; mutants B–E were identified in plants II and III. The figure shows the 3′ region of RNA3 for the five mutants downstream to the coat protein open reading frames (ORFs). The open regions adjacent to the ORFs represent wild-type BMV RNA3 sequences. The cross-hatching indicates regions identical to wild-type RNA1 or RNA2, possessing the stem-and-loop region of arm D, and also differing from wild-type RNA3 at the following base positions: RNA1 has distinctive bases at positions 101, 44 and 43 while RNA2 has distinctive bases at positions 101 and 44 and has a point deletion corresponding to base 74 of RNA3 (refs 13, 20). The boxes enclose regions in which the recombination event occurred, assuming a recombination mechanism involving a single event. Sequences of wild-type RNAs 1, 2 and 3 are identical in these regions.

Methods. Mutant A RNA3 was sequenced directly by a chain-temination (dideoxy) technique with RNA-dependent DNA polymerase (reverse transcriptase[30]. Briefly, 2 μg of RNA3, obtained after fractionation on a sucrose gradient[31], was hybridized with 1 μg of either the 15-mer d(GAGATTTTCTCTGGT), complementary to nucleotide positions 1–15, or the 15-mer d(TCTCACAGATCCTCG), complementary to nucleotides 129–143, and these primers were extended with 10 units of reverse transcriptase (Life Science) in the presence of dideoxy nucleoside triphosphates. RNA3 preparations obtained from plants II and III (mutants B–E) were sequenced as cDNA clones in an M13mp19 vector by a chain-termination (dideoxy) technique with a synthetic 17-mer primer (BioLabs) and DNA polymerase large fragment (Klenow)[32,33]. Two cDNA libraries were created for BMV RNA3 preparations obtained either from primary infection in plant II or after a second passage of the virus in plant III. The first cDNA strand was synthesized with reverse transcriptase as described elsewhere[34], using the d(TAGAGATTTTCTCTGGT) primer complementary to the last 17 nucleotides of BMV RNA3. After purification on a 1 × 20 cm Sepharose CL2B column, the second strand was obtained by means of a replacement reaction with RNase H, *Escherichia coli* DNA polymerase and *E. coli* DNA ligase[35]. After treatment with T_4 DNA polymerase (blunt-ending), the resulting double-stranded cDNA preparation was cloned into a *Sma*I restriction site of M13amp19 vector and the sequence of the corresponding single-stranded M13 DNA templates was determined by a chain-termination procedure using the Klenow fragment of *E. coli* DNA polymerase and a synthetic 17-mer (BioLabs) as primer.

Conversely, RNA recombination between plant viral RNAs may be important for the preservation and stabilization of crucial functional sequences of multipartite genome viruses. Because it facilitates the association of unrelated genes, recombination also represents an attractive candidate for the mechanism of origin of viruses and for the insertion of new genes into existing viruses.

We thank Ola Dzianott-Bujarska for technical assistance, and G. Duke, P. Shaklee and P. Ahlquist for valuable advice with respect to cDNA cloning. This work was supported by NIH research grants AI01466 and AI15342 and Career Award AI21942.

A tobacco mosaic virus-induced tobacco protein is homologous to the sweet-tasting protein thaumatin

Ben J. C. Cornelissen, Rob A. M. Hooft van Huijsduijnen & John F. Bol

Department of Biochemistry, State University of Leiden, PO Box 9505, Leiden, The Netherlands

Infection of tobacco plants with tobacco mosaic virus (TMV) results in an increase in the activities of several enzymes and induces the *de novo* synthesis of about 10 proteins that are protease-resistant and soluble at *p*H 3. These proteins accumulate in the intercellular leaf space[1,2]. The appearance of pathogenesis-related (PR) proteins is closely associated with the phenomenon of 'systemic acquired resistance' and it has been suggested that such proteins have an antiviral function[3,4]. Previously, we cloned complementary DNAs to the messenger RNAs for the three smallest PR proteins, PR-1a, -1b and -1c, and these clones were used to show that there is an increase of more than 100-fold in the concentration of PR-1 mRNAs following TMV infection of tobacco[5,6]. Here, we describe the cDNA cloning of another mRNA whose synthesis is induced by TMV infection. Sequencing of the cDNA showed that the encoded protein is highly homologous to thaumatin, the intensely sweet-tasting protein from the fruits of the monocot *Thaumatococcus daniellii* Benth, a West African rainforest shrub. The conservation of a gene encoding a thaumatin-like protein in tobacco suggests that the encoded protein may have a more general function than that of being sweet-tasting.

Poly(A)-containing RNA from TMV-infected Samsun NN tobacco was used as a template to construct a cDNA library; 1,400 transformants were screened by a differential hybridization procedure, using ^{32}P-labelled DNA complementary to poly(A) RNA from healthy or TMV-infected tobacco as probes. Forty transformants were found to correspond to TMV-induced mRNAs and an analysis of their inserts showed that they could be divided into six clusters, with cross-hybridization occurring within but not between the clusters. Details of the cloning and selection procedure will be given elsewhere (R.A.M.H. *et al.*, in preparation).

Fig. 1 Northern blot loaded with poly(A) RNA from healthy tobacco (H), tobacco sprayed with salicylic acid (S) and tobacco infected with TMV (T). The blot was probed with ^{32}P-labelled PROB 12. Samsun NN tobacco plants were sprayed with salicylic acid (5 mM, adjusted to *p*H 7) on three successive days before RNA extraction. RNA was extracted from TMV-infected tobacco plants 7 days after inoculation. The method of extraction, Northern blotting and the cloning of PROB 12 are described in ref. 6.

One cluster was represented by a single clone, PROB 12, which was used to probe the Northern blot shown in Fig. 1. The gel used to make the blot was loaded with poly(A) RNA from healthy tobacco (lane H), tobacco sprayed with salicylic acid (lane S), and tobacco infected with TMV (lane T). Salicylic acid is known to induce the synthesis of several PR proteins, notably proteins 1, 2 and N[2]. The mRNA corresponding to PROB 12 occurs at a low level in healthy tobacco, is not induced by treatment with salicylic acid, but is strongly induced by TMV infection. This mRNA is estimated to be 1,000–1,100 nucleotides long. Sequencing studies showed that the insert in PROB 12 is 845 base pairs (bp) long. As no poly(A) tract was found in the cDNA, the 3′ end of the mRNA is probably not represented in the clone. Figure 2 shows that the insert contains an open reading frame for a protein of 226 amino acids, flanked by 5′- and 3′-noncoding regions of 3 and 164 nucleotides, respectively.

The nucleotide sequence of the insert of PROB 12 was compared, by computer analysis, with plant sequences stored in a databank (Genbank). Extensive homology was found with the mRNA for thaumatin, the sweet-tasting protein that occurs in the arils of *Thaumatococcus daniellii* Benth, a West African shrub[7]. At least five different forms of thaumatin (I, II, III, b and c) can be isolated, all of which are almost 100,000 times sweeter than sucrose on a molar basis[8]. The most abundant forms are thaumatin I and II, polypeptides of 207 amino acids each that differ at only five positions[9]. The mature protein is derived from preprothaumatin by removal of an amino-terminal signal peptide of 22 amino acids and an acidic carboxy-terminal extension of 6 amino acids[7]. In Fig. 3, preprothaumatin II is aligned with protein encoded by PROB 12; the amino-acid sequence homology between the two proteins is 65%. In addition, there are several conserved amino-acid changes; when these are taken into account, the homology is more than 70%. The Ala-Ala sequence, which represents the site of cleavage of the signal peptide, is conserved in both proteins. However, except for their hydrophobic nature, there is little similarity between the signal peptides of the two proteins, and the tobacco protein lacks the C-terminal extension of the thaumatin precursor. Because of its homology to thaumatin, we provisionally refer to the PROB 12-encoded protein as a thaumatin-like (or TL) protein of tobacco.

The alignment shown in Fig. 3 suggests that PROB 12 contains the complete coding region for the precursor of the TL protein. A possible polyadenylation signal in TL mRNA (underlined in Fig. 1) is located 80 bp upstream from the 3′ end of the cDNA insert. There may be additional polyadenylation signals in the TL mRNA sequence that are not represented in PROB 12. Three potential polyadenylation signals have been found in thaumatin mRNA[7].

The relative molecular mass (M_r) of the mature TL protein of tobacco is 21,596. It is unknown whether the TL protein

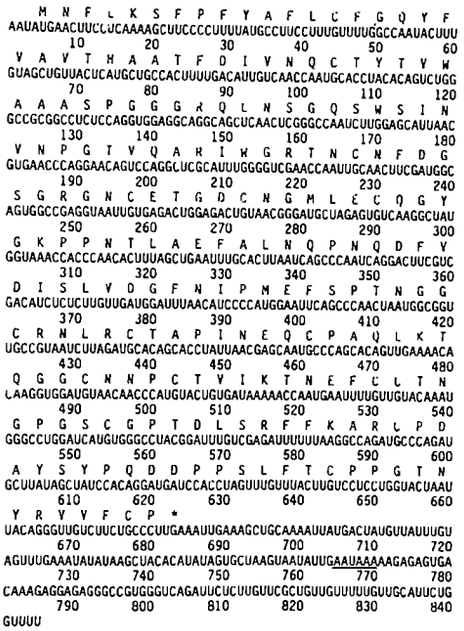

Fig. 2 Nucleotide sequence of the coding strand of PROB 12 cDNA. The amino-acid sequence corresponding to the open reading frame is indicated (one-letter code). The polyadenylation signal in the 3'-noncoding region is underlined.

corresponds to a known PR protein, for example, P or Q (each of estimated M_r ~27,000; ref. 5). In preliminary immunodiffusion experiments, purified PR proteins, or a total protein extract from TMV-infected tobacco, did not react with an antiserum to thaumatin. The PR-1 proteins are derived from their precursors by the removal of a 30-amino-acid signal peptide, probably during excretion into the intercellular space of the tobacco leaf[5,6]. The evidence for a signal peptide in the TL primary translation product also suggests that the TL protein is translocated through a membrane. The thaumatins are known to accumulate in intracellular vesicle-like organelles[10]. If, by analogy, the TL protein is not localized extracellularly in tobacco, it may not belong to the PR class of proteins.

The extreme sweetness of thaumatin, which is only recognized by man and Old World monkeys, may contribute to the spreading of the seeds of *T. daniellii* Benth. The conservation of a thaumatin-like gene in tobacco and possible other dicotyledonous plants suggests that in these plants the encoded protein performs a more general function. Thaumatin ($pI = 12$) has a high proportion of basic residues and modification studies indicate that some lysine residues are important for the sweet taste[11,12]. In the tobacco TL protein there is an excess of acidic residues over basic residues, which may alter its properties with respect to taste perception. Recently, the three-dimensional structure of thaumatin I has been deduced at 3.1 Å resolution[13]. It will be interesting to compare the predicted TL protein structure with the thaumatin backbone.

The presence of two very small introns at different positions in several thaumatin genes has led to the suggestion that the genes encoding thaumatin are structurally similar to those encoding storage proteins such as zein (maize) and glycinin (soybean)[9]. The availability of PROB 12 offers the possibility of monitoring for a tissue-specific expression of the TL gene during the life cycle of tobacco. A model has been proposed in which the burst of ethylene production that is evoked by TMV infection of tobacco, is responsible for the induction of PR proteins and of several enzymes[1]. In this respect it is noteworthy that ethylene production increases considerably during specific developmental processes such as fruit ripening.

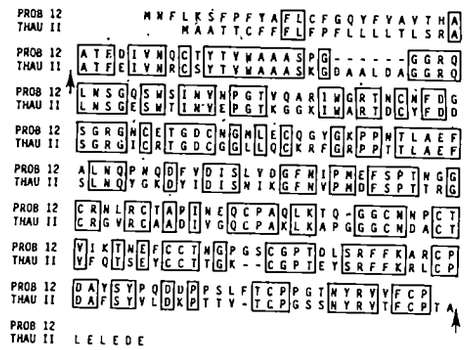

Fig. 3 The amino-acid sequence encoded by the open reading frame in PROB 12, aligned with the preprothaumatin II sequence[7]. Amino acids that are identical in the two sequences are boxed. The arrows indicate the cleavage sites that are used to remove the N-terminal signal peptide and the C-terminal extension from preprothaumatin II.

We thank Dr A. M. Ledeboer (Unilever Research Laboratory, Vlaardingen, The Netherlands) for providing an antiserum against thaumatin. This work was sponsored in part by the Netherlands Foundation for Chemical Research (SON) with financial aid from the Netherlands Organization for the Advancement of Pure Research (ZWO).

Nature Product Review

MANUFACTURERS and distributors of scientific equipment are reminded that the following special features are appearing in July and August:

3 July: **Microscopy/Image analysis,** covering all aspects of microscope hardware and techniques as well as latest developments in image analysers.

3 July: **Immunology.** Also in this issue, details of exhibits at the Toronto International Congress of Immunology, to be held on 7–10 July.

4 August: **New on the Market:** A selection of recently introduced laboratory equipment with the accent on novelty.

14 August: **Computers in the laboratory:** Information technology and computer services in the modern laboratory.

Press releases, photographs and comments on these features should be addressed to the Editor in *Nature*'s London office or to:
Karen Wright,
Nature,
1134 National Press Building,
Washington, DC 20045, USA

Was there 26-Myr periodicity of extinctions?

HOFFMAN[1] has questioned our claim[2] that extinction events during the past 250 Myr exhibit a 26-Myr periodicity. Hoffman argues that the apparent periodicity originates not from any evolutionary signal but from arbitrariness in the choice of taxonomic level, treatment of data and selection of geologic timescales in our analysis. His letter succeeds in outlining many problems inherent in working with data from the fossil record. However, we find his conclusion unconvincing because there is no hypothesis-testing. In fact, when statistical tests and independent criteria are applied, we find that Hoffman's results support our contention of periodicity better than our initial analyses.

In our initial paper[2] we analysed a set of data on fossil marine families that was highly culled in order to enhance the signal-to-noise ratio. Hoffman implies that this culling may have induced an appearance of periodicity. However, our subsequent analyses[3,4] indicate that this culling had no important consequences and an evident 26-Myr periodicity remains when a variety of extinction metrics (including rate and probability of extinction) are computed from the complete, unculled data set. Indeed, Hoffman's own measures of extinction intensity, summarized in his Table 1, also show this if consistent patterns rather than random noise are sought. Ten of Hoffman's 43 stages exhibit peaks (local maxima) in more than half of the 21 metrics (including the unillustrated regression residuals for number of family extinctions per stage). The ten stages are the Guadalupian, Olenekian, Norian, Pliensbachian, Bajocian, Tithonian, Cenomanian, Maestrichtian, late Eocene and middle Miocene. Of these, all but the Olenekian, Bajocian and middle Miocene have been independently recognized as containing extinction events by palaeontologists using detailed biostratigraphic data on species and genera[3,5], and only one other stage (the Pliocene) in the Guadalupian-to-Recent interval has been so recognized. The probability that the family data would encompass 7 of 8 events in 10 random peaks among 43 stages is <0.00003, strongly indicating that the consistent peaks among Hoffman's metrics result from evolutionary variation rather than artefact. This conclusion is further supported by the good correlation between familial and generic[4,6] extinctions throughout the 43 stages. (For per cent extinction, $r = 0.893$ and for probability of extinction $r = 0.877$.)

Statistical tests similar to those used in our initial paper indicate that the 10 stages listed above exhibit a significant ($p < 0.002$) nonrandomness at a 26-Myr periodicity. Tests of this periodicity result in a standard deviation of differences between observed and expected peaks of 3.28 Myr using the Harland *et al.* timescale[7] and 5.53 Myr using the Odin timescale[8]; both fits are better than those obtained in our original analysis[2]. Fits with even higher significance are obtained if only the four most recent, and therefore most reliably dated[9], stages are tested[4].

Why did Hoffman conclude that the familial data appeared random with respect to extinction? It may have been because he used a necessary but not sufficient criterion for randomness. He argued that if random, the extinction metrics should display an average frequency of one peak in four stages; because our data displayed this frequency, he concluded that they were random. But there is a great difference between an average frequency of occurrence and a regular occurrence. A fair coin will, on average, come up heads once in two flips, but if it comes up heads regularly every other flip, we should suspect its fairness. In our analysis of the extinction data, our randomization test[2] actually converted the data into random walks with the same frequency of maxima as in the observed time series. Yet, when compared to these random walks, we found that the observed distribution of maxima was significantly ($p < 0.01$) more uniform than in the random walks. Thus, we rejected the hypothesis of randomness in favour of periodicity. We suggest that Hoffman might have done the same if he had performed the proper statistical tests.

HOFFMAN[1] and Hoffman and Ghiold[2] recently presented a statistical argument that has been widely regarded[3-5] as casting serious doubt upon Raup and Sepkoski's[6] proposed 26-Myr extinction periodicity. Here I show that their conclusion is false and reflects an incorrect application of their own neutral model. When properly applied, the model actually supports Raup and Sepkoski's position and underscores the need for a causal explanation.

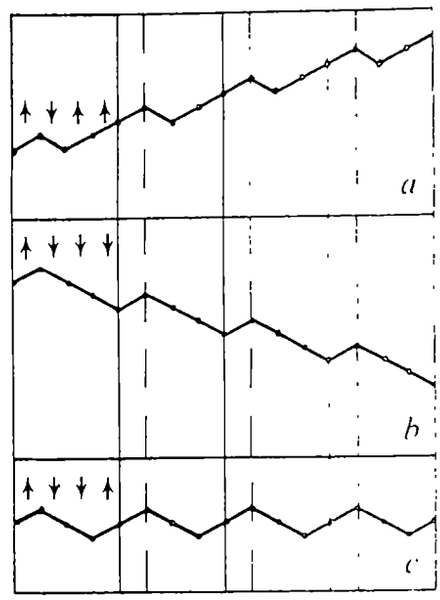

Fig. 1 The leftmost column shows the three ways of producing exactly one local extinction maximum in the second of a sequence of 4 stages. These are the unit sequences referred to in the text. Arrows indicate the direction of change (increase or decrease) in the extinction metric in each unit sequence. The unit sequences are repeated, producing three long periodic sequences of period 4. Although *a*, *b* and *c* each involve repetition of a single unit sequence, any unit sequence may follow any other and still create a periodic series. The magnitudes of the changes in extinction metric are ignored

Hoffman and Hoffman and Ghiold's argument is as follows:

(1) Given Raup and Sepkoski's definition of mass extinction as any local maximum of extinction metric; that is, any increase followed by decrease, and

(2) Given that the probabilities of increase and decrease in extinction metric both equal 0.5, and

(3) Given that the average stage length in the late Phanerozoic is 6.4 Myr, then the following conclusions hold:

(i) The probability that any particular stage is a local extinction maximum is equal to $(0.5)^2 = 0.25$.

(ii) Local extinction maxima are to be expected, on average, every four stages or every $4 \times 6.4 = 25.6$ Myr.

(iii) "The appearance of approximately 26 million year periodicity is inevitable."[2]

Conclusions i and ii are true. However, conclusion iii does not follow from premises 1-3 above and is false. The mistake is clarified by the following: Conclusion ii in more precise language, means that in a large number of samples of four stages, the arithmetic mean number of mass extinctions per sample will be 1. However, for an extinction pattern to be periodic with a period of four stages requires that every fourth and only every fourth stage

be a local extinction maximum. As these two statements are not equivalent conclusion ii does not guarantee an extinction periodicity of 4 stage-lengths, and the neutral model does not predict that a 26-Myr periodicity is "inevitable". Conclusion iii is false.

To calculate the probability of producing an extinction periodicity of 4 stage lengths by a random process under the neutral model, one must determine the number of ways of producing an extinction periodicity of this period that persists for n stages, and multiply this by the probability of generating any sequence n stages in duration. Let us treat a periodic sequence of period 4 and duration n as a series of unit sequences four stages in duration. In order for such a series to be periodic, each unit sequence in the series must have exactly one local extinction maximum, and these maxima must be in the same position. There are only three unit sequences that have the local maximum at the second stage (Fig. 1). Thus there are only three infinitely long periodic sequences of period 4 that can be built by infinite repetition of the same unit sequence. But since the conditions for periodicity allow any of the three unit sequences of Fig. 1 to precede or follow any other, it follows that there are exactly $3^{n/4}$ possible ways of producing a periodicity of period 4 with the extinction peak at the second stage. Because there are actually 4 different positions where the extinction peak may occur, corresponding to shifts of phase, there are a total of $4\times3^{n/4}$ possible periodic sequences of length n and period 4. The probability of generating any particular sequence of length n under the neutral model is 0.5^n; therefore the probability of generating an extinction periodicity of duration n and period 4 is $4\times3^{n/4}\times0.5^n$.

Applying this formula to the 39-stage periodicity reported by Raup and Sepkoski[6], the probability of an extinction event occurring every 4 stages (~26 Myr) under the neutral model is $4\times3^{39/4}\times0.5^{39}=3.3\times10^{-7}$. For a 43-stage periodicity, as proposed more recently[7], the probability is 6.1×10^{-8}. Thus the probability, under the neutral model, of the periodicity being a simple artefact of Raup and Sepkoski's definition of mass extinction and of the average duration of stratigraphic stages is essentially zero.

The neutral model, like all models, is an oversimplification of nature. Thus, even my exact solution is only an approximate assessment of the probability of producing the observed pattern by chance. In fact, the complexities of the real palaeontological record would render an exact analytical calculation of probability extremely complex, if not impossible. Accordingly, Raup and Sepkoski employ a non-parametric randomization technique to allow them to include real-world complexities implicitly in the approximation of a probability value. The neutral model and randomization yield consistent results, and both support the conclusion that the proposed periodicity is real and needs to be explained.

I thank I. J. Good for discussion of the probability calculation.

STATISTICAL testing, essential to the effective argument of controversies based on data and hypotheses, depends on distributions of random processes. Raup and Sepkoski[1] present data describing the ratio of marine families believed to have become extinct during each of 39 stratigraphic stages in the past 250 Myr. Ratios record the number of extinct to extant families, per stage, exclusive of families extant today or during the past 11.3 Myr. On the basis of these data, Raup and Sepkoski[1] have suggested that these extinction ratios have varied with regular periodicity. Hoffman[2] proposed a non-periodic random model, which formed the basis of his criticism of the work of Raup and Sepkoski. Hoffman's argument rests on the claim that the empirical mean time between peaks of extinction ratios reported by Raup and Sepkoski is not very different from the mean expected under this random model. However, the variance, and not the mean, tests the hypothesis of periodicity.

To compare the empirical variance with that expected under Hoffman's model, we have simulated the distribution of the statistic used to estimate variance, which should be the basis of Hoffman's criticism. The problem of the expected variance in the spacing of peaks, given this random process, can be restated as follows: what is the variance in waiting time to a reversal from increase to decrease in extinction ratio? For each time interval the extinction ratio either increases or decreases relative to the preceding interval. An interval of increase is recognized as a peak (that is, a local maximum in extinction rate) if the time interval immediately following is an interval of decrease. The number of time intervals between successive peaks (measured by counting the peak at the beginning and all time intervals until but not including the next peak) is the length of time, L, between successive peaks. In the data of Raup and Sepkoski[1] the lengths of these inter-peak times are: 2, 4, 4, 2, 2, 3, 3, 4, 5, 5, 4. The average of these lengths is 3.454, which would be the approximate period of the hypothesized periodicity.

To retain equivalency with the non-periodic random process described by Hoffman, we assumed, as he did, that (1) the probabilities of increase and decrease are equivalent and equal to 0.5, (2) the probabilities are independent, and (3) the time steps are of equal duration. To test whether extinction rate is a periodic function of time, we need to consider the distribution of the random variable L, its mean and variance, and the distribution of estimators of its mean and variance calculated from the sampling procedure used to observe the data of Raup and Sepkoski[1]. The distribution of L is

$$\Pr(L=r)=\sum_{i=1}^{r-1}(1-p)^i\,p^{(r-1)},$$

$$r=2,3,4,\ldots$$

When $p=0.5$, as suggested by Hoffman, the probability of an inter-peak time of r intervals is

$$\Pr(L=r)=\frac{(r-1)}{2^r}$$

The expected mean and variance of L are both equal to 4. Most of this distribution occurs in the inter-peak lengths 2–5, with frequencies of 0.25, 0.25, 0.19 and 0.125, respectively. If the observed inter-peak lengths are more uniform than would be expected under Hoffman's random hypothesis, this would support the idea that extinction rate is a periodic function of time. Thus, if the variance estimated from the data were significantly less than the value of this estimator of the variance of L expected under Hoffman's hypothesis, then periodicity would be supported; otherwise, periodicity would seem less plausible. The observed variance among the inter-peak lengths of the Raup and Sepkoski[1] data is 1.19. To determine its significance, however, we need to know the distribution of the variance estimates according to Hoffman's null hypothesis, based on a sequence of the same length as that observed, namely 40 time intervals (39 stages plus the assumption of a decline following the last datum).

To determine this distribution, we generated 10,000 such sequences with a random number generator. We observed the collection of inter-peak lengths for each sequence, calculated a mean and variance of these lengths, and empirically observed the distribution of these means and variances. The mean of the 10,000 sampled means was 3.966, very close to the mean of L. A non-significant one-sixth of the sampled means were less than the mean (3.454) observed in the data. Hence, Hoffman correctly asserted that the mean of the data is not significantly different from the mean expected under his hypothesis. But the mean of the 10,000

sampled variances (3.580) was less than the variance (4) of *L*. This is because rare, very long lengths are eliminated or made less likely by considering only sequences of 40 intervals and because short lengths are made slightly more common by requiring that the sequence end with a decrease.

The central purpose of this note is to determine the significance of the variance estimated from the data. Only 0.07 of the 10,000 sampled variances of inter-peak length under Hoffman's hypothesis were less than 1.19, the variance observed in the data of Raup and Sepkoski[1]. Our results verify statistically that the average spacing of peaks is not significantly different from the expected from Hoffman's random process, but show that the variance of spacing is sufficiently small to suggest that Hoffman's non-periodic random process is an inadequate explanation. The observed low variance in the Raup and Sepkoski data string can instead by interpreted to indicate that the pattern is more periodic than Hoffman's random model would imply. Our note is intended to show how statistics can better enable this controversy to be argued on the bases of data and hypotheses.

HOFFMAN REPLIES— Sepkoski and Raup disagree with my view[1] that 26-Myr periodicity of extinctions is only insufficiently demonstrated and may reflect an effect of stochastic processes. They argue that their more recent, as yet unpublished analyses of the complete, unculled data set on marine animal families and genera still indicate a significant 26-Myr periodicity. This result is not surprising, given the nature of their statistical test, the definition of extinction events as local maxima, and the geological timescale with approximately constant stage durations. In fact, it is precisely what should be expected if my arguments about the stochastic nature of the pattern of extinctions are correct. Genus-level data do not avoid the biases of the fossil record and the arbitrariness of taxonomic decisions.

Two other predictions made in ref. 1 appear to be confirmed by these more recent analyses. I suggested, first, that the test developed by Raup and Sepkoski[2] should not reject periodicity even if a few minor peaks are omitted; and second, that 35- to 40-Myr periodicity should appear in the Palaeozoic. As reported by Jablonski[3] and Rampino and Stothers[4], both these predictions have been confirmed by Raup and Sepkoski's new analyses.

Sepkoski and Raup now contend that my illustration of the variety of geological stages that appear to contain extinction events, depending on definition and timescale, in fact provides strong support for 26-Myr periodicity. They reach this surprising conclusion by identifying the stages which consistently (that is, in more than half of the examples I considered) stand out as peaks of extinction, and by subsequently analysing their distribution according to the timescales of Harland *et al.*[5] and Odin[6]. This procedure, however, is inappropriate. The majority of these examples are normalized for duration (and are thus strongly timescale-dependent) and each assumes a different timescale. The periodicity can be validly analysed only if the extinction rate is plotted against the timescale for which it was calculated (as in Fig. 1 of ref. 1). Moreover, my illustration assumes two different extinction processes. If the process of family extinction is viewed as possibly continuous rather than necessarily catastrophic, and hence if time normalization of extinction data is required, then the Coniacian and Rhaetian show up as peaks more consistently than the Cenomanian and Norian. The pattern of variation illustrated in ref. 1 does not represent statistical noise but mutually incompatible assumptions. Therefore, its statistical analysis as a single sample is meaningless.

Sepkoski and Raup's contention is also based on factually incorrect premises. Contrary to their assertion, I did illustrate peaks of the number of family extinctions per stage (*B* in Table 1 of ref. 1). One is therefore left with 20 (instead of Sepkoski and Raup's 21) patterns of extinction. The Barremian and Ladinian show peaks as consistently as the Cenomanian and Norian. These two stages—and also the Pliocene, explicitly acknowledged by Sepkoski and Raup as a major event—should also be included in their list of presumed extinction events. Contrary to their other assertion, this list does not include all events recognized by palaeontologists in the late Permian—Quaternary interval. The Toarcian (rather than Pliensbachian) event was identified by Hallam[7], and Sepkoski[8] cited additional preliminary evidence. The Callovian (ref. 9 and W. Brochwicz-Lewinski, personal communication), mid-Oligocene[10,11], and of course Pleistocene[12] have also been cited as extinction events. On the other hand, the late Eocene event is strongly contested even as regards the marine plankton[13], the only group that, according to Sepkoski[6], experienced at least fairly severe extinction at that time.

Finally, Sepkoski and Raup argue that the pattern of family extinctions deviates significantly from randomness. Their original test, however, involves randomization of the extinction pattern within the constraints of the definition of extinction events as local maxima and the timescale with approximately constant stage durations[2]. That these constraints are not trivial is clearly indicated by the fact that, whether the extinction data were all assigned to the beginnings, the mid-points, or the ends of individual stages, the periodicity was essentially the same[2]. This is possible only with constant stage durations. Otherwise, discordant shifts in the timing of events would affect the pattern of temporal relationships among events. Thus, the random distribution generated by Raup and Sepkoski is inherently biased. It is artificially truncated and its variance is smaller than it would be in a truly random model of the temporal distribution of peaks of extinction. Consequently, it is inadequate for testing my proposed hypothesis of randomness.

It takes only a glance at the pattern of peaks in family extinctions per stage[14] to see that it is not perfectly periodic. Therefore, Gilinsky misses the point of the argument when he calculates the infinitesimally small probability of a random walk yielding a perfectly periodic pattern. Precisely the same mistake was made by Gould[15]. (Gilinsky, however, correctly points out that Hoffman and Ghiold's[14] statement about inevitability of "the appearance of approximately 26 million year periodicity" may suggest an incorrect conclusion; we should have emphasized more strongly the words "appearance" and "approximately".) The question to be addressed is not if a perfect periodicity is likely to be produced by random walk, but rather if the approximate periodicity observed in the fossil record is sufficiently close to perfect regularity that it is unlikely to be produced by random walk. A world of difference distinguishes these two questions. I suggest that available statistical tests are insufficiently

sensitive to reject the hypothesis of randomness in this case.

In fact, Kitchell and Estabrook tested in a rigorous fashion the appropriate null hypothesis. Given their result that 7.9% of 10,000 random walks appear more periodic than the actual pattern of extinctions, one may conclude that my model is not unlikely to provide an adequate explanation for the empirical pattern.

As explicitly stated in my original article, there may be periodicity in late Permian to Quaternary extinctions, but the evidence is as yet insufficient. On the basis of my analysis, which is now confirmed by Kitchell and Estabrook's result, I concluded that I could not reject the hypothesis of randomness of the pattern of extinctions. I suggest that Raup and Sepkoski might have done the same if they had considered the appropriate null hypothesis.

Endocast morphology of Hadar hominid AL 162–28

ACCORDING to Falk[1], the endocast morphology of the Hadar hominid AL 162-28 is ape-like, contrasting with Holloway's[2] original conclusion that this specimen exhibits important human-like cortical features. We contend that Falk's interpretation is the result of a major error in her orientation of the endocast.

A comparison of Falk's Fig. 1 (redrawn here as Fig. 1*a*) with a photograph of the AL 162-28 calvaria in norma lateralis (Fig. 1*b*) demonstrates Falk's error. In her orientation, the middle arched portion of the squamosal suture, clearly identifiable on the calvaria (SS in Fig. 1*b*; see also ref. 3), lies below the level of asterion, and the planum occipitale faces almost directly superiorly with the planum muchale almost vertical. Clearly, this combination of features does not characterize any normal hominoid cranium (nor is it found in any other hominid crania from Hadar or elsewhere), and it is apparent that the endocast must be rotated some 40° in a clockwise direction to achieve correct anatomical orientation. When this is done, the cerebellar fossae are tucked under (and are rostral to) the occipital poles, as in all hominids and almost all apes. Falk[4] has defended her orientation by citing Kimbel[3] to the effect that the cerebellar fossae are deeper than the cerebral fossae. Correcting the specimen's orientation, the cerebellar fossae are deeper, but certainly not more posteriorally projecting, a position Kimbel never claimed.

Figure 1 indicates Falk's identification of the cortical features on the endocast.

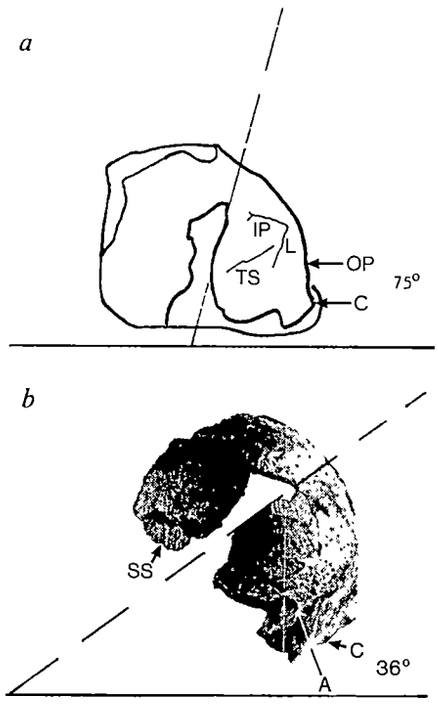

Fig. 1 Diagrams showing the error in Falk's[1] orientation of the Hadar AL 162-28 endocast. *a*, A tracing from Falk's Fig. 1; *b*, a lateral view of the AL 162-28 original cranial fragment correctly oriented. The difference between the two orientations is approximately 39° as measured from the dashed lines intersecting the horizontal planes, using the notch created by the missing bone as a landmark. Falk rotated the endocast 39° in an anticlockwise direction, thereby erroneously positioning the cerebellar lobes posterior to the occipital poles of the cerebrum. SS, squamosal suture; A, asterion; C, cerebellum; OP, occipital pole; IP, interparietal sulcus; TS, the superior temporal sulcus, and L, the lunate sulcus are Falk's designations[1].

The rostral position of the lunate sulcus (L in Fig. 1*a*) is said to be an ape-like condition. When the endocast is correctly oriented, however, L (as identified by Falk) crosses the posterior aspect of the endocast in a more caudal position than on ape brains[5]. The relative caudal location of Falk's L is confirmed by its close proximity to the occipital pole (OP); the distance between L and OP on the AL 162-28 is approximately half that separating these structures in a sample of 10 chimpanzee brain casts (the hominid falls 5.5 s.d. below the ape mean), despite the fact that eight of these brain casts have volumes less that the 375-400 cm^3 estimated for the Hadar endocast, including one chimpanzee infant. (See data in ref. 6, in which the distance from the interparietal sulcus (IP) to OP is the same as the OP-L distance.)

The lambdoidal suture is discernible on the internal aspect of the Hadar calvaria[3], where, on both sides, it is 2 mm (not 5 mm, as claimed by Falk[1]) below the feature corresponding to Falk's L. We suggest that Falk's L may be a manifestation of the lamboidal sutural complex which is frequently reproduced on chimpanzee endocasts as a distinct furrow (feature 'x' in ref. 7). Holloway[2,6] recognized the likelihood that feature 'x' masks the position of L on the AL 162-28 endocast. We do not, therefore, believe that L can be identified unequivocally on this specimen. But if Falk is correct in her identification of the lunate sulcus, and does accept Holloway's[2] identification of the interparietal sulcus, then both the correct orientation of the specimen and metric data[6] confirm that this structure occupies a caudal position on AL 162-28, a major derived hominid condition.

FALK REPLIES—Holloway and Kimbel claim that my interpretation of the sulcal pattern of AL 162-28 is due to an error in the orientation of the endocast because "in her orientation, the middle, arched portion of the squamosal suture, clearly identifiable on the calvaria . . . , lies below the level of asterion . . .". Kimbel *et al.*'s photograph of the left side of the calvaria shows neither the apex of the squamosal suture nor the external (temporal bone) portion of that suture[1]. What it does show is a 13.5 segment of the temporal margin of the parietal bone that is, by their own description, *posterior* to (where) the apex of the squamosal suture (would have been). Furthermore, because of overlap at the squamosal suture, the temporal margin of the parietal bone which is present in AL 162-28 would have been *below* the external (temporal bone) portion of the squamosal suture. Unfortunately, "a long, narrow strip of external table is lost just above the left parietal's temporal margin"[1]. Neither the squamosal suture nor asterion is reproduced on the endocast, and I do not think the calvaria of AL 162-28 is complete enough to allow speculation about where the locations and relative positions of both features would have been on the (whole) endocast. Even if Holloway and Kimbel's SS and A identifications (Fig. 1*b* above) could be

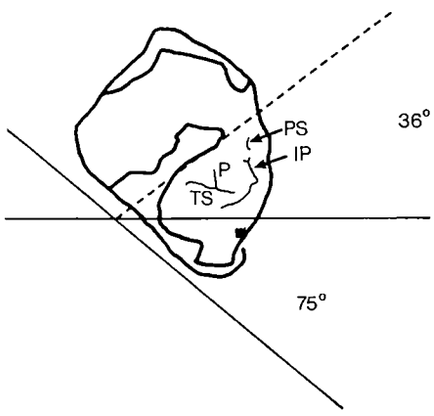

Fig. 2 Holloway and Kimbel's Fig. 1*a* rotated to correspond to their preferred orientation. Such an orientation for the sulci on AL 162-28 is unlike that seen in other primates. On the other hand, the configuration of these sulci oriented as in Fig. 1*a* is common for primates. PS, superior parietal sulcus; P, superior parallel branch of TS; other abbreviations as for Fig. 1*a*.

interpreted and projected onto the endocast as they suggest, given the overlap at the squamosal suture and the variation of its course in hominoids, there is ample room for forward rotation of their calvaria within the normal hominoid range. (Walker *et al.*[2] describe a hominid cranium with a vertically oriented planum occipitale, which is what I believe Holloway and Kimbel meant by the planum occipitale facing almost "directly superiorly".)

More to the point, I have rotated Holloway and Kimbel's Fig. 1*a* to correspond to their preferred orientation, and traced the sulci back on to my original[3] Fig. 1 (see Fig. 2). The angle of the intraparietal sulcus (IP, an identification on which Holloway and I agree) is nearly vertical, whereas the angle of the superior temporal sulcus (TS, not mentioned by Holloway and Kimbel) is nearly horizontal. This combination of sulci does not occur in this orientation for primates[4], but this combination of sulci in the orientation shown in Fig. 1*a* is common for primates[4]. The question of orientation of sulci is not to be dismissed lightly, since Radinsky[5] has shown that the issue of direction and orientation of sulci is fundamentally important for primate brain evolution (especially the origin of anthropoids).

If I am correct in my observations, then Holloway and Kimbel's statistics on distances between points on the endocast are not useful since all of them would depend on an incorrectly identified occipital pole (OP) (if one is used which is consistent with Holloway and Kimbel's orientation of the endocast). The OP which I have identified, on the other hand, does not project as far caudally in this specimen as it does in most hominoids. This alone would account for shortened distances. Furthermore, absolute distances should not be used to refute a chimpanzee-like sulcal pattern; ratios would be better.

Holloway and Kimbel contend that the feature I identify as the lunate sulcus (L) may be a groove cuased by lipping at the lambdoid suture, and they cite LeGros Clark's[6] study of six chimpanzee brains and corresponding endocasts to support their contention. I have shown that the course of the lambdoid suture (determined from its traces and their relationship to ridge X on the endocast that corresponds to the nuchal crest) runs 5 mm caudal to the feature I identify as L on AL 162-28 (Fig. 1 of ref. 3). Holloway and Kimbel say (above) that the lambdoid suture is 2 mm rather than 5 mm below the feature I identify as L. I have repeated my analysis and again find the distance to be 5 mm. How can this feature be due to lipping of a suture that is 5 mm behind it? Furthermore, how can Holloway and Kimbel attribute a 'groove' on an endocast to a skull suture which is so smooth and obliterated that it can be traced only with difficulty[1]?

Both the lunate sulcus and a groove due to the lambdoid suture may be reproduced on endocasts of chimpanzees[6] and presumably on those from early hominids. How are we to decide which of these two features is the disputed feature on endocast AL 162-28? As noted above, the feature in question cannot be due to lipping at the lambdoid suture because that suture is 5 mm away and because the suture does not lip in this specimen, that is, it is so smooth it is almost obliterated.

On the other hand, the feature in question merges with the intraparietal sulcus (IP in Fig. 2), as does the lunate sulcus in *Pan*; it is rostral to the lambdoid suture, as is the lunate sulcus in *Pan*; and has a sulcus-like texture and shape similar to the lunate sulcus in *Pan*. I therefore believe that the feature in question on AL 162-28 is a lunate sulcus that is similar to those seen in brains of chimpanzees, a finding that is consistent with the entire sulcal pattern that is reproduced on the endocast of AL 162-28.

Maternal investment in mammals

IN a recent paper Martin and MacLarnon[1] claim to clarify the allometry of neonatal size and gestation period of mammals, attributing particular importance to the distinction between altricial and precocial taxa. In addition, Martin and MacLarnon suggest that maternal investment, as reflected by a fetal growth parameter, is higher for altricial than precocial mammals. Unfortunately, we find that such conclusions are not warranted and propose that other interpretations are possible.

We are confused by Martin and MacLarnon's definition of maternal investment. They suggest that altricial mammals have high maternal investment indicated by high fetal growth "factors", with precocial mammals having the opposite traits. Yet, in mammals bearing altricial young, overall maternal investment at birth actually is low: gestation periods are relatively short[1,2] and neonatal weights are typically low[1]. Hence, it confuses the issue to say that high fetal growth rates are indicative of high maternal investment. Using different measures of parental investment is revealing[3]. However, we maintain that the neonate's developmental status and the time and energy put into it are the most important criteria in evaluating maternal investment at birth.

Also, we cannot accept their definitions of altricial and precocial: precocial mammals are those with a litter size less than 1.5 and eyes open at birth; altricial mammals have litter sizes equal to or greater than 3, and the eyes are closed at birth. Taxa that do not conform to either of these criteria are placed in an "intermediate" group. Even humans, which are highly altricial[4], would be classified as precocial by such standards. We[2] and others[5] have experienced difficulty classifying neonates as altricial versus precocial because these categories are discrete and arbitrary, whereas in reality mammalian species occur along a continuum of developmental maturity at birth. In a previous study of the relationship between maternal investment at birth and mating systems in mammals, we at first used definitions from the literature to classify a species as altricial or precocial. However, because of problems with a simplistic 'either/or' categorization scheme, we subsequently used several relative measures of maternal investment at birth instead[2]. One of these measures, neonate weight/litter size standardized for body weight, is useful as it describes investment in an individual neonate relative to the number of siblings it shares that investment with. Indeed, we found that 78% of mammals with litter sizes of ≤ 2 bear precocial young and 87% of those with at least 3 young have altricial offspring. Yet, this does not imply that

litter size should be a criterion for classification of neonate development.

Classifying species as altricial versus precocial based on differences in litter size introduces a serious confounding effect not discussed by Martin and MacLarnon[1]. In particular, we note that fetal growth parameters for precocial taxa are essentially standardized for constant litter size as most of these taxa have only one young per litter (by Martin and MacLarnon's definition). By contrast, we find a great variability in litter size among altricial species (again, using their definition). That litter size is inversely correlated with adult body size among mammalian species[6-8] confounds Martin and MacLarnon's analysis of how fetal growth relative to body size differs between altricial and precocial species. A larger litter size results in each individual offspring obtaining a relatively smaller fraction of the mother's total parental investment at birth[9]. Growth rates of such offspring might be comparatively high simply to increase survivorship.

If a more rigorous consideration of neonatal status is used[2-4], the discreteness of altricial and precocial taxa is not as great as suggested by Fig. 1 of ref. 1. Related to this, we find the legend to Fig. 2 inappropriate because it is not obvious that an "overall best-fit line of fixed slope 0.1" essentially constitutes a linear discriminant function between the 'altricial' and 'precocial' taxa. Their discriminant function with a 0.1 slope is as effective with a slope of 0; there are about five misclassified points using either slope. This suggests that Martin and MacLarnon's altricial and precocial categories are more explicitly defined as groups of short versus long gestation period. Realization of this leads us to question seriously the relevance of Martin and MacLarnon's use of this 0.1 slope as an allometric coefficient, as in their equations (6) and (8)[1], since it has no biological basis.

Allometric pattern is often presumed to reflect physiological constraints to life history alternatives. Although we recognize that such constraints certainly exist, we caution that sampling bias might be present because the representation of mammals of various body sizes is seldom independent of environmental variation. Large mammal species are most numerous in regions of pronounced seasonality[10]. We suggest that natural selection may favour rapid growth rates in highly seasonal environments to ensure that the young attain adequate size during the limited growth season to enhance survival through the oncoming winter or seasonal drought. This implies that environmental seasonality selects for a suite of life-history attributes which increase survival during periods of resource shortage, but which capitalize on abundant resources during the growth season[11,12]. Such a sampling bias may well account for the positive correlation between "fetal growth factor" and body mass as described by Martin and MacLarnon[1].

MARTIN AND MACLARNON REPLY— The points raised by Zeveloff and Boyce indicate the need for further clarification of issues raised by our paper[1], and we are glad of the opportunity to comply.

There is, indeed, potential confusion surrounding the definition of 'maternal investment'. In our paper, we implicitly used this term in relation to the mother's investment per unit time in the growth of an individual fetus. In order to convert this to total investment per unit time during pregnancy, it would, of course, be necessary to multiply each fetal growth factor by litter size for the species. Thus, the distinction between altricial and precocial mammals in this respect is far more marked than indicated in our Fig. 3. However, we recognize that maternal investment could be defined as total investment in individual neonates, regardless of the time over which the investment is spread. By such a definition, mothers clearly invest more in precocial neonates than in altricial neonates. We would defend our definition on the grounds that it relates to the mother's division of her total resources (which are heavily influenced by her body size) between reproduction and other functions during pregnancy. Clearly, accurate calculation of total maternal investment by any definition would require data on lifetime reproductive performance.

The double criterion that we used to define altricial as opposed to precocial mammals (combining time of eye opening and litter size) was a quantitative translation of two features originally emphasized by Portmann[2] in his pioneering studies separating '*Nesthocker*' from '*Nestflüchter*' in both birds and mammals. While we accept that some gradation exists (and, in fact, we allowed for it in our paper—intermediates), the important point is that a clear bimodal distribution among mammals emerges when gestation period is considered in relation to body size, closely matching the distinction between altricial and precocial categories. Incidentally, although human infants are often described as 'altricial', they are precocial both by Portmann's definition and by ours. It has been shown that the relative helplessness of the human neonate is a special condition, unique among mammals, related to an unusual pattern of postnatal brain development[3,4].

The fixed slope value of 0.1 used to derive the histogram in our Fig. 2 was initially determined by the average empirical value for major mammalian groups with a single neonate type (our Table 1). The iterative technique reported was used as an additional approach, primarily to investigate the distributions of residuals generated with different slope values. As Zeveloff and Boyce point out, altricial and precocial mammals (as defined by us) are to a large extent separated by gestation period even without taking maternal body size into account (that is, slope value of 0). This, surely, is one of the most convincing indications that there is an underlying split between altricial and precocial mammals. The histogram of residuals in fact becomes trimodal when a slope value of 0 is used for all gestation periods, as certain large-bodied altricial mammals (for example, some carnivores) overlap with certain small-bodied precocial mammals (for example, some primates, and some hysticomorph rodents). This overlap is largely eliminated when a slope value of 0.1 is used, and an order-by-order analysis of residuals (unpublished) shows that the resulting pattern is entirely in accord with Portmann's interpretation of the altricial/precocial division.

As Zeveloff and Boyce themselves produce a separation of mammals into two groups that are 80% in agreement with our altricial/precocial division, despite an entirely different approach, there would seem to be an underlying biological reality in such distinctions, regardless of any disagreement about finer details. It is important that debate about the details should not obscure this fact.

ANNOUNCING

MOLECULAR BRAIN RESEARCH

A section of Brain Research devoted to the publication of molecular studies.

Editor-in-Chief:

D. P. Purpura,
Brain Research, Office of the Dean, Albert Einstein College of Medicine, 1300 Morris Park Avenue, Bronx, NY, U.S.A.

The powerful techniques and approaches of molecular biology have greatly enriched brain research in recent years. The wide application of recombinant DNA technology, monoclonal antibody production, molecular analysis of receptor – ligand interactions and ion channel mechanisms have generated a wealth of data bearing upon fundamental processes underlying the structure and function of nervous systems. Indeed it is anticipated that reports dealing with the application of molecular biological techniques will increase greatly over the next few years and require appropriate recognition and organization. Cognizant of the need to make such interpretations available to the readership of **Brain Research,** we are pleased to announce publication of a new section of **Brain Research** entitled **"Molecular Brain Research".** This decision carries with it awareness of the rapid progress in molecular biology of the nervous system as well as the desirability of encouraging the focus of molecular biological research on brain mechanisms.

Aims and Scope
Molecular Brain Research is a special section of **Brain Research** which provides a medium for the prompt publication of studies of molecular mechanisms of neuronal, synaptic and related processes, that underlie the structure and function of the brain. Emphasis is placed on the molecular biology of fundamental neural operations relevant to the integrative actions of nervous systems.

Subscribers to Brain Research automatically receive this section.

Reader Service No.24

Molecular dynamics resolved

from David D. Thomas

Time-resolved optical and magnetic resonance techniques offer complementary views of large-scale cooperative molecular motions within macromolecular assemblies.

ONE of the most exciting trends in biophysical chemistry is the increasing emphasis on understanding, quantitatively, the role of molecular motions in biological function. While much of the study of molecular dynamics has focused on small-scale intramolecular motions on the picosecond or nanosecond time scale, it is increasingly apparent that the large-scale motions within assemblies such as membranes and chromosomes are crucial to the understanding of cellular biophysics. This article presents an overview of recent advances in the technology for probing rotational molecular motions in the microsecond time range. The discussion will address the two most effective techniques: transient optical anisotropy and saturation transfer electron paramagnetic resonance (ST-EPR).

Both of these techniques rely on the use of extrinsic spectroscopic probes with excited-state lifetimes in the microsecond to millisecond time range[1]. The optical probes are mainly derivatives of eosin or erythrosin, organic dyes that have efficiently populated and stable triplet states. The paramagnetic probes are nitroxide spin labels.

Each experiment begins with a pulse of exciting radiation that causes a transient decrease in the number of ground-state probes available for subsequent excitation. This pulse of radiation is delivered so that it selectively excites molecules with a particular orientation in space ('photoselection'), and the sample's absorption or emission is monitored with the same orientational preference. The system re-equilibrates as excited probes return to the ground state; the recovery is accelerated by rotational motion that brings unexcited molecules into the detectable orientation range. Of course, rotational motion is detectable only if it occurs within a time comparable to or less than the excited-state lifetime of the probe — hence the need for μs lifetimes in the study of μs motions.

Optical anisotropy

An example of the optical data for transient absorption anisotropy (TAA) is shown in Fig. 1. The instrument used in this experiment has evolved from those designed by R. Cherry and others in the 1970s[2-4]. In this case, a nitrogen-pumped dye laser excites the sample with an intense vertically polarized 5-ns pulse, and a low-intensity beam from an argon-ion laser is used to monitor the time-resolved recovery of the polarized absorption following the pulse. The fast transient digitizer (LeCroy 2256, 50 ns/time point) permits high time-resolution, while the high-repetition-rate (200 Hz) pulsed laser (Lambda-Physik EMG-53MSC), along with a microcomputer-controlled direct-memory-access (DMA) circuit (LeCroy 3500) permits very rapid data acquisition and signal averaging, minimizing the time required for high-quality data acquisition. Although this particular configuration was constructed of commercially available components[1,5], an instrument that approaches some of its capabilities is available from PRA (London, Ontario).

The function plotted in Fig. 1 is the absorption polarization anisotropy, whose exponential decay constants (rotational correlation times) and amplitudes are related directly to the time constants and amplitudes of molecular rotational motions[1,5,6]. Similar experiments probing emission instead of absorption do not usually achieve the same high time resolution because the laser pulse interferes with detection. But emission studies offer sensitivity sufficient to study extremley small samples, possibly even single cells[7].

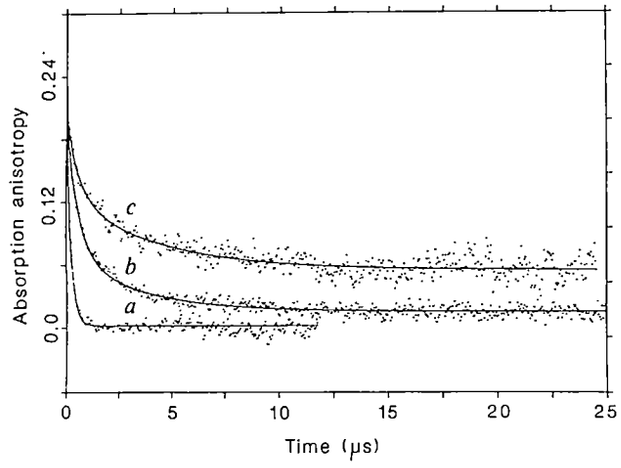

Fig. 1. Transient saturation transfer EPR (saturation recovery) data from maleimide-spin-labelling haemoglobin solutions corresponding to the rotational correlation times τ. The bottom trace in each case is the motion independent recovery, governed by T_1, and the top trace shows the increase in the recovery rate when the effects of rotational motion are included[8].

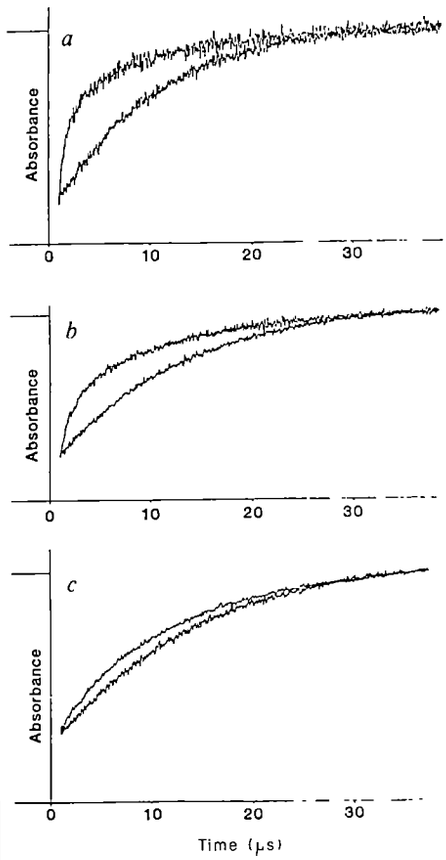

Fig. 2. Transient absorption anisotropy data from eosin-iodoacetamide attached to myosin heads in (*a*) the proteolytically isolated head (S-1), (*b*) the intact myosin monomer, and (*c*) myosin filaments (several hundred myosin molecules self-assembled essentially as in a muscle fibre)[5]. Note that the rate and amplitude of decay are much less in the filaments, indicating that the microsecond segmental protein motions have been restricted in both rate and amplitude.

Saturation recovery EPR

As in optical spectroscopy applications, EPR experiments involve transient absorption, which is often referred to in magnetic resonance as saturation recovery or as pulsed saturation transfer EPR, since rotation transfers saturation away from the irradiated spins.

In EPR the exciting radiation is a microwave pulse from a klystron. Photoselec-

tion arises because spin labels with different orientations absorb at different frequencies[1,7]. This selectivity is more specific than that conferred by optical spectroscopy. Because EPR is an inherently weaker effect than optical absorption, rapid data acquisition and signal averaging (at thousands of transients averaged per second) are even more important[8]. A key element in this instrument is a loop-gap resonator, a device that facilitates the use of intense microwave pulses in EPR spectroscopy[9].

A pulsed EPR spectrometer[8] with increased sensitivity was recently developed which expands the range of biological samples that can be studied. Many of the components of this instrument are now commercially available, but commercial systems (from IBM Instruments/Bruker) still fall considerably short in terms of sensitivity and signal averaging rate. Figure 2 illustrates the sensitivity of pulsed ST-EPR to microsecond rotational motion[10]. When the motion is slow on the microsecond time scale (Fig.2*c*) it has very little effect on the absorption recovery, which occurs with a time constant equal to the relaxation time (excited-state lifetime) T_1. However, sub-millisecond correlation times result in dramatic increases in rate of recovery (Fig.2 *a*,*b*).

In both EPR and optical spectroscopy, time resolution increases the range of motions and systems that can be studied and decreases the ambiguity of data interpretation. While optical spectroscopy has better absolute sensitivity (and can therefore be used to study smaller amounts of material), EPR offers the advantage of orientational resolution[11]. Thus, a pulsed EPR experiment on a macroscopically oriented system (for example, parallel muscle fibres or stacked membranes) offers the potential for unequaled resolution and accuracy in the elucidation of large-scale motions involved in the function of biological assemblies.

David D. Thomas is in the Department of Biochemistry, University of Minnesota Medical School, Minneapolis, MN 55455 USA.

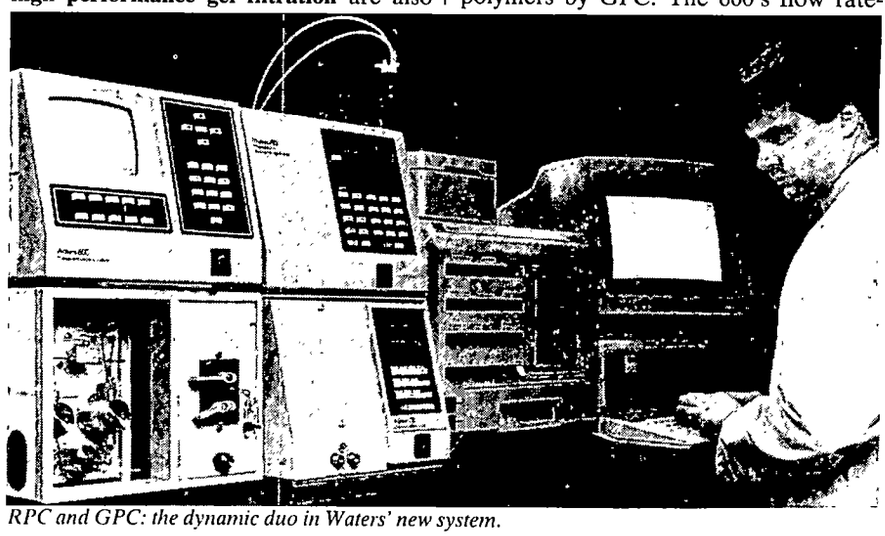
Biochemists converge at the capital

Washington, DC is the host city for the ASBC meeting this year. Almost 200 exhibitors will be competing for the attention of conference visitors.

TIME-resolved **fluorescence detection** can reveal the dynamics of molecules kept in solution or embedded in membranes and proteins. The GREG 200 from ISS Inc. is a multi-frequency cross-correlation phase and modulation fluorometer with the capability to perform such analyses (Reader Service No. 100). Displayed at booth B32, the instrument uses lifetime measurement ranges from a few picoseconds to one millisecond to unravel complex decay processes. With the aid of a dedicated PC, ISS's fluorometer can solve multi-exponential and non-exponential decays; phase- and modulation-resolved spectra allow the separation of spectral components from a mixture of several emitting species with overlapping bands. The GREG 200 will also provide time-resolved spectra in three dimensions, with time along the *z* axis. ISS can say more about their machine at their ASBC booth.

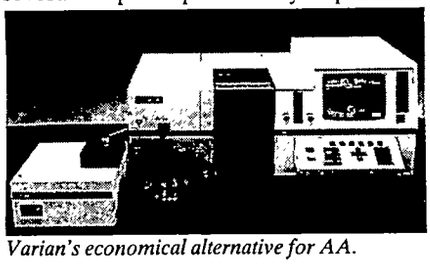
Pharmacia have filled out their chromatography products with two more additions to the family. The MinoRPC S 5/20 is a **reversed-phase column** designed for the gradient or isocratic separation of small biomolecules, including amino acids and nucleotides (Reader Service No. 101). The bonded phase affords selective recovery of such molecules due to an end-capping process which, Pharmacia claims, also makes column results highly reproducible.



Two preparative-grade matrices for **high performance gel filtration** are also being offered by Pharmacia to scale-up their prepacked Superose 6 HR 10/30 and 12 HR 10/30 columns (Reader Service No. 102). The new, rigid Superose 6 and

Pharmacia's scale-up matrices.

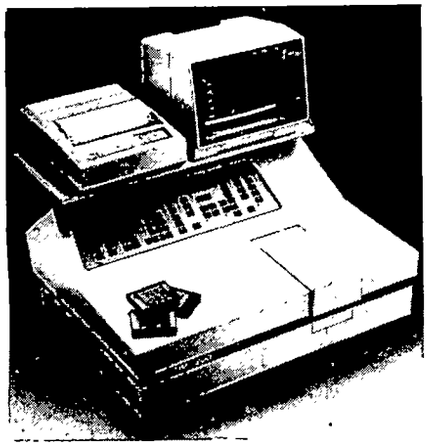
Superose 12 prep grades are based on 30 μm agarose beads, stable from *p*H 2 to 14. With Pharmacia's scale-up grades, preparative separations can be achieved in a few hours. The Pharmacia divisions represented at ASBC will be in the area of booths E46 – F51.



Combining reversed-phase gradient chromatography and detection modules, Waters has created a **gel permeation chromatography** (GPC) system with isocratic or gradient operation, programmable UV detection and stable refractive index (RI) detection (Reader Service No. 103). With the Waters 600 gradient module, the GPC system can analyse additives and low-molecular-weight polymers by gradient RPC, then perform molecular weight determinations for larger polymers by GPC. The 600's flow rate-

RPC and GPC: the dynamic duo in Waters' new system.

control is accurate to ±0.5 per cent, and its gradient composition will conform to specifications within ±0.15 per cent. The two detectors in the GPC III system are the Waters 490, which can optimize spectroscopic information for analyses between 190 and 600 nm, and the 410, which carries out refractive index detection. As an option to their new machine, Waters has the 840 data and chromatography control station with Expert software. The package will provide several types of calibrations, processing and storage of GPC data. Waters are showing in the area between booths G46 and H51.

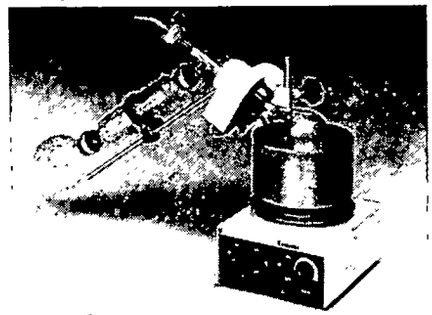


Varian, at ASBC in booths G63 through G70, have recently released several spectrophotometry products

Varian's economical alternative for AA.

including a lower-cost version of their SpectrAA 30/40 series **atomic absorption spectrophotometers.** The new SpectrAA 10 single-beam and the double-beam SpectrAA 20 have retained several automation features of the earlier models, such as centralized control for the automatic sample changer and the GTA-96 graphite furnace (Reader Service No. 104). But the SpectrAA 10/20 series machines can sell for as much as £10,000 (UK) less than the 30/40 series counterparts. A single keyboard ties in to all system components and allows access to the measurement and system control software. Method development and instrument set-up procedures can be stored on the instrument's floppy disk.

Plug-in modules for Varian's latest **UV-vis spectrometer** will make the machine more flexible for individual



The DMS 200, with more modules in store.

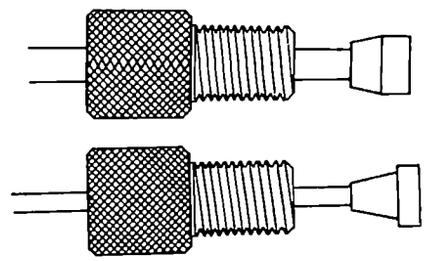
analytical needs (Reader Service No. 105). The first such module offered has a soft-key menu that enables the user to construct data and mathematical routines for calculating final results from raw data. This so-called scan application module includes built-in functions such as spectral subtraction/addition/division, absorbance ratio, peak area and multi-wavelength and dilution correction calculations; stored instrument parameters can be linked with calculation routines to create methods for specific applications. The £8,000 (UK) DMS 200 can then present final results on a high-resolution plotter.

A **compact scintillation counter** from Integrated Genetics fills the niche between low-cost survey meters and high-volume counting instruments that can cost up to $35,000. The Gene-Trak beta detector directly measures beta particle emissions from samples on membrane filters (Reader Service No. 106). The system was designed to complement Integrated Genetics's *Salmonella* hybridization assay, but many researchers working with DNA and ^{32}P may find the Gene-Trak works well in their experimental regime. Gene-Trak's maker says its counting efficiency compares with that of large-scale instruments, yet their instrument costs less to purchase and operate. Integrated Genetics sells Gene-Trak at $3,600 (US).

Biochemical side-kicks

For small-scale evaporation, reflux or off-distillation, Haake Buchler makes a **micro rotary evaporator** with variable speed

Small-scale evaporation with a twist.



between 80 and 200 r.p.m. (Reader Service No. 107). The adjustable speed allows effective evaporation of viscous liquids; an inlet tube which feeds to the evaporation flask removes the need for operator intervention. Haake Buchler's evaporator comes with a stainless steel bath and complete set of glassware (evaporating flasks in 50, 100 and 250 ml sizes, with corresponding receiving flasks) for less than $1,200 (US). The entire unit measures 200 mm width × 235 mm depth × 165 mm height. At ASBC, Haake Buchler will have more information in booths G16 through G20 even.

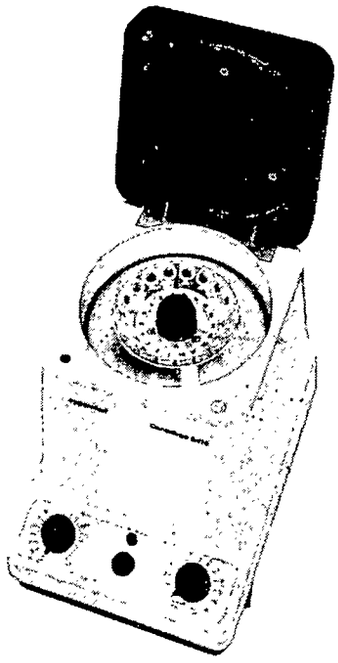
Two equipment companies have recently tackled problems with Teflon tubing. Zeus Industrial Products invites custom designs for multi-lumen subminiature tubing (Reader Service No. 108). The company can manufacture **Teflon tubing** with two or more constant-diameter, continuous-length passages in a range of internal and outer diameters. Such tubing is flexible, impervious to most corrosives, inert, non-toxic and heat-resistant up to 500°F. Zeus's prices vary for standard ready-made and customized tubing.

Customized lumen configurations from Zeus

Upchurch Scientific have developed flangeless fittings for Teflon and plastic

Ferrules replace flanging.

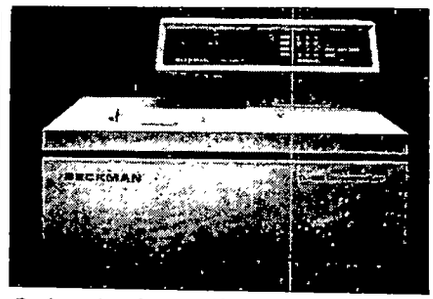
tubing that can be directly substituted for all flange-type fittings (Reader Service No. 109). These fittings consist of a Tefzel ferrule, which slides onto the end of the tubing, and a Delrin male nut which must be finger-tightened. Upchurch's fittings are compatible with ¼-28 or metric threads. The ferrule for 1/16-inch tubing holds to over 1,000 p.s.i., and the 1/8-inch ferrule is good for over 500 p.s.i., according to Upchurch. The fittings go for less than $4 (US) each.



Another brand of **acrylamide** has become available to biochemists: this one, from Serva Fine Biochemicals (Reader Service No. 110). Serva maximize their product's stability by packaging it in nitrogen and storing it at −20°C. Servalyt Precotes, Serva's 0.1 mm precast gels, are made from the same acrylamide, which Serva is now offering for home-made gels at $27 (US) per 100 g bottle.

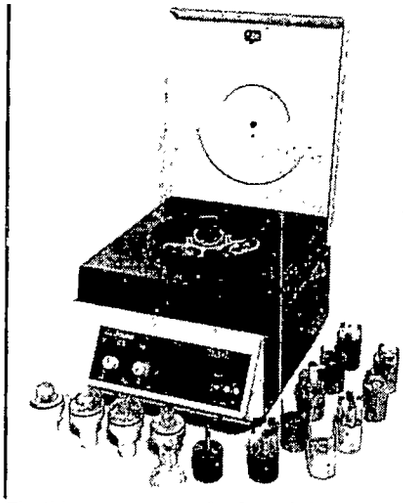
Hamilton's PB600 **dispenser** can be fitted with syringes of different sizes to yield repeated volumes, each 2 per cent of the syringe capacity (Reader Service No. 111). Depending on syringe size, the instrument's range of volumes extends between 0.5 µl and 200 µl. Fitted with

Hamilton's LT syringes, the dispenser-syringe unit is autoclavable at 121°C; alternatively, the dispenser can be attached to an adaptor that enables standard disposable tips to be used. Hamilton will be located at booth G23 at ASBC to answer questions on this and other products.



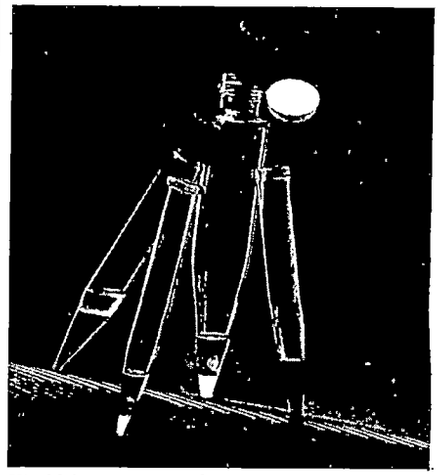
Bench-top varieties

An updated version of the Eppendorf **microcentrifuge** came from Brinkmann this year. The new model 5415 can accommodate up to eighteen 1.5-ml microcentrifuge tubes, or accept adaptors which expand its capabilities to 250, 400 and 500 µl tubes (Reader Service No. 112). The Eppendorf rotor holds tubes at a 45° angle, the ideal inclination for pellet formation. The rotor is also enclosed to reduce air turbulence and noise. Brinkmann's new Eppendorf costs $1,295 (US) and can be operated in a cold room. Its speed tops out a 14,000 r.p.m., and timing, as well as speed, is adjustable. Brinkmann will be in booths E15 through E19 (odd) at ASBC.



Eppendorf expands its accommodations.

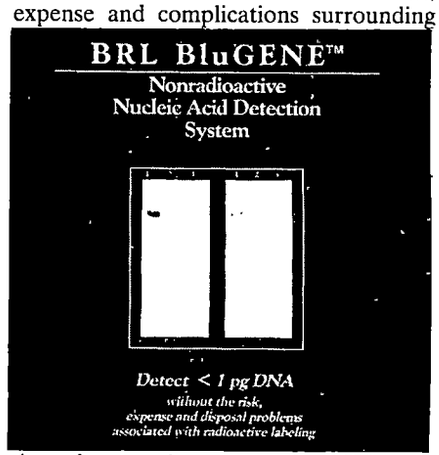
In scores of booths between D4 and F11, Beckman Instruments will be exhibiting their wares, one of which is the TL-100 **table-top ultracentrifuge**. Beckman has brought out another rotor for the $19,590 (US) machine, itself just introduced this spring. The fixed-angle TLA-100.3 rotor spins larger sample volumes than previous varieties could accommodate, in 3 ml open-top or 3.5 ml sealed tubes (Reader Service No. 113). Six tubes at a time can be spun at speeds up to 541,000 g. Beckman's TLA-100.3, with a k factor of 16.5 at top speed, sells for $2,970 (US). With the other rotors available, the TL-100 allows ultracentrifugation of samples as small as 0.2 ml, and can process samples up to four times faster than floor models, says Beckman. It has a controlled temperature environment ideal for applications such as rapid sample clarification, density gradient separation, isolation of plasmid DNA, molecular weight determinations and binding studies.



Beckman's ultracentrifuge: smaller, but still speedy.

A **compact bench-top centrifuge** from Jouan will centrifuge up to 48 5 ml tubes at 1,630*g*. The B311, designed for laboratories that do not require high carrying capacities, features closed loop speed control, digital speed readout, dynamic electric braking and an imbalance detection and shutdown system (Reader Service No. 114). In addition, the B311 has several adaptors and options that broaden its usefulness without sacrificing its $1,500 (US) base price. A swing bucket rotor carries tubes ranging from 1.5 ml microtubes through 180 ml bottles. Fifteen and 50 ml conical tubes can also be centrifuged using a different carrier, and aerosol containment covers are available for toxic or pathogenic samples. Jouan will have booths at J37 and J39 in Washington.

Flexible arrangements for Jouan's benchtop.

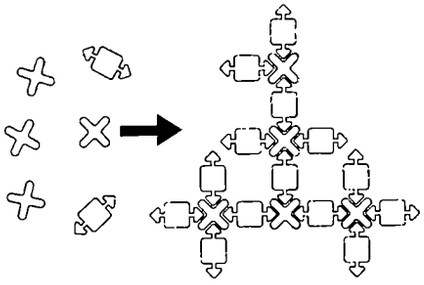


Kimble now manufactures a selection of plain-top and 50 ml screw-top **disposable glass centrifuge tubes** (Reader Service No. 115). The tubes come in 5, 10, 15 and 50 ml sizes, and all but the 50 ml are available with polyethylene snap caps. In screw-thread sizes, the new 50 ml complements an existing array of disposable tubes. These tubes are topped by black phenolic caps with rubber or PTFE/rubber liners. All of Kimble's disposable centrifuge tubes are made from borosilicate glass that resists organic solvents and preserves *p*H-sensitive solutions. Kimble protects its product from contamination in shrink-wrapped low particle trays; costs vary depending on size and quantity.

Kimble's toss-away tubes.

Away from radiation

Bethesda Research Laboratories (BRL) have a **nonradioactive nucleic acid detection system** called BluGENE that they think will turn the heads of autoradiography users (Reader Service No. 116). Using a streptavidin–alkaline phosphatase conjugate developed at BRL, the BluGENE method can detect single-copy genes of genomic DNA in Southern blots in less than one hour. BluGENE's detection levels reach down to the 0.25 pg level. BRL says the system has several advantages over autoradiography, and by circumventing sandwich methods, their conjugate heightens sensitivity and saves time. Biotin-labelled probes, once prepared, are good for at least a year, and signal development is complete in three hours. BluGENE also avoids the risk, expense and complications surrounding

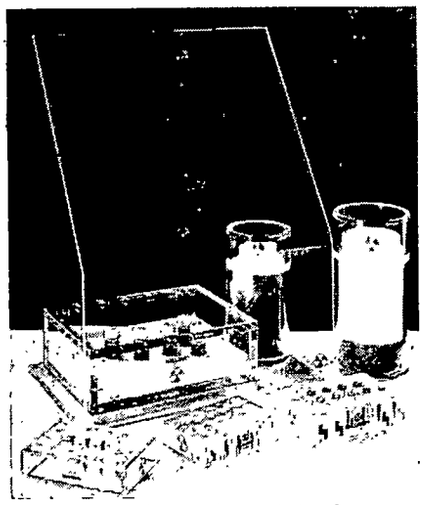


A novel streptavidin conjugate from BRL.

radioactive labelling techniques (as do all nonradioactive methods). BRL prices their BluGENE kit at $75 (US) for 40 assays; they are in booths D31 and D33 at ASBC.

Photo-activatable biotin (PAB) from Clontech has many of the same advantages as BRL's system (Reader Service No. 117). Determined colorimetrically, PAB's detection can be as sensitive as that afforded by ^{32}P, according to Clontech. One μg of PAB will label 1 μg of DNA, and the label sells for $75 (US) per mg or $300 (US) for 5 mg.

Streptavidin, a protein product of *Streptomyces avidinii*, is counterpart to biotin in nonradioactive signal amplification

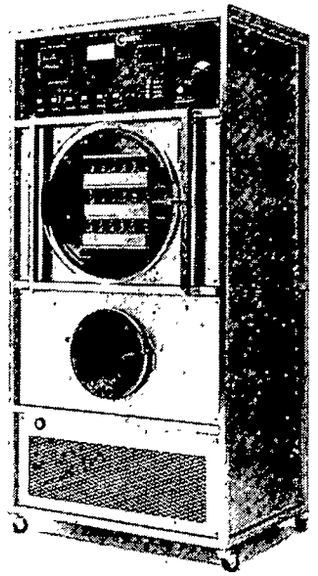


Signal amplification via streptavidin-biotin complexes.

systems. Porton Products Ltd now makes **streptavidin,** purified to X-ray crystallographic standard, for immunological and biochemical techniques (Reader Service No. 118). In comparison to avidin, streptavidin seems to have numerous advantages, including a reduction in nonspecific background effects and improved performance at neutral *p*H. The chemical is available in bulk quantities from Porton for £5 (UK) per 100 mg, the minimum order.

Vector Laboratories have their own version of a **biotin labelling reagent,** called Photoprobe (Reader Service No. 119). With photoactivation, Photoprobe biotin can produce stable hybridization probes that can be detected via a variety of enzymatic of fluorescent detection systems (including avidinbiotin interaction). In addition to this new probe, information and protocols for Southern, Western and Northern blot detection using Vectastain ABC and Vectastain ABC-alkaline phosphatase kits will be at Vector's booth E0 at ASBC. These kits provide a means of localizing hybridized biotinylated nucleic acid probes, biotinylated antibodies and biotinylatd lectins. Photoprobe sells for $120 a milligram, while the kits cost $100 (US) each.

When nonradioactive probe labels can't do the trick, Nalge has **acrylic beta radiation shields** to keep exposure to a minimum (Reader Service No. 120). Although acrylic cannot supply protection against

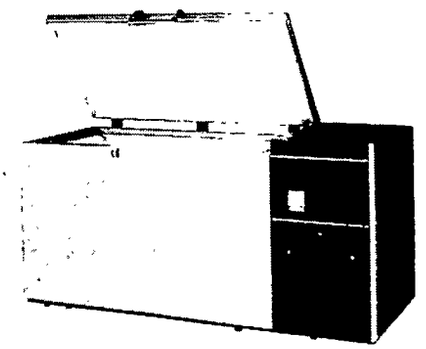


Acrylic shields keep radiation in its place.

gamma radiation or secondary X-rays, Nalge's 3/8-inch-thick layer has been proven effective against the beta emissions from isotopes such as ^{32}P, ^{3}H, ^{14}C and ^{35}S. Nalge's line includes benchtop shields and waste containers, test tube racks and microcentrifuge tube racks. A standard benchtop shield costs about $100 (US).

Freeze-dried and frozen

A dedicated **control system for freeze drying** was recently granted a patent, and the company holding the patent will be at ASBC showing their wares. VirTis Co., in booths H27 and H29, devised the FCP-II microprocessor-based system with electronic circuitry and a three-way mixing

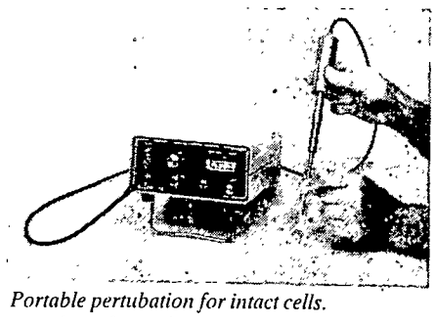


VirTis has freeze drying under control.

valve that can ensure shelf temperature control to 1/10°C (Reader Service No. 121). Their programmer requires no special computer training, has complete manual override capability and provides a hard copy summary (in keeping with FDA requirements) at the end of each run. Any combination of heating, cooling and vacuum level control can be preprogrammed and used repeatedly from memory. The FCP-II takes readings from 14 different probes monitoring product, shelf and condensor; if any sensors become defective, it discounts their readings, and it automatically takes corrective measures if part of the system malfunctions. VitTis's $29,750 (US) software and hardware fits all VirTis SRC sublimators.

Fisher just published a 16-page colour brochure detailing their new Isotemp family of laboratory cold units (Reader Service No. 122). *Fisher Isotemp Refrigerators, Freezers, Ultracold Freezers* describes several acid-and-chemical resistant general-purpose refrigerators, chromatography refrigerators, ultra-cold freezers for research and red cell storage and units approved for whole blood and plasma storage. Also making an appearance, above and beyond the 23 models introduced in the booklet, is a variety of new accessories — and plenty of penguins.

The Supercold 135, a recent addition to Gallenkamp's **freezer** collection, runs



The deathknell for LN, storage?

from a standard wall socket and may jeopardize the popularity of conventional LN_2 storage devices (Reader Service No. 123). The unit is part of a generation of very low temperature freezers posed as an alternative to LN_2 freezing; it combines digital temperature display with a convenient height (37 inches) and a lid that makes opening and closing less of a struggle. For about £10,000 (UK) and potentially less power consumption, the Super-cold 135 might yet beat out liquid nitrogen varieties.

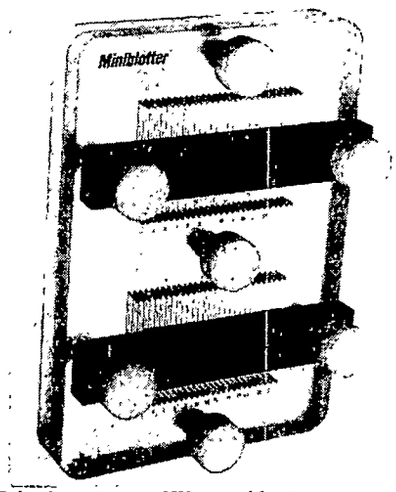
Cells in pieces

An **ultrasonic cell disrupter** that can homogenize, disaggregate, disintegrate and otherwise influence sample integrity will be demonstrated at booth G42, Sonics & Materials' display. The 40 W model VC-40 is compact and portable, designed for processing small laboratory samples from 100 μl to 25 ml (Reader Service No. 124). The functions of S & M's machine are multi-faceted: it can disrupt cells, bacteria, spores or tissue; prepare an emulsion down to 1/100 μm; homogenize liquids; disaggregate particulates; solubilize difficult compounds; and prepare

Portable pertubation for intact cells.

samples for electron microscopy and particle size analysis. S & M says their instrument will also accelerate and catalyse chemical reactions and degas liquids, as well as extract serums, toxins, enzymes and viruses from organic sources. For $1,080 (US), the VC-40 covers all bases.

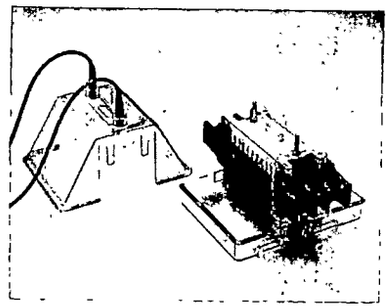
For biochemists studying cell surface reactions, Genetic Research Instrumentation Ltd. has presented a **compact electrofusion instrument** that punches holes in the cell walls of plant and microbial cells, or the cell membranes of animal cells (Reader Service No. 125). These holes, according to GRI, can facilitate the incision of material into cytoplasm or improve the yields of cell fusion experiments; GRI reports up to 50-fold increases in incision for its electroporation systems. The Labpulse electrofusion/poration apparatus consists of an oscilloscope to determine pulse shape and strength and control circuitry for voltage outputs of 1 to 1,000 V, which generates pulses 5 ms to 150 ms and pulse-by-pulse repetition to 10 Hz. The system is fully integrated, and the electrodes, which fit into 9 ml polypropylene tubes, can be sterilized by autoclaving or methanol washing and flaming. GRI's instrument works by creating a volatage gradient across the cells that is carefully controlled to puncture, rather than rupture, the cells. Labpulse sells for £5,500 (UK).



The Artek **dismembrator,** model 301, makes many of the same claims for ultrasonic disruption as do Sonics & Materials for their instrument (Reader Service No. 126). But Artek's model is not compact; this 2-litre 300 W version features a proprietary feedback system to keep the dismembrator working at maximum efficiency, and the percentage of ultrasonic power emitted is indicated by an output meter. Artek will supply a standard 3/4-inch tip, a 5/32-inch diameter microtip or a 3/8 diameter intermediate tip to accompany the model 301. In addition to disintegrating most cells, bacteria, spores and tissue, Artek's 301 will prepare emulsions down to 1/100 μm, homogenize immiscible liquids, accelerate enzymatic and chemical reactions and stimulate bacterial activity, among other things. Artek offers the model 301 at $1,950 (US).

Artek's dismembrator: a disturbing prospect.

Enzymes and antibodies



Western blot screening of hybridomas at early stages is made possible by a device recently released by Immunetics that required only 100 μl of an antibody solution to perform an analysis (Reader Service No. 127). The Miniblotter, on booth C29 at ASBC, is effective with both hybridomas and serum antibodies: 28 separate antibodies can be screened against a single blot the size of most minigels. Hybridoma supernatants can be transferred directly from 96-well plates into the Miniblotter's channels using a standard 8-channel automatic pipedtter. The blot, sandwiched between two plates, receives antibody solutions through holes in the upper plate, and the solutions are kept in their respective channels with a simple clamp system. For larger loads, Immunetics also offer a Miniblotter version with 45 channels, which requires 200 μl of antibody solution. Both sizes cost $295 (US).

Take the wait out of Western blotting.

The latest developments at Promega Biotec include an alkaline phosphate-based Western blotting system and ten new restriction enzymes. Promega will

First In Electrophoresis!

Mighty Small II Dual 7cm Slab Unit

Hoefer Scientific pioneered small-gel electrophoresis with its Mighty Small I. The new Mighty Small II can run two 7 x 8 cm gels in as little as 45 minutes—with no smiling. Heat dissipation is outstanding. Gel sandwiches have alumina back plates that conduct heat 40 times faster than glass. Also, there is a serpentine cooling channel sealed between the two vertical upper buffer chambers.

Formerly, Hoefer's Mighty Small I was distributed through Bio-Rad as its Model 360. Hoefer products are no longer available from Bio-Rad. Mighty Small I and II and all parts and accessories are available from the distributors listed below.

For Nucleic Acid Hybridization Compare With Hoefer's **HYBRID-EASE™** —— The **PLASTIC BAG**

COMPARE RESULTS

Membrane I: 40μg/lane of total cellular RNA blotted to Nylon (NYS) membrane. Membrane was hybridized to a ^{32}P labeled Actin cDNA probe (2 x 10^8 cpm/μg) in Hybrid-Ease.

Membrane II: Similar RNA samples and identical reagents used as in Membrane I. Prehybridized and hybridized in a sealed plastic bag and washed using large volumes and high stringency.

COMPARE EASE OF USE

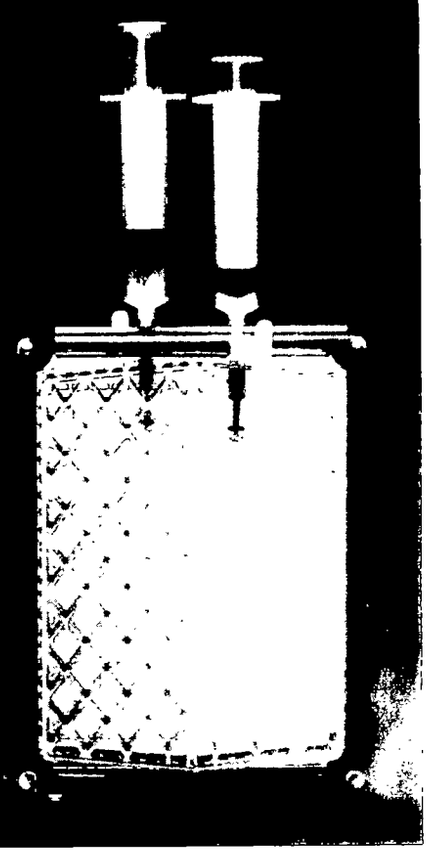
Simply mount the membrane in the Hybrid-Ease and carry out prehybridization, hybridization and stringency washing without opening the unit again.

Prehybridize in plastic bag. Remove solution. Add solution for hybridization. Reseal bag. After hybridizing, remove solution. Remove membrane and do stringency washing in lab tray.

COMPARE EFFECTIVENESS

In the Hybrid-Ease, solution contacts both sides of the membrane equally. Fluid entering the inner chamber goes through a unique laminar flow induction device that ensures uniform and bubble-free liquid contact with the entire membrane. No shaking necessary.

Contact with plastic bag leaves marks on membrane. Even flow of solution around membrane is nearly impossible. Shaking is necessary. Inside a plastic bag, a membrane is more likely to get damaged.



COMPARE SAFETY

Hybrid-Ease reduces the danger from radioactivity. A sturdy, leakproof unit, it uses solutions in small amounts, introduced and withdrawn safely through syringes. In addition, the unit is automatically decontaminated during wash cycles.

Plastic bags can be tricky to seal and open and are prone to leaking. Adding and removing large volumes of radioactive solutions increases the likelihood of spilling.

Reference: Hardy, K.J., et al. Proc. Natl. Acad. Sci., 82, 8173-8177, 1985.

Compare it to the plastic bag...

NICHOLAS COPERNICUS

THE COMPLETE WORKS

In 1985 Macmillan were proud to publish the third and final volume of Copernicus' Complete Works. These volumes, published as limited editions, are the result of many years' research and will make a significant contribution to the advancement of scientific scholarship.

VOLUME III: **NICHOLAS COPERNICUS: COMPLETE WORKS**
The Minor Works
Translated by Edward Rosen

This volume contains English translations of all his writings other than on the *Revolution of Heavenly Bodies* which was contained in Volumes I and II. This project was undertaken by the Polish Academy of Sciences and many of his writings have been translated into English for the first time.

Volume III contains astronomical writings – The Commentariolus and the Letter Against Werner – as well as other scientific, economic and administrative documents. These give a fascinating insight into this turbulent period of European history, and into the mind of one of the greatest and most influential of scientists.

Contents of Volume III
Introduction
Editor's Notes on Volume III
Copernicus' Translation of Theophylactus Simocatta
Copernicus' Minor Astronomical Works
Copernicus and the Money Question
Copernicus' Administrative Documents
Letters written by Copernicus
Indexes
Polish Places in Copernicus' Life and Work
Additions and Corrections to Volumes I and II

Volume III 380pp 0 333 14531 3
£60.00 1985

Other volumes in the series:

VOLUME I
This volume is a facsimile copy of Copernicus' autograph the Revolutions.

Volume I 0 333 14034 6 **£40.00** 1973

VOLUME II
Edited by Jerzy Dobrzyki. Translation and Commentary by Edward Rosen.
This volume is a translation of Volume I the Revolutions.

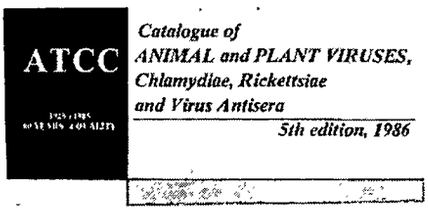
Volume II 0 333 14530 5 **£35.00** 1978

MACMILLAN PRESS

Please order these titles from your bookseller – or in case of difficulty from Judy Chappell, Macmillan Press, Houndmills, Basingstoke, Hants RG21 2XS, UK.

have plenty of information on both of the fledgling products at their ASBC booths GO1 and GO2. The $175 (US) ProtoBlot **immunoblotting system** is a nonradioactive method which Promega claims has greater sensitivity than either protein A or HRP-based systems (Reader Service No. 128). The **restriction enzymes** come with enzyme-specific 10× digest buffer and acetylated nuclease-free bovine serum albumin, both of which have been optimized for reaction efficiency (Reader Service No. 129).

A **recombinant protein A** for the study of cell surface antigens and receptors and for the detection of antibody-secreting cells has emerged from the laboratories at ICN Immuno-Biologicals (previously ICN Biomedicals). The high-affinity protein is just one of the many chemicals for immunology research that ICN will feature at their booths J15 through J19 (odd) (Reader Service No. 130). Other recent introductions, such as monoclonal and polyclonal antibodies for cytoskeletal elements, should be prominent in ICN's display.



A **neurotransmitter** commonly known as AMPA (and less often called 3-isoxazolol amino acid (*RS*) α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid) is a newcomer to Cambridge Research Biochemicals' cadre of neurotransmitters. AMPA, a synthetic analogue of the less stable natural compound ibotenic acid, is a powerful agonist of a subclass of glutamic acid receptors (Reader Service No. 131).

From the pamphlet file

"Filtration — the separation of materials from a gas or a liquid — is one of the most basic and important laboratory procedures." Thus begins Fisher Scientific's new catalogue, the *Fisher Filtration Catalog* (Reader Service No. 132). In full colour spreads, the brochure follows products for micro, macro and process filtration down avenues of applications in biological, microbiological, clinical and pharmaceutical procedures.

As Bond Elut and Chem Elu **sorbent extraction methods** gain a healthy reputation, keeping track of their potential uses becomes more difficult. Analytichem has published a bibliography listing nearly 500 applications for their two extraction methods as a resource for method development ideas (Reader Service No. 133).

The fifth edition of the American Type Culture Collection's *Catalogue of Animal and Plant Viruses* has now made it to the scientific newstands (Reader Service No. 134). This year's 193-page brochure houses descriptions of over 2,200 strains,

The consummate bug collection.

including molecularly cloned viruses. At ASBC, information on how to obtain a free edition can be had at ATCC's booth C32.

Late in March of this year, BioSciences Information Service (BIOSIS) launched a free sample issue campaign and a discount programme for its *BioResearch Today* publication series (Reader Service No. 135). It may not be too late to catch up with these offers at BIOSIS's ASBC booth A27. BIOSIS describes **BioResearch Today** (BRT) as a 'group of monthly current awareness abstract journals' that covers 14 specific research topics such as addiction, carcinogenesis, human and animal aging and pesticides. Each issue offers between 75 and 250 abstracts selected from the latest two issues of Biological Abstracts, BIOSIS's main publication. □

These notes are compiled by Karen Wright from information provided by the manufacturers. To obtain further details about these products, use the reader service card bound inside the journal.

JOURNALS FROM MACMILLAN

SCIENTIFIC AND MEDICAL DIVISION

In 1986 Macmillan are launching two new journals for new fast developing areas of science as well as strongly supporting their established titles. The publication of **Anti-Cancer Drug Design** and **Bone Marrow Transplantation** respond to new developments in scientific research, and will provide a valuable forum for exchange of ideas.

At the same time our already established journals – Postgraduate Medical Journal will shortly be celebrating its 60th anniversary – continue to chart and report new developments. If you are out of touch with our journals – or would like to see sample copies of our new ones as they are published, we would be pleased to send you a sample copy.

ANTI-CANCER DRUG DESIGN

NEW JOURNAL – FIRST ISSUE DUE SOON

Bi-monthly

Editors: Dr S. Neidle, Dr S. T. Crooke

The development of new clinically-useful anti-cancer agents is increasingly dependent on rational scientific principles drawn from a wide range of disciplines. This new journal aims to promote such approaches, providing a common meeting ground for medicinal chemists, pharmacologists, biochemists, biophysicists and oncologists involved in both fundamental and clinically orientated aspects.

This journal is published with the support of The Cancer Research Campaign.

£45 (UK) $95 (USA/Canada) £63 (ROW)

BONE MARROW TRANSPLANTATION

NEW JOURNAL – FIRST ISSUE DUE EARLY 1986

Quarterly

Editor: Dr J. M. Goldsman, Co-Editor: Dr R. P. Gale

A new journal which will publish clinical results in man and experimental results with animals; allografting and autografting; HLA and other methods of selecting donors; graft-versus-host disease and all types of methods to prevent and treat it; and much more.

BRITISH JOURNAL OF CANCER

Monthly

Chairman: Professor D. G. Harnden, Editor: Dr M. Moore

One of the leading cancer journals in the world publishing articles on all the major scientific disciplines. Publishes papers from scientists and researchers throughout the world and the proceedings of meetings of the British Association for Cancer Research and other symposia.

£125 (UK) $275 (USA/Canada) £165 (ROW)

PHARMACEUTICAL MEDICINE

Quarterly

Editor: Dr R. N. Smith, Assistant Editor P. J. Keen

..."a quarterly journal, which includes papers on the validation of new and established methods of testing drugs in man written by investigators both inside and outside the pharmaceutical industry. It also provides a forum for the exchange of ideas about issues affecting drug development. These new developments merit support from all involved in the management, sale and use of drugs." – *Lancet*

£48 (UK) $99 (USA/Canada) £65 (ROW)

BRITISH JOURNAL OF PHARMACOLOGY

Monthly

Chairman: Professor J. F. Mitchell
Secretary to the Editorial Board: Dr G. M. Lees

One of the top five most cited pharmacology journals in the world

A vital source of relevant information for physiologists, immunologists, molecular biologists

£175 (UK) $410 (USA/Canada) £289 (ROW)

POSTGRADUATE MEDICAL JOURNAL

Monthly

Editor: Dr B. I. Hoffbrand

A monthly compendium of current clinical research and practice invaluable to the graduate in training

£68 (UK) $155 (USA/Canada) £85 (ROW)

HUMAN TOXICOLOGY

Bi-monthly

Secretary to the Editorial Board: Professor P. Turner

Covers all aspects of human toxicology embracing both animal research and studies with humans

£80 (UK) $168 (USA/Canada) £120 (ROW)

To receive sample copies, details of rates and how to submit papers indicate the titles you are interested in and contact: Alison Baverstock, Macmillan Press, Houndmills, Basingstoke, Hampshire RG21 2XS. Customers in the United Kingdom may mark their envelope FREEPOST and need not affix a stamp.

NATURE VOL. 321 5 JUNE 1986

Scrapping treaties is wrong

The United States seems to be losing patience with the only existing agreement on strategic arms. But the US's tetchy demeanour may prove to be an embarrassment.

PRESIDENT Ronald Reagan's announcement last week that the United States will not necessarily honour the Salt II treaty after September of this year is almost certain to prove more of an embarrassment for the United States than for the Soviet Union. While it is good news that the president has agreed to scrap two Poseidon submarines to make room, within the limits of Salt II, for a new Trident submarine in the US strategic fleet, it is bad news that he has also, for practical purposes, set an arbitrary limit on the time for which the complicated negotiations at Geneva should continue while simultaneously diminishing the chance of their success. The immediate consequence is that the other members of the North Atlantic Treaty Organization (whose foreign ministers were conveniently meeting last week in Canada) have been outspokenly dismayed by what seems to have been a needless provocation in the fragile climate of the arms control process. Much more of this and Europe's inclination towards Gallic ways will be strengthened. Worse still, the United States may find that it has lost the benefit of the charitable doubt it has enjoyed for the past six years. All kinds of people, many in the United States, will now be asking whether the administration can be serious in its protestations that arms control is at the centre of its attention.

The most curious feature of the president's decision is that it appears to have been unprovoked. This is not the first time that a working strategic submarine has had to be laid up so as not to violate Salt II; the same happened last September. Ostensibly, the warning that Salt II may not be kept after September is intended as a riposte to alleged Soviet violations of the treaty, and indeed is conditional on the failure of the Soviet government to mend its ways, yet nothing new has happened in the past few months except that Mr Mikhail Gorbachev has put out a whole string of proposals on arms control, many of which are sensible and well worth talking about.

Change

It is true that much has changed since Salt II was signed (it has not been ratified) just ten years ago. The Soviet Union has broken the spirit but not the letter of the treaty by deploying several hundred SS20 missiles in positions from which targets in Western Europe could be attacked, and has been able to modernize its force of longer range missiles by pretending that the new SS25 missiles are but more modern versions of older rockets. And, in an undisputed violation of the treaty, the Soviet Union has also taken to coding the telemetry from test rockets, thus depriving the United States of one of the most effective means at its disposal of "national verification", acknowledged by the treaty to be necessary. But there is no suggestion that the Soviet Union has broken the chief restriction of its freedom of action — the numerical ceiling on the missiles it may deploy.

Nothing in this list of supposed transgressions justifies the US administration's display of impatience last week. The most substantial complaint, about the encryption of telemetry from Soviet test rockets, is long-standing. Is President Reagan now saying that the United States will withdraw its threat to breach Salt II if Soviet telemetry is no longer encrypted? Or is he asking that the SS25s should be dismantled, which is a much taller and more impractical order, and which would also raise questions from the Soviet Union about the legitimacy, within Salt II, of the development of both the MX and the Midgetman missiles in the United States? Even if last week's statement were intended merely as a piece of public diplomacy, it has the thoroughly unsatisfactory feature that neither the Soviet Union nor the rest of the world can tell what must be done to ensure that the United States does not follow the threatened breach of Salt II.

All these are matters that are capable of being resolved within the framework of the bilateral negotiations of Geneva. Indeed, to the extent that one of the chief objectives of those negotiations is an agreement on strategic weapons at a reduced level (half as many warheads as at present, or thereabouts), the negotiations are plainly also a way of replacing Salt II by a treaty that is not "fatally flawed" — President Reagan's description last week which is ominously borrowed from his rhetoric of the 1980 election campaign. One obvious defect is that it counts missiles rather than warheads (although the calculations of supposed strategic balance are based on the assumption that missiles with multiple warheads are fitted with their full complement). The treaty is also cumbersome, well provided with potential bones of contention. If the United States were now urging the potential benefits of a better treaty, nobody would complain. From the Soviet point of view, there are also good reasons why Salt II is unsatisfactory. It says nothing about the British and French nuclear forces, for example, although the calculations of strategic balance were made by subtracting from the US missile quota an allowance for the European striking forces of a decade ago. Both sides could fairly ask for a better treaty than Salt II. But Salt II is far better than no treaty at all. Moreover, there is no sense in which the present treaty, which allows each side the equivalent of 5,000 nuclear warheads, restricts the freedom to deploy a sufficient retaliatory force.

These are the reasons why last week's announcement that Salt II will not necessarily be considered binding later in the year is bound to unsettle opinion and policy elsewhere. Both parties to the Geneva negotiations have been saying for months that the other is not seriously interested in an agreement, but Mr Mikhail Gorbachev is the one who has been stunning everybody with a string of tangible proposals, some of which may be practical. The US administration seems not to have calculated (or cared?) what the effect will be in, say, Western Europe of presenting itself as the party that will tear up an existing treaty unless the other meets certain vague requirements. The new development seems all the more sombre because it virtually coincides with the curious refusal of the United States at Berne to sign the modest but useful agreement (within the Helsinki treaty framework) on personal and professional freedom to travel. One common reaction will be to wonder whether the time has come for separate agreement with the Soviet Union on the British and French nuclear forces, which would disastrously spell the end of thirty years of planning for the defence of Western Europe. Another, more constructive, will be to ask whether the cause of arms control is not so important that it can no longer be left to the superpowers. One specific issue is likely to become a thorn in Mr Reagan's flesh in the next few months; hitherto, most European

governments have accepted that the time has not been ripe for a comprehensive test-ban treaty, given the US argument that there is a need to develop warheads for the Midgetman, but that position will now almost certainly be eroded.

Where all this will end is anybody's guess. The United States seems to have calculated that, what with one thing and another, its impatience will not dissuade Mr Gorbachev from going to Washington later in the year for a replay of last year's Geneva summit. The calculations may be correct, but the consequences will be that Mr Gorbachev will travel intransigently. But he may decide not to go at all, which will be a greater embarrassment for the United States in its dealings with its friends. □

Who pays for AIDS?

The alarming financial implications of the US epidemic of AIDS creates another social dilemma

ACQUIRED immune deficiency syndrome (AIDS), a haunting source of trouble for the past five years, has become a problem for the US insurance industry. In several states, it is now a matter for vigorous controversy whether insurance companies should be allowed to deny health or life insurance to people who test positively for antibodies against the virus for AIDS, human immunodeficiency virus (HIV). California and Wisconsin have already enacted legislation that forbids the use of HIV antibody tests in this way, and similar proposals are being considered in New York. In the District of Columbia, the council is likely soon to approve a bill that would forbid insurance companies using any type of test for AIDS for the purpose of determining insurability. The insurance industry, aware that similar proposals are likely to be enacted elsewhere, has started an energetic (and expensive) lobbying campaign to oppose legislation of this kind.

The kernel of the problem is that a positive result in a test for HIV antibodies by no means proves that a person will develop AIDS, which in its fully developed form is at present always fatal. Estimates of the proportion of those who test positively who will eventually succumb to the disease vary, and because of the long incubation period of the virus it will be years before this is known with any accuracy. The federal Centers for Disease Control estimate that the proportion is between 5 and 19 per cent, although it could be much higher. As a consequence, and because the hospital costs of an AIDS patient average $147,000, those who test positively are in practice uninsurable.

Recent estimates of the number of people in the United States infected with the virus range from 500,000 to 2 million. The number of AIDS cases may reach 100,000 by 1989 if current trends continue, corresponding to claims under "life" (more accurately, death) insurance policies worth perhaps $5,000 million by the early 1990s. But if the insurance companies are able to deny insurance to those testing positively to the antibodies, many seeking new insurance in most of the United States are liable to find themselves being denied coverage.

AIDS is not unique; similar problems have been raised by other high-risk conditions such as diabetes and cystic fibrosis. A solution that has been adopted in nine states so far is the "high-risk pool", a special state-administered insurance scheme for individuals known to be bad medical risks. The pool is maintained by contributions from insurance companies in approximate proportion to the amount of business they do. Individual premiums are capped, typically at 150 per cent of the standard premium, ensuring that high-risk individuals can buy coverage.

Organizations representing victims of chronic diseases applaud such schemes, which allow their members to get insured. The insurance industry approves because it avoids divisive strains on individual companies. Ultimately, of course, other insurants still pay for the misfortunes of the high-risk groups. Congress should consider legislation that would effectively oblige other states to set up high-risk pools, bringing them into line with those that already have successful schemes. □

Who will pity Africa?

The plight of Africa commands attention, but throwing money in that direction is no solution.

THIS has been a bad week for Africa, but that is not unusual. The number of black Africans killed in the Republic of South Africa (mostly in intra-racial fighting) exceeds the number of those killed by radiation at Chernobyl. The death-toll among students in Nigeria, where most of the universities have been closed, is almost as great. The willingness of perhaps 20 million people elsewhere to run to raise funds for Africa is a moving proof that Africa can still stir the world's compassion; it is only natural that the organizer, Mr Bob Geldof, should be furious that the special session of the United Nations last week failed to echo his runners' enthusiasm. But Geldof's tirade last week against the "politicians", whom he alleges have neglected a golden opportunity to put Africa to rights, is thoroughly misplaced, at least so long as it stems from the assumption that Africa will become a Garden of Eden if only enough money is thrown at it.

The plain truth is that many of Africa's most serious problems have been created in Africa by Africans, and that only palliation of them is possible while these policies persist. The recent history of Africa is a sufficient proof of the validity of that charge. Ghana, relatively prosperous among African countries a quarter of a century ago on the basis of a successful cocoa-growing industry, is now among the poorest. Nigeria, rich more recently at the height of the oil boom, has squandered its brief wealth, becoming one of the world's major debtors. Uganda, already a kind of paradise in the early 1960s, has now settled for inter-tribal violence and the chaos that follows. Ethiopia, sadly ravaged by two years of serious drought, would have found that ecological catastrophe less damaging if the previous food distribution system had not been undermined by the government's ideological conviction that middle-men (admittedly a grasping lot) should be replaced by a public bureaucracy whose efficiency is notoriously below par, and which offers farmers prices that provide no worthwhile incentive to increase production. This same error is the rule elsewhere in Africa, East and West, where governments' attempts to keep their urban populations happy by fixing food prices at unrealistically low levels has contributed powerfully to the decline of agriculture, the hunger of those same urban populations and the dependence of potentially fertile Africa on food imports. Mr George Shultz, the US Secretary of State, was right to say, at last week's meeting of the United Nations, that poor Africa's governments should prudently mend their ways. Geldof and the many who contributed to international fund-raising should understand that as well.

This does not mean that there is nothing to be done. Africa's request of the United Nations last week was for an increase of aid by donor nations amounting to more than $80,000 million over the next four years, together with a moratorium on foreign debts that would cost about half as much. Given the need, the figures are not unreasonable. But there was never a chance that the rich countries would or could respond on such a scale.

Indeed, the years immediately ahead are likely to make the rich countries seem to Africans more skinflint than they have ever been, as the United States struggles to control its budget deficit and cuts its direct contributions to foreign aid in the process. Yet there are now enough illustrations of how development projects can succeed, even in Africa, to suggest that many of Africa's problems could be tackled successfully with much more modest sums of money. What is needed now is not a meeting of the United Nations at which politicians rehearse their government's well-known positions, but a practical clearing-house for the good ideas that have already contributed to the improvement of African conditions on a small scale, and which could, with the imagination and enthusiasm of the Geldofs of this world, be spread more widely. □

US research funds

Defense Department to shed unwanted monies

Washington

A FIGHT is brewing in the US Senate over provisions in a money bill to divert $80 million of defence research funds to support unreviewed research and construction projects at 10 named universities. The Department of Defense (DoD) has refused to allocate funds that Congress has already pressed upon it for the purpose, and support is growing for an amendment that would free the $80 million for competitively awarded research.

The disputed funds were added piecemeal to DoD's appropriations during the legislative process as rewards for political favours by influential members of Congress. None of the 10 named projects has been subjected to competitive merit review, and the favoured institutions are "not the sort of places where one would normally go" to find the best high-tech research, according to one DoD official.

Academic and scientific organizations are uniformly opposed to Congress awarding research and construction funds by political horse-trading. But most of the disputed projects are in the home states of members of Congress who occupy senior positions on key committees, and the effort to block them, to be introduced in the Senate by John Danforth (Republican, Missouri) will be hard fought.

Ten such "pork barrel" projects worth $65 million were provided for in DoD's 1986 appropriations bill, which passed Congress at the end of last year. Several of them, notably the $13.5 million proposal of Northeastern University for a research complex, consist mainly of buildings and look more like campus improvement schemes than defence research.

Defense Secretary Caspar Weinberger refused to spend the $65 million on the grounds that DoD had no legal authority to support construction projects from its research account, and that the sums were recommended, not mandated, in the bill.

DoD also invited the universities in question to submit research proposals that would be subject to normal competitive review; the reviews are still in progress. But Weinberger has also made plain that DoD would oppose non-competitive construction funding even if it had legal authority to spend the money. "It isn't a matter of legality, it's a matter of policy", says Robert Rozenzweig of the Association of American Universities, which has consistently opposed pork-barrelling.

In response to DoD's refusal, seven US Senators last month introduced wording into an emergency supplemental bill approved by the Senate Appropriations Committee that would, if approved by Congress, oblige DoD to spend the money anyway. In addition, the committee introduced a special provision that would allocate an extra $25 million for a proposed Center for Science and Engineering Technologies at Arizona State University. A spokesman for the university explained that the proposal was the consequence of efforts to help the university by Senator Dennis DeConcini (Democrat, Arizona).

A sum of $10 million that had been intended for a Floating Point Systems supercomputer at Cornell University was dropped after Cornell's president, Frank Rhodes, refused on principle to accept the grant unless it had been awarded by competitive review. Cornell's proposal is now being scrutinized by DoD; ironically, one DoD source close to the review process says that of all the original pork-barrel proposals, the supercomputer is the most likely to be successful in the review.

Pork-barrel provision have been used in numerous federal appropriations bills over the years to buy special favours for universities, but there is now alarm in the academic community over the unprecedented scale of the proposals in the 1986 DoD appropriation.

One previous attempt to defeat the pork-barrel provisions, led by Senator William Proximire (Democrat, Wisconsin) was defeated in the appropriations committee. But supporters of Danforth's amendment believe that the bipartisan support now emerging gives it a good chance when it is introduced on the floor of the Senate, probably in the first half of June. Among the supporters of the move is, surprisingly, Senator Barry Goldwater, the Arizona Republican who heads the Senate Armed Services Committee. DoD's stand might carry the day.

Space launchers

Launch failure; boardroom fracas

THE failure of the third cryogenic stage of Ariane, Europe's space launcher, at the weekend, coming after the recent serious setback to the US space programme, has put the West's space launching capacity into jeopardy. It has also thrown into vivid relief the sacking just a couple of days earlier of the president of the company that makes Ariane rocket motors.

Ariane has now lost two out of its last three launches and four out of the past eighteen — the last two as a result of third-stage failure. Last week's launch was aborted with an Intelsat communications satellite aboard. A long investigation by an independent commission of all possible sources of error in the manufacture of the liquid hydrogen–liquid oxygen third stage will now be started, and delays to the programme now seem likely to be months rather than weeks. A complete redesign of the third stage engine might be necessary, so even longer delays are possible.

Strangely enough the president of the company, Roger Lesgards, was precipitately sacked last week in circumstances that suggest that the reasons may have been political rather than commercial.

M. Lesgards had been a close adviser of the previous minister of research and technology, Jean-Pierre Chevènement, and is thought to have been letting his feelings about the recent reductions of research support become widely known. Contracts with the government and government agencies are the chief source of work for SEP (Societé Européene de Propulsion).

Late last week, M. Lesgards had already quit his office and could not be reached at home, but he has made no secret of his anger at his treatment by the board of SEP. The company appears to be doing well commercially, having increased its turnover by 42 per cent in the year to October 1985 and having taken orders worth FF 3,000 million (£300 million) during last year. With half of the company's activity concerned with Ariane, whose commercial prospects have been strengthened since the shuttle disaster and failures of US Titan and Delta rockets, SEP's future seemed bright.

Lesgards' successor is M. Jean Sollier of the aerospace company SNECMA, another supplier for the Ariane programme. SNECMA happens to hold a marginal majority (50.14 per cent) of the shares of SEP, and there has recently been some friction over the rate and regularity with which SEP has been supplying components for Ariane.

Robert Walgate

• Meanwhile, Britain changed its mind last week about which rocket will launch the first Skynet military communications satellite. The Ministry of Defence can get a guaranteed launch date "several months" earlier by using Ariane, rather than the US space shuttle, to launch Skynet 4B, the first satellite in the series. It has therefore cancelled its booking with the shuttle and Ariane will launch Skynet 4B in late 1987 unless the latest setback calls for more changes to the schedule. The shuttle will still carry the next satellite, Skynet 4A, in 1988, and Ariane will carry Skynet 4C in 1989. □

Chernobyl

Fusion may be a better way

ONE lesson to be learned from last month's nuclear accident is that there should be a renewed effort in thermonuclear fusion. This was the opinion offered last week by Academician Evgenii Velikhov, vice-president of the Soviet academy and a member of the investigating commission at Chernobyl, speaking at a press conference in Moscow.

The same point was echoed at an international conference on nuclear technology in Yalta last week. Academician Boris Kadomtsev, director of plasma physics at the Soviet Atomic Energy Institute, called for greater international collaboration in the field. The Soviet Union is a partner in the International Atomic Energy Agency's project for the design of a thermonuclear reactor and also has a number of bilateral agreements on collaboration on fusion work.

The main emphasis of Velikhov's statement was that the clean-up operation at Chernobyl has presented those involved with unprecedented problems. Little had been done in advance, he said, to construct models that would assist in the management of the damaged reactor, while such data as were available were often contradictory. The mound of concrete, lead and boron under which the damaged Number 4 reactor is now buried prevents access, so that it will be necessary to estimate its future behaviour by extrapolation. Even so, it appears that it has been possible to install sensors for temperature and radiation intensity in and around the reactor.

After the burial of the reactor, the main task has been, according to Velikhov, that of trapping airborne particles, for which purpose a special film of polythene has been used. Velikhov added that, in any case, only a "certain percentage" of the fission products in the reactor core has reached the atmosphere.

As the most urgent problems were dealt with, others emerged. As well as the pollution of agricultural land and livestock, the forests of the Polessye region and their wildlife aroused concern. These forests — mostly managed plantations of conifers (although the original tree-cover was deciduous) — appear to have taken the brunt of the pollution. Valerii Brezhnev, deputy minister for forests of the Ukranian SSR, said last week that many plantations will have to be felled and the clearings ploughed up, while veterinary monitoring of wild animals (elk, roe deer, boar and other species) has begun.

Boris Paton, chairman of the Ukranian Academy of Sciences, also said last week that there are plans for establishing "artificial geochemical barriers" on the "migration paths of radionuclides in the groundwater". The river Pripyat' and the Kiev reservoir were mentioned specifically. Paton was presumably referring to techniques more specific than the emergency mechanical barriers thrown up to prevent the run-off of rainwater from Chernobyl into the river Pripyat', and which were said to have been completed two weeks after the accident.

On the future of nuclear energy in the Soviet Union, there seems to be a conflict of opinion. The first deputy minister for electrification of the Soviet Union, Alexsei Makukhin, said somewhat offhandedly last week that the accident at Chernobyl had been a "hitch" in the "mastering of the atom". Velikhov was more cautious, saying that although it is unlikely that reactors of the Chernobyl type will be closed down, "it is unlikely that they will stay in the same form".

Vera Rich

Counting the score on transplants

Washington

PROFESSOR Robert Gale, normally to be found at the University of California, Los Angeles, but who has spent most of the past month in Moscow carrying out bone marrow transplantations on victims of the Chernobyl accident, has contributed an account of the present status of marrow transplantation to a new journal *Bone Marrow Transplantation*, first published this week. Gale estimates that there will be some 2,500 transplantations worldwide during 1986, not many fewer that the 4,000 such operations reported to the International Bone Marrow Registry during the past decade.

Radiation exposure is a comparatively rare cause for transplantation, which is most commonly used in the treatment of leukaemia and other diseases of the blood-forming process. The international registry is meant as a means by which data about the effectiveness of transplant operations can be compiled and compared.

Gale's article, which is the first in the new journal, cannot fail to be widely read by those elsewhere than in the Soviet Union who are concerned to know what part marrow transplantation should have in case of future nuclear accidents.

The new journal, published by Macmillan from the United Kingdom, is meant to be a quarterly in the first instance. The editor is Dr John Goldman from the Medical Research Council's leukaemia unit at the Royal Postgraduate Medical School, London. Dr Gale is the journal's co-editor for the United States and Canada. □

British universities

Reputation by repute

BRITISH academics learned last week a great deal more about the reasons why their institutions had done relatively well or badly in the carve-up of the public subsidy for the impending academic year (see *Nature* **321**, 459; 1986). The explanations are contained in letters sent to the heads of academic institutions by the University Grants Committee (UGC), and together constitute the most detailed survey of the state of British universities ever.

The two successive sheaves of letters are the first steps in UGC's policy of concentrating resources considered to be inadequate on what are deemed to be the institutions of the highest quality. In this first stage, UGC has made relatively modest steps in that direction, but in the autumn a further word-processing exercise will tell universities what they can expect to receive from public funds in the succeeding three academic years (1987–90).

Apart from providing universities individually with a inkling of how the harsher winds will be blowing in the autumn, last week's letters give the university system as a whole warning of far-reaching and unexpected structural changes. In particular, it is now clear that UGC intends to give less on account of the cost of student education to universities (Oxbridge and some others) organized in a collegiate fashion, and that it will in future exercise its right to deal individually with the member institutions of federal universities.

The first change arises because the collegiate universities and the several colleges to which students are required to belong are able to charge separate tuition fees, mostly paid in respect of British students by local education authorities. The universities chiefly concerned are Oxford and Cambridge, but Durham, Kent, Lancaster and York charge similar but smaller fees. By deciding that half the income derived from college fees should be subtracted from the annual recurrent grant, UGC is in the short run releasing funds to spend in universities under greater pressure. With the prospect that the time will come when British students' fees will not automatically be paid by local authorities, UGC is requiring Oxbridge to choose between conformity and the privatization of at least their collegiate functions.

Last week's sheaf of letters also explains why both Oxford and Cambridge were placed below the middle of the previous week's league table, with increases of cash income of zero and 0.7 per cent respectively, compared with the average for the system as a whole of 1.0 per cent.

UGC's decision to circumvent the

federal structure of the University of London by providing its constituent colleges with an account of what the future holds for them (the University of Wales has always been dealt with in this way) is also potentially far-reaching, and could presage the break-up of the university. Imperial College has been able to talk directly to UGC since the early 1960s, but the other member colleges have had to wait on the university court for the reallocation of UGC's grant to the university as a whole. Now that the university has been reorganized into only five general colleges and the number of its medical schools is shrinking by almagamation, the proof of the case for the contiuation of what is widely thought to be an inefficient system will fall to the central organization.

The consequence of last week's letters from UGC which cannot as yet be calculated is the effect of its opinions on student recruitment. All university departments have been categorized on the basis of their research performance as average, below average and above average, while departments whose research attainment is judged to be of international character are singled out for special mention. UGC has said separately that it will attempt to categorize departments by the quality of their teaching when there are tools available for carrying out that task. Meanwhile, however, it must be expected that students will flock to the departments praised by UGC and will shun the others, which may accelerate the selectivity exercise.

Many academics are complaining that the time remaining between now and the autumn is not sufficient for the implications of UGC's judgement to be grasped. A crucial unknown quantity is whether the new Secretary of State for Education and Science, Kenneth Baker, will be able to wring extra funds from the Treasury. Nothing was heard of Baker last week. □

• The grant for 1986–87 for the University of Essex has not been reduced (as reported last week) by 0.5 per cent but, rather, increased by 1.7 per cent.

Chilean physicians

Campaign against torture grows

Philadelphia

CHILEAN physicians are leading a new national movement demanding an end to the dictatorship of General Augusto Pinochet. The Chilean Medical Association (Colegio Medico de Chile, CMC), which has for the past four years been investigating and exposing physicians' cooperation in torture by the security forces, has been joined by 17 other professional organizations in a new national assembly (Asamblea Nacional de la Civilidad) that is calling for immediate national democratic elections. With the expiration last week of the assembly's 31 May deadline for its demands, CMC is likely soon to be at the centre of an escalating series of strikes.

The president of CMC, Dr Juan Luís González, and its general secretary, Dr Francisco Rivas, were in Philadelphia last week at the annual meeting of the American Association for the Advancement of Science (AAAS) to receive on behalf of CMC the AAAS award for scientific freedom and responsiblity. AAAS has been monitoring human rights in Chile since the early 1980s. The award was shared with Dr Victor Paschkis of the United States, who founded the Society for Social Responsibility in Science.

CMC was honoured for its efforts to track down physicians who cooperated in torture of government prisoners during the 1970s. Some 10,000 civilians, including 80 physicians, were murdered by the secret police or disappeared in the period between 1973 and 1978, and the use of torture is said to have been widespread.

CMC represents 14,000 physicians, more than 90 per cent of Chile's total. It was run by puppet officers appointed by the government until 1982, when Pinochet gave in to demands for election of officers in order to avoid a showdown with the profession. González and Rivas, who head a council of 23 members, were elected on a three-point platform of solidarity in the profession, peaceful protest against the government's health policies, and investigation of physicians who participate in torture.

As a result of the torture investigations, two physicians, Luis Losada and Manfred

Jurgensen, have been expelled from the association. They admitted examining and certifying as healthy a government prisoner, Frederico Alvarez, who had been tortured and who died a few hours later from respiratory insufficiency due to multiple rib fractures. Two other members of the association accepted suspension for a year for examining a blindfolded prisoner who was being forced to remain standing, and CMC is continuing investigations of five others.

Rivas suspects that between 70 and 80 CMC members have cooperated in government torture, although in most cases firm evidence is lacking. The association conducts its investigations by examining court records (many of the torture deaths have been examined by the judiciary, although usually to no effect) and by interviewing torture victims or their families. In addition, files left over from the period when CMC was a government organization have provided many clues; the outgoing puppet officials apparently made no attempt to destroy evidence that would help the new CMC council.

Rivas stresses that those under investigation are allowed to retain the lawyer of their choice, at CMC's expense if neccessary. Penalties are recommended by CMC's ethics committee and are decided finally by the full 23-member council.

After the most brutal period of Pinochet's rule in the 1970s, there was a lull in political repression in Chile during the early 1980s. But, according to Rivas, the reemergence of organized opposition parties and the end of a temporary economic boom has increased discontent, so that repression is once again on the rise. Recently the Reagan administration has backed away from its policy of "quiet diplomacy" towards Chile, and spokesmen have started to refer to the administration's opposition to dictatorships both of the left and the right.

CMC has already held one and two-day strikes of its members to protest against the government's summary dismissal of the head of Santiago Medical College, Dr Ricardo Vaccare. According to Rivas, a neurosurgeon in private practice whose work for CMC is unpaid, 85 per cent of members supported the strikes. It is therefore not surprising that CMC's activities have attracted the government's unfavourable attentions. Rivas says that CMC officials frequently receive anonymous death threats to themselves and their families and are often shadowed by secret police. In recent months CMC's headquarters in Santiago has been under constant overt police surveillance.

Among the organizations supporting CMC in calling for a return to democratic rule is the National Association of Academics of Chilean Universities. CMC has received expressions of moral support from most major national medical associations, although representatives of governmental organizations such as the World Health Organization have declined to offer their support for fear of compromising their impartiality. But the medical profession has already become a significant political force in Chile. Supported or not, physicians seem determined to make a still larger impact. **Tim Beardsley**

SDI

Congress embraces restraint

Washington

NEARLY half of the US Senate has signed a letter criticizing the rapid increase of the budget sought by the Reagan administration for the Strategic Defense Initiative (SDI). The administration is asking for a 77 per cent increase in SDI funds for 1987.

The letter was addressed to Senator Barry Goldwater (Republican, Arizona), chairman of the armed services committee, which will be taking up the SDI budget request this month. The 35 Democrats and 9 Republicans say they are concerned that SDI has received "excessive and inappropriate emphasis" in the Department of Defense (DoD) budget request, threatening "vital" military research programmes.

While expressing support for "vigorous" ballistic missile defence research, the senators worry that the SDI research programme is being rushed in an attempt to meet unrealistic deadlines. The administration hopes that a decision about SDI deployment will be made in the early 1990s.

Support for SDI this year is set at $3,050 million, of which $2,760 million comes from DoD and the rest from the Department of Energy (DoE). For next year, the administration is seeking $5,400 million for SDI — $4,800 million to go to DoD and $600 million to DoE. The senators argue that SDI funds have out-paced technological progress, and that a 3 per cent increase, allowing for inflation, will keep the programme going on an even keel.

The House of Representatives may take an even more restrictive approach to the SDI budget. Representative Charles Bennett (Democrat, Florida), a member of the House Armed Services Committee, believes there is backing for a freeze at the present year's level of support. This committee will also be considering the SDI appropriations request this month.

The White House has reacted quickly to this rebuke from the Senate. The President's spokesman Larry Speakes said the administration "disagrees strongly" with the letter's recommendation, and urged Congress to support the President's budget request.

In future, the administration should have a new ally in its battle for support of SDI. The Science and Engineering Committee for a Secure World, comprised of some 77 scientists and engineers, believes SDI deserves the "full support of the scientific community, Congress and the American people". Fred Seitz, president emeritus of Rockefeller University and acting chairman of the committee, says the group was formed in response to recent efforts by academics opposed to SDI (see *Nature* **321**, 369; 1986). Spokesman John Kwapisz says that one of the committee's chief goals is to correct the growing public misconception that all scientists and engineers oppose SDI. But with no financial support and no clear agenda for the future, Seitz says he cannot tell how large a part the committee will play in the debate over SDI.

Joseph Palca

Laser cut down to size

LOCAL residents in the predominantly rural and conservative area of California in which the Lawrence Livermore Laboratory is located have forced the laboratory to modify its plans to build a free-electron laser (FEL) too big to fit within the laboratory fence. A high-level panel under Dr George Dacey, president of the Sandia National Laboratory, has been convened to settle the issue.

The Livermore FEL is part of the development of the Strategic Defense Initiative (SDI) and in its original form would have cost $1,000 million. The device was to have been a 300 MeV induction linac (linear accelerator) designed to produce 1 μm radiation at a power of 100 MW.

Local opposition to the proposal to extend the laboratory's perimeter fence to accommodate such a large machine has led Livermore to propose a new plan for two FELs operating at half the linac voltage (150 MeV), one at the laboratory and one at the army range at White Sands, New Mexico. The second FEL would be capable of being upgraded to 300 MeV.

Enthusiasm at Livermore for free-electron lasers as part of the SDI programme stems from the recent success of the 1.5 MeV induction linac at Livermore, at which 40 per cent of the beam energy is converted into 3 cm radiation. The larger versions would incorporate long tapering "wiggler" sections for generating radiation output by the motion of fast electrons through a corrugated magnetic field.

Among the outstanding problems are the construction of a pair of laser mirrors separated by 4 km so as to match the linac beam. Another problem faces the "second" FEL — apparently neither Livermore nor the US Army will accept responsibility for its maintenance.

Livermore is now the main centre in the United States for military FEL research, with a budget of $80 million a year. As with many other SDI elements, supporters argue that recent developments constitute a major breakthrough; opponents of the ground-based FEL system say it would be, at best, cumbersome and vulnerable. □

Neolithic Jericho

Ancient wall theory teeters

Rehovoth

HEBREW University Professor Ofar Bar-Yosef seems bent on seeing the walls of Jericho come tumbling down again. Bar-Yosef says that the structure identified by the British archaeologist, the late Dame Kathleen Kenyon, as part of a mediaeval city wall, was in fact part of a flood control system used by farmers to control the flow of water from neighbouring wadis. If confirmed, this may mean that Jericho was not the world's first walled city.

This development has emerged from a programme of research that has thrown new light on the first use by farmers of cereals in the Middle East. Bar-Yosef has, for example, excavated from the site of another Neolithic village at the brief settlement of Netiv Hagdud, 15 km to the north of Jericho, samples of carbonized grain which, according to Mordechai Kislev, contain both wild and cultivated barley dating from the period 8,200 BC to 7,500 BC.

The fact that both wild and cultivated barley were found at the same site suggests that both were growing there 10,000 years ago. Bar-Yosef believes that his new find is the earliest record of the use of cultivated cereals, and he believes that wheat as well as barley was part of the Neolithic farming pattern. By the biblical era, the use of cereals was sufficiently well established to support the well-known statement in *Deuteronomy* that "Man doth not live by bread alone...".

Several research groups in Israel are involved with the search for the origin of modern cereals. Since the discovery almost exactly eighty years ago of a surviving primordial wild wheat plant growing out of a crevice in a rock near the village of Rosh, in what was then Turkish Palestine, much has been done to conserve these ancient plants. The agronomist Aaron Aaronsohn who found the first plant, followed by others in Syria and trans-Jordan in succeeding years, had hoped to transfer some of the genetic characteristics of the wild wheat to the commercial strains, but breeding techniques at the time were not good enough. But now Professor Moshe Feldman at the Wiezmann Institute, by manipulating chromosomal segments, claims to have incorporated some of the ancient genes into commercial strains of wheat that yield as much as existing varieties but boast a protein content up to six per cent greater.

Meanwhile, Feldman and his colleagues are asking that the existing fields of wild wheat will be carefully fenced off so as to preserve the pristine genetic constitution of the plants.

Nechemia Meyers

Japanese psychiatry

Fetus research criticized

Tokyo

ARGUMENT over the rights of psychiatric patients in Japan has resurfaced with the release of a report from the Japanese Society of Psychiatry and Neurology's human rights committee. The report censures the conduct of an experiment on a fetus aborted from a schizophrenic woman. The "human experiment", performed at Gifu University, is seen as a test case by those critical of current psychiatric practice, as is spelt out in a letter from one of their representatives in this issue of (see page 556).

There is general agreement only on the bare facts of the Gifu case. The patient concerned was a 34-year-old schizophrenic woman with a long history of mental illness. She was admitted to a Gifu hospital in January 1984 and found to be about five months pregnant. Shortly afterwards she was transferred to Gifu University Hospital where the pregnancy was terminated. The fetus was dissected and its brain examined for the effect of the drugs the woman had been taking.

It was not until May 1985 that the case attracted the attention of the press. It was alleged that the woman had been forced to undergo an abortion simply so that the doctors could experiment on the fetus. Those critical of psychiatric conduct quickly labelled the case as an example of the "research supremism" that leads psychiatrists to view patients merely as opportunities to further their academic careers. Protests over the case grew to such an extent that fear of violence led the Japanese Society for Biological Psychiatry to cancel a meeting that was to have been held at Gifu with doctors involved in the experiment present.

Two invited foreign speakers also had to abandon their talks even though they were moved to a secret venue. Both speakers have expressed their views in *Nature* (**319**, 172; 1986; and **320**, 392; 1986). They had been told that protesters were radical "anti-psychiatrists" who frequently disrupted meetings with violence and that Dr Moriyama of Tokyo University who was their *de facto* leader. Dr Moriyama has clearly rejected the label of "anti-psychiatrist" for himself and denied any violent intent on the part of Gifu protesters (*Nature* **318**, 308; 1986).

Did the Gifu case involve malpractice? On the evidence supplied by the Gifu doctors alone there is no reason to think so. They say that the woman was admitted to hospital because she was showing schizophrenic symptoms; that she freely chose to have an abortion because of the difficulties she would face in bringing up a child; and that the idea of examining the fetus came up only after the woman had decided to have an abortion.

The Society of Psychiatry and Neurology's report does not accept this view of events and raises some fresh ethical issues. In the committee's view there was evidence that the woman wished to have the baby and that she had been pushed into receiving an abortion: "informed consent" had not been properly obtained. There were also suspicions that admission procedures had not been properly observed. Finally, consent to the fetal experiment was not obtained from the patient, only from her mother.

Further problems stem from the experiment. Japan is without clear guidelines for such experiments so criticism was made in the light of foreign guidelines, principally there of Britain's Department of Health. Here it is made clear that a living fetus retains its rights even if it is going to die in an abortion — thus a pregnant patient should not be allowed to take a drug that could harm the fetus, even if an abortion has already been planned and even if the doctors would like to know what the effect of the drug on the fetus would be. It is not clear whether the Gifu doctors agree with this point, and further public discussion of the issues involved is called for in the report.

What is certain is that there is a need in Japan for clear research guidelines for those who perform experiments involving human beings. At least reform is now in the air. The legal rights of psychiatric patients (or the lack of them) has already become a topic of international concern and the Ministry of Health and Welfare has promised to produce changes in the law by next spring. Ethical committees are now appearing in hospitals and increasing numbers of doctors are involved in providing alternatives, such as community care, to the long stays in isolated mental hospitals that are a much criticized feature of the Japanese psychiatric system. Soon, the present controversy may be seen as one step towards an improved psychiatric care system. **Alun Anderson**

***Nature* in Tokyo:** next week (9 June) David Swinbanks takes over from Alun Anderson as *Nature's* Tokyo Correspondent.

Ageing research

Japan faces the old old problem

Tokyo

A NEW study from Japan's Council for Science and Technology tackles the nation's most serious long-term problem — its rapidly ageing population.

At present Japan has relatively few people over 65 compared with those in the working population; European countries and the United States have to divert a far larger percentage of their economic resources to care of the aged. But in 15 years' time the situation will have reversed. By the year 2000, one out of every five Japanese will be more than 60 years old. And by 2025 there will be two and a half times as many elderly people per worker as at present. The trend is a result of the remarkable longevity achieved by the Japanese coupled with a declining birth rate.

The government is already planning changes in health insurance and pension laws to ensure that it is not saddled with a bill it cannot pay in the next century The proposals from the Council for Science and Technology are complimentary changes in the scientific field and are expected to serve as guidelines for the next ten years. The council, directly answerable to the prime minister, is the top government policy body and all government ministries are expected to begin promoting research according to the guidelines. A likely outcome is the establishment of a new research centre for the study of ageing, perhaps equivalent to the US National Institute of Aging.

Senile dementia is likely to be the main research topic. In Japan around 5 per cent of the over-65 age group (more than 600,000 people) suffer from senile dementia, causing serious social problems. This total will double by the end of the century. Some means, the report says, must be found to enable old peole to live healthy and independent lives to maintain the national economy. Some forms of senile dementia are largely due to cerebrovascular disorders and there have already been successes in treatment. Research will focus on finding methods of early diagnosis when chances of recovery are high. The causes of other forms of senile dementia are still unknown. Alzheimer's disease, already a major problem in advanced countries with large populations of the elderly, will be another major research topic, as will improved methods of nursing. **Alun Anderson**

Yellow rain

Another treaty threatened

Washington

THE Canadian government last week reluctantly released new information casting further doubt on charges that the Soviet Union has engaged in biological warfare in South-East Asia. The new data show that trichothecene toxins, claimed to be the toxic agent in yellow rain, can be found in individuals who do not report being exposed to yellow rain attacks.

The data were collected as part of a Canadian effort to monitor the use of biological and chemical weapons. A spokesman for the Canadian Ministry of External Affairs said investigators obtained 272 blood samples in 1984 from different locations in Thailand. By early summer 1985, Agriculture Canada had analysed all the samples using gas chromatography and mass spectrometry. Blood from five individuals in three different locations showed signs of trichothecene toxins T-2 and HT-2 ranging from 2 to 76 parts in 10^9. The analysis also correctly detected 7 of 8 control blood samples that had been spiked with 100 parts of 10^9 of trichothecene toxins.

Although the Canadian government has had the results of the analysis for more than a year, government officials are quick to deny that the information was being supressed. Ron Cleminson for the Ministry of External Affairs explained that the information is for a report to the United Nations on arms-control verification procedures, and was never intended as a study on toxin poisoning.

Officials from the US State Department had no specific comment on the Canadian data. But department official Tom Reich says that the United States still maintains that the Soviet Union engaged in biological warfare in South-East Asia in the early 1980s. Unofficially, however, a government official did say that the new data should have a profound effect on the US position.

The past few weeks have seen a spate of new data on yellow rain. Reports from both Canada and the United Kingdom found insignificant levels of trichothecene toxins in yellow rain samples (*Nature* **320**, 699; 1986 and **321**, 459; 1986) gathered in 1982. Matthew Meselson of Harvard University, a principal author of the theory that yellow rain is not a biological weapon but rather mass bee defecation, believes that the Canadian evidence makes the US position untenable.

The latest controversy comes as the United States is preparing to attend the Geneva conference reviewing the 1972 Biological Weapons Convention. Hailed as the first step on the road to true disarmament, the treaty requires signatories to destroy existing stockpiles of biological weapons. It further prohibits any future development of production of biological agents that have no justification for "prophylactic, protective or other peaceful purposes".

The United States now takes the position that the Soviet Union has violated the terms of that treaty. In addition to charges that the Soviet Union has used biological weapons in South-East Asia and Afghanistan, the US government also believes that the Soviets have a biological weapons programme under way at a research facility near Sverdlovsk. But James Leonard, former US disarmament negotiator who negotiated the 1972 treaty, says the United States has made charges that "cannot be substantiated." To reverse the present climate of mistrust, Leonard recommends steps to encourage communication among the superpowers, such as an international registry of high-containment laboratories and greater participation in international scientific exchanges. While there is no indication that the treaty will collapse, Leonard believes the prospects for strengthening or expanding it in the fall review are nil.

Joseph Palca

French research

Chevènement's expected outburst

JEAN-Pierre Chevènement, the architect of the past administration's buoyant policy on research, last week accused France's new government of "unilateral disarmament in the economic war". He was referring to the cuts on science spending which flow from the conviction of the right-wing Prime Minister, M. Jacques Chirac, that reduced public spending will revitalize the economy by releasing private enterprise from tax burdens.

Chevènement's complaint, published in *Le Monde* last week, stems from his belief that world competition now threatens "whole economic and social systems" and that research is particularly important, and will "more and more decide the winners". So, says Chevènement, the Chirac government's transformation of real growth of four per cent a year in science spending into a four per cent cut was "a grave blow".

Chevènement fears that the new government is allowing the "two conservatisms" against which he had to battle to reestablish themselves. One conservative influence is industry, where only 100 companies employ more than 50 researchers and only 1,500 have any at all. The other is the academic community, which Chevènement fears may abandon its flirtation with industry and retreat to its old ivory towers.

Chevènement has a kind word for General de Gaulle, who he says was the only president before Mitterrand to recognize the importance of research, but who took ten years (1958–68) to make an economic impact with it. But the Mitterrand–Chevènement policies have now been "halted in mid-stream", while power has now returned to those who, under President Pompidou, presided over a steady decline of scientific output. Chevènement quotes Pompidou as saying that, of three ways to lose money "the most agreeable is women, the most rapid gambling, and the most certain research".

Chevènement also credits the new minister of research and higher education, Alain Devaquet, for "courageously defending" the research councils against dismemberment. On the break-up of his own ministry of research and technology, Chevènement said that it would not now be possible to establish joint programmes across research institutions. What Chirac has dismembered is the "ministry of the future".

Robert Walgate

Optical computer in sight

Edinburgh

A GALAXY of stars of European science politicians gathered at Herriott-Watt University in Edinburgh on Monday to celebrate what former French science minister Pierre Aigrain described as a "spectacular" success along the road to the development of an entire optical computer.

EJOB, the European Jount Optical Bistability programme, has cost just 1.8 million ECU (about £1.2 million) over two years but it has stimulated 20 research groups around Europe to produce what was first demonstrated in Edinburgh this week — broad-band optical switching and a basic "classical finite state machine" (the guts of a computing engine) using nothing but lasers and nonlinear optical material. "Massively parallel" optical image processing and new forms of laser-driven television are also just plausible.

Professor Desmond Smith of Herriott-Watt University and leader of the EJOB project, says the programme could absorb a tenfold increase of funding to 10 million ECU per year, but the European Council of Ministers, meeting in Luxembourg next Tuesday, has yet to be convinced of the need for an increase. Parliamentarians at Edinburgh agreed, and pressure is now increasing on European ministers, to divert a small part of the enormous Commission agricultural policy funding to science and technology. Robert Walgate

Beckman anniversary

Analysing profitable research

Fullerton, California

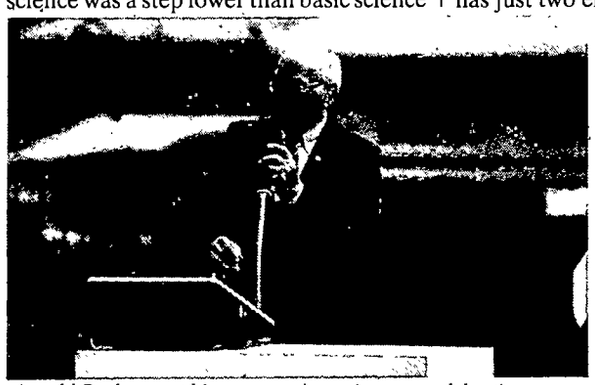
AT the age of 86, Arnold O. Beckman still has his sights set on the future.

Beckman launched his corporate career with the innovation of the *p*H meter in 1935. Many years and many millions of dollars later, the founder and chairman of Beckman Instruments still considers himself more a scientist than a businessman. Today, with his $1,000 million company safely tucked under the Smith Kline Beckman wing, the former chemistry professor from the California Institute of Technology spends most of his time and money supporting programmes that he hopes will shape scientific enterprise in the years to come. He has contributed more than $100 million in the past decade, nearly $70 million in the past year alone.

Last month, at the festivities to mark the company's 50th anniversary, Beckman spelled out his formula for keeping science in the United States alive and well. The key ingredient, he says, is education.

Of the US education system, Beckman says "we've got a big repair job to do". He sees education as a dynamic, rejuvenating escort that directs an individual throughout his or her lifetime, and he feels that the present structure of higher education misrepresents that vision. "This strange idea of dividing education into four-year packages", he says, blurs the mission of college education, which is "to teach people how to learn".

Beckman maintains that degrees awarded at the conclusion of an arbitrary period of time give the impression that education is a static commodity. The one big advantage to be gained from having a PhD, he claims, "is to realize it doesn't mean anything. I've seen PhDs who are nitwits."



How would he restructure higher education? "Like a department store" that people would patronize whenever the need for a particular item arose, not like a remote citadel whose doors shut firmly behind those who graduate.

Certainly Beckman's own career has been spurred on by insatiable curiosity. A blacksmith's son from Cullom, Illinois, he had built his own chemistry laboratory before he reached his teens. He graduated first in high school class and, within four years, earned both bachelor's and master's degrees in chemistry from the University of Illinois. A brief spell at Bell Laboratories gave Beckman the electronics background he would later exploit in instrumentation design. In 1928, when Beckman received his PhD in photochemistry from California Institute of Technology, the institute invited him to join the faculty.

Beckman and his wife Mabel were settled at Caltech when, late in 1934, one of Beckman's fruit-growing friends asked him to build a device to measure the acidity of lemon juice. Within a few months, Beckman had developed the "acidimeter"; the term *p*H had not yet been established.

By 1939, Beckman's instrument had spawned a business that demanded a full-time manager. Beckman left Caltech, not without considerable deliberation, to pour his energy into National Technical Laboratories, Inc., which eventually became Beckman Instruments. A year later, his company began marketing the model DU quartz photoelectric spectrophotometer, the Helipot potentiometer, and a portable oxygen analyser. These three products guaranteed the company's success, and by 1966, Beckman had received a business statesman award from Harvard Business School of Southern California.

Beckman's philosophy on research echoes his personal experience. "The end result of research is to find out something useful", he says. "The days when applied science was a step lower than basic science are gone." For Beckman, academic research should not be spiked with financial incentives from outside an institution. Unless patent proceeds go to the individual's employer, a researcher will find himself "working for two masters".

Arnold Beckman at his company's anniversary celebration.

Patent royalties aside, Beckman expresses concern over the lack of reliable sources of research support. "We've been too affluent", he laments. "The money (for research) comes from the public, but look at what the public is interested in; look at the salaries they pay someone for throwing a few baseballs over a plate. I'd like to see a small percentage of the GNP automatically devoted to basic research." Beckman also advocates industry support in the form of cooperative arrangements. These are in industry's best interests, he contends, because industry needs academic links.

Since the 1982 merger with Smith Kline Corporation relieved Beckman of many of his executive responsibilities, he has been kept busy practising what he preaches. Last month Caltech students, faculty and trustees gathered for the dedication of a $6.5 million chemistry building established through a Beckman donation. Beckman had previously remembered his alma mater with $7 million for an auditorium and behavioural biology laboratory. A $3.5 million gift created the Beckman Laser Institute and Medical Clinic at the University of California, Irvine and another $3.5 million set up a vision centre at the University of California, San Francisco.

Beckman also donated $10 million to form the City of Hope Beckman Research Institute; Stanford University received $12 million to erect the Arnold and Mabel Beckman Laboratories of Biochemistry. Finally, Beckman outdid himself last October with a $40 million gift to the University of Illinois, the largest amount ever given by any individual to a public university (see *Nature* **317**, 568; 1985).

Although Beckman suggests that he is "not a generous man", this lack of generosity has saddled him, to his dismay, with the label of philanthropist. Today Beckman distributes his beneficence through the Beckman Foundation, which has just two employees, Beckman and his secretary, and which receives 1,300 proposals every year.

Despite Beckman's apparent nonchalance about his benefactions, he shrewdly manipulates his wealth to promulgate his philosophy. He supports only proposals that fit his criteria for the successful research community. Beckman encourages interdisciplinary interaction, which he thinks will become imperative as science becomes more complex. He also looks for a steady "infusion of young brains, people who don't know what you can't do".

Tempering his confidence in the saving powers of science, Beckman is also keenly aware of the thorny problems it thrusts upon society. Last November, Beckman gave the National Academy of Sciences and the National Academy of Engineering $20 million for a west coast headquarters to study and adjudicate the ethical and social challenges posed by scientific advance (see *Nature* **318**, 97; 1985).

Vital to Beckman's action-oriented formula, however, is one component that cannot easily be institutionalized: enthusiasm, which he considers the best motive for any endeavour. "If you're not enthusiastic about what you're doing, you're probably doing the wrong thing", says the spirited octogenarian. By that measure, Arnold Beckman must be doing all the right things.

Karen Wright

State of Japanese psychiatry

SIR—I have read the letters from T.J. Crow (*Nature* **319,** 172; 1986) and D.P. van Kammen (*Nature* **320,** 392; 1986) and greatly appreciate the interest shown by both authors in my letter on the deplorable situation in Japan's psychiatric hospitals (*Nature* **318,** 308; 1986). I should like to repeat once again that the protest action taken against the seventh congress of the Japanese Society for Biological Psychiatry was not directed against either of these visiting scientists.

The reason for the protest was that, in Japan, the scientists responsible for experiments involving humans often refuse to acknowlege criticism. As they remain silent and avoid discussion, concerned people have to resort to protest. Such action is then sensationalized and described as "violent". Protest actions are not illegal and it is regrettable that this is their only response.

This year, on 27 March, we were able to carry out a discussion in the assembly hall of the eighth congress on biological psychiatry held in Kanazawa. We discussed with many members of the society the problem of the previously mentioned experiment on a human fetus carried out by Dr Namba and his colleagues. The doctors actually involved in the experiment did not participate in the discussion. Dr N. Hatotani, the chairman of the board of directors of the society, answered written enquiries supplied beforehand and commented that the experiment of Dr Namba was not to be censured so much. However, the discussion made clear that the investigation carried out by the society into Dr Namba's experiment was inadequate. The society had heard about the experiment from Dr Namba but did not listen to the views of those who had brought up the ethical problems of the experiment. We suggested this was biased and criticized such a method of investigation. Dr Hatotani promised further investigation and discussion.

It seems to us that the measure taken by the society on the ethical problem is quite inadequate. Professor Hidebumi Hazama of Tottori University, a member of the society, has already thrown doubt on the existing ethics of biological psychiatry in Japan and has suggested the need for a system of ethical committees. He had expected the society to take a more positive and serious attitude in this respect (*Seishin igaku* **27,** 118–119; 1985).

We also hear that the president of Gifu University orally admonished Dr Namba and other staff in February 1986 about inadequate procedures in an experiment on a human fetus. In the near future, we expect the *ad hoc* committee of the Japanese Society of Psychiatry and Neurology to make a report on that experiment.

I have previously stated that some of the published summaries of papers that were to have been delivered at the 1985 Gifu congress provided evidence of unethical conduct. As requested, we will send these summaries to Dr Crow and Dr van Kammen along with several articles on ethical issues in Japan. In my opinion, in order to assess these papers, it is necessary to be conversant with the real background of such research in Japan, for example the very low standing of patients compared with that of doctors, the difficulty of peer review owing to the absolutism of some professors, the closed character of psychiatric departments to avoid discussion and investigation of their research and so on. Such a situation is far from that envisaged in the *Proposed international guidelines for biomedial research involving human subjects* (CIOMS/WHO, Geneva, 1982).

I sincerely hope that Dr Crow and Dr van Kammen will understand the actual state of Japanese psychiatry. I would advise them both to investigate especially the experiments carried out by Dr Namba and his colleagues and to refer to the more detailed report of the *ad hoc* committee of the Japanese Society of Psychiatry and Neurology which we will send them as soon as possible.

Dutch legislation

SIR—Your leading articles have frequently highlighted developments in the United States and the United Kingdom concerning ethical and legal aspects of the use of animals in research. New regulations, based on the 1977 Act of Animal Experimentation, recently became effective in the Netherlands.

From 1 January 1986, institutes in which animal experiments are performed require a government licence, issued only if and when a number of conditions are fulfilled. One of these is that the welfare of the experimental animal must be supervised by a specialist in laboratory animal science. This officer, who is on the payroll of the institute, is a veterinarian or biomedical scientist who has taken a one-year postgraduate course in laboratory animal science and who also has some years' experience in this field. He or she reports to the director of the institute and also to the Inspectorate of Veterinary Public Health. If the animals endure extreme and/or unnecessary discomfort, the inspectorate may advise the Minister of Public Health to withdraw the licence.

A unique provision is that the scientists responsible for animal experiments must have taken an introductory course in laboratory animal science. This applies to all scientists who began animal experimentation after 2 July 1985. Courses in laboratory animal science are now being incorporated into the biomedical education programme of most universities. The course takes three weeks and its contents have to be approved by the Minister of Public Health. It covers topics such as husbandry, gnotobiology and anaesthesiology as well as the ethical aspects of animal experimentation. The primary goal is to set the stage for a justified and humane use of animals for a scientific purpose.

The training programmes are coordinated nationally and commissioned in the department of laboratory animal science at the veterinary faculty in the University of Utrecht.

Search for truth?

SIR—I disagree with Leo Uzych (*Nature* **320,** 480; 1986) that "science involves a search for truth", and with the inference he draws from this, that the orchestration of data in support of a particular point of view is an impediment to scientific advancement. I do not see science as being the gradual excavation of a buried city, but rather as the inspirational formation of structures *de novo*. What one builds is determined by the existing foundations, vision and experimental data. As such, science is not a search for truth but for quality. The extent to which one is justified in advocating individual predilections is therefore a matter for careful judgement based on the consideration that while all constructions are ephemeral, some are more so than others. Unless one is selective with data, all one can hope to produce are bricks for use by others who do not show this restraint.

Danger of delay for genetic tests

Molecular biology is providing novel means of testing for genetic disease, with the result that researchers are having to spend their time on repetitive testing. Now is the time to make better plans.

THE detractors of molecular biology used to complain that its discoveries might be interesting in an academic fashion, but would have no clinical significance. But recent years have shown that position to be untenable. Indeed, the growing impact of molecular biology on medicine is nurturing a band of clinicians with a deep interest in research while bringing molecular biologists face to face with some of the realities of disease. So much was clear, for example, at the latest International Titisee Conference (24–27 April) on human gene mapping and molecular pathology; progress is rapid, in both the laboratory and the clinic. But it will need a great deal of care, at least in Europe, if present enthusiasms are not to dissipate under the weight of that age-old resentment in which clinicians unthinkingly demand more (and different) diagnostic testing from researchers who believe, rightly or otherwise, that they have better ways in which to spend their time.

The high crest of the common ground between the laboratory and the clinic is undoubtedly, just now, the hunt for the unidentified genes whose defects are responsible for diseases such as cystic fibrosis and muscular dystrophy for which no molecular basis has as yet been determined. The magnitude of this task should not be underestimated, but, as Peter Little explains on page 558, adequate techniques are now available, if not perfected. Each gene has been located in a rather small fragment of a chromosome, but which corresponds to a stretch of DNA which is long by the yardstick of what can now be sequenced. Yet there should not be too long to wait before the first of them is identified.

The molecular probes used in location of these genes are already valuable in the prenatal diagnosis of carriers of defective genes, for the time being only within families in which the disease is known to be present. So long as the genes themselves have not been identified, success depends on a variety of factors — how many independent gene probes there are, how close they lie to the defective gene and whether there are enough close relatives of the two parents of the fetus who are 'informative' in the genetic sense. For some diseases, there is clearly room for improvement, but for many others diagnosis is already reliable. So there is a growing demand, by physicians on behalf of their patients, for tests to be carried out. Already the demand sometimes outstrips the time and people available, not to mention the people's interest in work that may seem routine.

The procedures are far from simple. Obtaining the prenatal samples is often the least of the problems, but may sometimes be limiting. This may be especially so as pressure grows to replace sampling of the amniotic fluid by sampling of the placenta as a means of obtaining fetal material, which in principle allows diagnosis earlier in pregnancy and thus earlier termination (if indicated). Curiously, although chorionic villus sampling of the placenta was originally thought to be more risky (for the fetus) than amniocentesis, experience has tended to reverse that view, although chorionic villus sampling is still relatively uncommon.

Sampling, however done, is for physicians. It is the samples that demand the immediate attention and the experience of the researchers. For the time being, most of them are likely to be eager to devote time and energy to this task, not only for humanitarian reasons but also, where the still-cryptic genetic diseases are concerned, because of the possibility that any new case may turn out to have a particular genetic defect that provides a short cut to the defective gene itself.

For each disease, this captive enthusiasm of the researchers must be a passing phase. The time must come when they want to move on to other problems. When, for example, the defective gene for cystic fibrosis or muscular dystrophy is identified, the laboratory emphasis is certain to shift to the function of the protein encoded by the gene and to the links between that function and the symptoms of the disease. Because these links are likely to lead both to new discoveries in fundamental science and to new approaches to therapy, it is in everybody's interest that they should be investigated. But who will then take over the presumably increased diagnostic load?

Even if prenatal diagnosis is confined to the industrialized countries, the imagination is challenged by the sheer scale on which testing may be required if the potential of the new discoveries is to be as fully exploited as preventive medicine. Tests which are at present complicated will no doubt be simplified as time goes on, but by then there will be other defective genes for which to test.

The problems occasioned by diseases that run in families may be relatively small, requiring as they do the testing only of family (including embryonic family) members, most probably at specialist centres which they attend already, so that there is a persuasive argument that the costs of diagnosis and even of the requested termination that may follow will be more than offset by what is saved in there being fewer afflicted patients to treat. But nobody will be surprised if this argument runs into the hidden buffers that so often hinder the application of preventative medicine.

How much greater will be the problems when it becomes feasible and seems to be desirable to screen whole populations for diseases that most often arise as new mutations, not as inherited genetic defects? Or what happens when the several genetic factors contributing to susceptibility to cardiovascular disease have been identified, a question now at the focus of a great deal of research? It should then be possible to categorize groups of people who are at risk, and who could (and should) take preventive steps, but only by complicated population screening.

At the rate at which this science is progressing, the diagnostic needs occasioned even by the simple single-gene diseases are almost certain to outstrip the creation of new testing facilities within public health-care systems, nowhere expansionist. Will medical charities feel compelled to spend less on research and more on testing? Commercial services will certainly grow to meet the need; in the United States, biotechnology companies seem bent on exploiting an emerging market, while, even in Britain, ICI's investment in a centre for providing DNA fingerprinting tests seems well set for moving to meet the growing demand of sophisticated prenatal diagnostic tests.

But where will that leave those who cannot afford the going commercial cost of tests? Especially when the need, in many industrialized communities, is most evident among immigrant populations? It will be frustrating for those laboratory scientists who have helped to open up this new vein of preventative medicine if they are faced, a few years from now, with the unpalatable choice of devoting themselves to routine analysis of a kind that they alone are able to perform or, alternatively, to see the potential benefits of their research simply run to waste.

Peter Newmark

Restriction fragment length polymorphisms

Finding the defective gene

from Peter Little

CHANGES in DNA sequences that introduce or destroy restriction-enzyme cleavage sites and cause restriction fragment length polymorphisms (RFLPs) are the key to identifying the chromosomal location of genes that cause major human genetic diseases. Here I will discuss how useful the linked RFLPs are as a starting point to isolating the defective gene itself, as this remains an unanswered question. I will then describe some ideas about how this might be achieved and some of the technical problems in reaching this goal.

What is the logic behind the use of RFLPs? Once linkage of a single RFLP with a defective gene has been demonstrated, other RFLPs that straddle the affected gene (G) can be identified. These flanking RFLPs (R_L and R_R to the left and right, respectively, of G) can be ordered by observation of the recombination between R_L and R_R, R_L and G or R_R and G. R_L and R_R then define a stretch of DNA that contains the gene. The distance between R_L and R_R must be small if these elements are to be helpful starting points from which to isolate the gene. The proximity with which R_R or R_L can be mapped to G is fixed by the number of meiotic events that are available for the analysis. Lange *et al.*[1] show that if 100 meiotic events could be studied, and assuming that 1 per cent recombination corresponds to a separation of 10^6 base pairs (bp), then the best resolution that could be achieved for the separation of R_R and R_L would be about $2 \times 10^6 \pm 1.4 \times 10^6$ bp of DNA. Steinmetz and co-workers have shown that the relationship between recombination and physical distance in one such locus, H–2 of mouse, is not linear; 1 per cent recombination can be equivalent to 5×10^5 and at worst, from an experimental point of view, 10^7 bp depending on the location within this gene family[2].

The DNA probe that defines a RFLP provides indirect information about the physical distance between R_R and R_L, because orthogonal[3] or field-inversion[4] gel electrophoresis can be used to fractionate DNA fragments of up to 2×10^6 bp generated by cutting with rare 6-, 7- or 8-base recognition restriction enzymes in combination with Southern blotting.

The RFLPs define a stretch of DNA which is probably 2×10^6 bp in length and located within or near a specific chromosomal band. Three strategies can be used to isolate the defective gene: candidate gene, chromosome rearrangement and cloning strategies.

The candidate-gene strategy involves the isolation of messenger (m)RNAs either from genes that are thought to be involved in the genetic defect (for example, those encoding membrane-associated ion transporters in the case of cystic fibrosis); or using randomly selected mRNAs from normal tissues that are affected by the disease, followed either by screening of somatic cell hybrid lines or by *in situ* chromosomal hybridization to show that the mRNA is encoded within the appropriate chromosomal band. Both approaches are technically feasible, but require a formidable amount of work if the normal transcript of the gene is at low abundance.

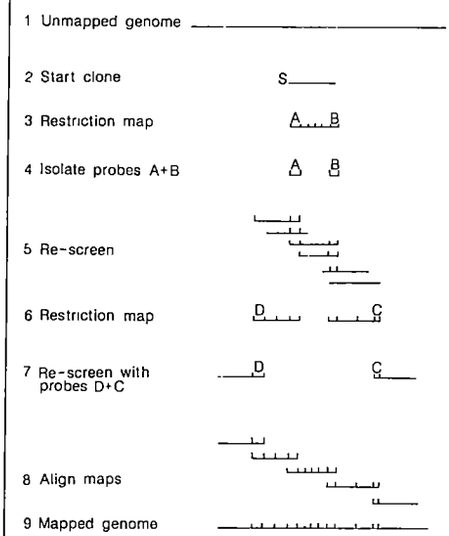

Fig.1 A and B, C and D; probes for each step.

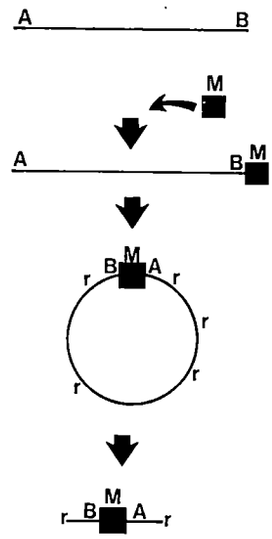

Fig.2 A and B are sequences 200,000 bp apart. M, marker DNA that can be selected in *E. coli*; r, restriction sites. The jumping library consists of many fragments with r sites at each end containing M and different As and Bs.

The chromosome-rearrangement strategy makes use of chromosome deletions, insertions and translocations to provide a marker that must be close to the affected gene[5]. Where these occur, the markers can be used to order the relative position of genes (or DNA probes) within or near the specific chromosomal region. Very little is known about the relationship of cytologically defined bands and their DNA content, but if one assumes a linear relationship (which is not true of the *Drosophila* polytene chromosome[6]) then a single band should contain about 2×10^6 bp of DNA. There are special circumstances where chromosomal rearrangements of known genes into regions of unknown structure or function can help to identify a region implicated in the gene defect[7], but these are generally rare and the precision of mapping of rearrangement breakpoints remains close to the level of the single band — again about 2×10^6 bp of DNA. Where they are available, chromosomal rearrangements will be powerful tools for the analysis of specific gene loci. Duchenne muscular dystrophy, Wilms' tumour of the kidney and retinoblastoma are the diseases that appear to be most tractable to this strategy.

The cloning strategy is based on isolating all the DNA between R_L, R_R and, by definition, the gene, and is itself divided into three approaches: mapping, walking and jumping. Mapping was first used by Steinmetz and co-workers[2,8] who isolated cosmids that contained mouse major histocompatibility complex (MHC) genes by cross-hybridization with MHC class I and II complementary DNA probes. These cosmids were restriction-site mapped and the structure of a substantial portion of the mouse MHC complex was established by aligning cosmids that contained overlapping sequences. The random mapping procedure has been extended by Olson and co-workers (manuscript in preparation) to the yeast genome (10^7bp) and by Sulston and Olson (in preparation) to the nematode genome (8×10^7 bp, which is about the same size as human chromosome 11). Similar techniques could be applied to a human chromosome isolated from a cell hybrid that only contains the required chromosome. It is well known that cosmids containing human DNA can be isolated from these cell lines by hybridization with human-specific repetitive DNA sequences. The mapping of a whole chromosome is a very considerable challenge but one that is technically achievable within the next 5–10 years. The isolation of cell hybrids that contain only a small region of the human genome by chromosome-mediated gene transfer of a naturally or artifically introduced selectable marker has also been achieved[9]. These cell lines generally contain less than 5×10^6 bp of DNA and could be ideal targets for the

mapping approach.

Walking consists of the systematic isolation of a DNA sequence located at the extreme left or right of a starting (S) cloned DNA and the use of this fragment to screen a library of cloned sequences for DNA that must be adjacent and slightly overlapping with S (ref. 10). This process is called a 'step' — a walk proceeds as a linear sequence of steps. Figure 1 shows the complex set of manipulations comprising a step. At present the cloning vectors with the largest capacity are cosmids that can carry 40,000 bp of human DNA. S.H. Cross and I have developed cosmid vectors that are designed to facilitate this procedure (manuscript in preparation). If the markers are separated by 2×10^6 bp, to walk from R_L to R_R would require at least 60 steps (allowing 20 per cent of cosmid overlap per step), which would be a formidable task. An exacerbating factor is that it is not normally possible to orientate R_L and R_R with respect to each other, and thus it is required to walk from R_R and R_L in both directions simultaneously, making the number of steps required twice as large — in the case of our procedure, a total of at least 120. The technique becomes much more attractive where several different 'starts' for the walk are available as well as R_L and R_R. Each walk can then be spread out from four or five starts, considerably reducing these difficulties.

Jumping has been suggested as a method that would reduce the number of steps that are required to walk large distances to an acceptable level — large jumps would be taken rather than individual steps[11]. Consider a 200,000-bp linear DNA molecule (Fig. 2). If it were possible to mark one end of the molecule with a short DNA sequence (M) and then to join the whole molecule into a circle, pieces of DNA (A and B) that were originally 200,000-bp apart would be on either side of the marker DNA. If many such random 200,000-bp circles (representing the whole human genome) could be constructed, and if the marker DNA plus flanking sequences could then be isolated, a 'jumping' library representing all DNA sequences 200,000-bp apart would be produced. We could isolate R_L from the library and 'jump' down the chromosome until we found R_R.

Collins (personal communication) and Lehrach (personal communication) have very recently overcome the considerable technical difficulty involved in constructing statistically complete jumping libraries. Their libraries will allow rigorous testing of the frequency of artefactual joining of sequences by inter- rather than intramolecular fragment joining and of the distance and difficulty of each jump. The use of these techniques, together with orthogonal- or inverting-field gel electrophoresis to locate jump sites, should enormously improve our chances of isolating the defective gene.

I have not approached the obvious question of how one can identify a single, defective gene in 2×10^6 bp of cloned DNA. The answer to this depends very much on the gene and the defect and will prove to be a technical challenge.

One question remains concerning all these approaches: are all human DNA sequences clonable in *Escherichia coli*? The answer is that most are but that some, probably less than 5 per cent, may not be. Wyman *et al.*[12] show that about 5 per cent of human DNA fragments cloned into lambda phage vectors will not propagate on the normal lambda phage *E. coli* hosts but require specific *E. coli* mutant strains for successful growth. The problem will probably be overcome by careful strain construction and testing.

In conclusion, it is certain that RFLPs will lead to the affected gene. Which route is taken in each case depends on the disease pathology, the chromosome location and the tenacity of the investigator, but the search will eventually be successful. It is to be hoped that the good luck which has accompanied some attempts at RFLP mapping will extend to the search for affected genes. □

Radiation detectors

Wirechambers in Vienna

from David J. Miller

BOTH 'wirechamber families' are growing; the family of users and the family of radiation detectors which they use. The Vienna meeting* serves as a reunion every three years for a worldwide community of astrophysicists, plasma physicists, medical physicists and biologists as well as the particle physicists who were the first to use proportional chambers and tubes.

The basic principle of all wirechamber devices is multiplication of the electrons released when a gas is ionized by radiation. In true wirechambers multiplication occurs in very high electric fields around fine-sense wires at positive high voltage. In parallel-plate chambers the multiplication is in more uniform fields between plates or grids. Some devices are best adapted to the detection of charged particles, but there are important developments in the detection of photons, especially at ultraviolet and X-ray energies.

Biologists are using multiwire chambers with X-rays from synchrotron sources (A.R. Farouki, MRC Laboratory of Molecular Biology, Cambridge) and with neutron beams (B.P. Schoenborn, Brookhaven National Laboratory). In both cases the chambers were developed by groups with their roots in high-energy physics. The Brookhaven chamber is filled with up to six atmospheres of ^{3}He, one of the few substances which detects slow neutrons. The chamber has a spatial resolution of just over a millimetre, which is close to ideal for resolving the neutron-diffraction patterns from laminated structures from, for example, frog retinas or crystals of complex proteins.

Recent developments in parallel-plate avalanche chambers for X-ray astronomy were discussed in a review by G. Charpak (CERN, Geneva), referring to work from the Mullard Space Science Laboratory of University College London and the University of Leicester. A minority gas (usually acetylene) has been used to enhance the avalanche gain and to reduce statistical fluctuations in measurement of X-ray energies from pulse height. Very simple readout with good position resolution has also been achieved by using fine intersecting patterns of wedges and strips on the anode. A. Breskin (Weizmann Institute, Israel) has achieved a gain of 10^8 in a multistep low-pressure parallel-plate chamber, and plans to use the technique to detect ultraviolet photons from cerenkov rings produced by electrons in a fixed-target experiment at CERN.

'The golden egg of Chicago', a large detector for primary cosmic rays which has been flown on the Space Shuttle (D. Mueller, Emrico Fermi Institute, Chicago), is a beautiful and complex device that contains cerenkov counters, scintillators and special transition-radiation detectors which are read out by xenon-filled multiwire proportional chambers. The detector already has results on the abundances of the lighter nuclei (such as C, N and O) in cosmic radiation, with a clear peak in the iron region, but there is much data still to be analysed. Wirechambers normally need a lot of tuning but these performed perfectly without any maintenance during the flight.

The new generation of storage-ring

*The fourth Wirechamber Conference took place in Vienna on 25–28 February 1986.

experiments in particle physics has generated dozens of new devices with at least two radically different solutions on offer for every problem. Almost every experiment contains a large cylindrical chamber to measure the moments of changed particles, but half of them use time projection chambers (TPCs) and the other half jet chambers. A TPC is a completely clear gas volume with a multiwire detector at one end onto which electrons drift in a uniform electric field. It is, in principle, the ideal three-dimensional detector, but the first big TPC had many teething troubles and has only begun to work well in the past two years (D. Nygren, Berkeley, California). Meanwhile the jet chambers, which use shorter drifts and large numbers of wires stretched throughout their volume, have accumulated a very good record of reliability. Their advocates claim that these chambers can resolve bundles (or jets) of closely correlated tracks much better than TPCs. The conference heard detailed reports on new developments in TPCs from Japan and on two detectors for the large electron–position (LEP) collider at CERN, Geneva. There are new jet chambers for the linear electron– positron collider (SLC) at Stanford, California, for the Cornell University e^+/e^- collider (CESR) and for the other two LEP experiments. Each of these jet chambers has different wire geometry and different electronics. It will be fascinating to see who has guessed right.

Perhaps the most ambitious detectors of all are the ring-imaging cerenkov (RICH) counters for the DELPHI expriment at LEP (J. Seguinot, College de France; M. Turala, University of California, Santa Cruz). As in Breskin's detector, the ultraviolet photons from high-energy tracks ionize an organic vapour (TMAE). Electrons from the ionization process then drift for very long distances before reaching the sense-wires. Apart from the mechanical problems of constructing large-area thin mirrors and windows for these counters, there is a fundamental problem in RICH counters arising from the multiplication process. Electron multiplication releases ultraviolet photons that can interact with the TMAE to produce extra spurious electrons. Test results suggest that this problem can be solved by shielding each sense wire from its neighbours with little 'fences' or tubes.

One of the most exciting potential applications of wirechambers is in positron emission tomography. Good spatial resolution is needed for the 511-KeV γ rays from electron–positron annihilation, with a fast data-collection rate to accumulate a picture of the distribution of the positron-emitting isotope inside an immobilized patient. Charpak thinks it can be done with barium fluoride crystals and parallel-plate avalanche chambers. But there are problems as well as several other competing techniques such as the use of bismuth germanate crystals with solid-state photodetectors. There is a good chance that a successful system will be working before the next family reunion in 1989. □

Immunology

A common form of killing

From Peter J. Lachmann

IT HAS been established for some years that serum complement kills cells by the insertion of pore-forming molecules (plugs) into the target membrane and the suggestion that lymphocytes kill target cells by an analogous process, discussed in a *News and Views* article[1] some time ago, has been amply confirmed[2,3]. Certain bacterial toxins — for example streptolysin-O and staphylococcal alpha-toxins act in a similar way[4] as does the bee venom toxin, melittin, whose pore-forming activity is rather similar to that of complement[5]. The paper by Young *et al.*[6] on page 613 of this issue extends the role of pore-forming molecules to the eosinophil, a cytotoxic cell of the myeloid series which is known to have important cytotoxic activities both in defence against parasitic infections and in the pathogenesis of the cardiac lesions associated with eosinophilia.

The evidence presented by Young *et al.* is based largely upon electrical potential changes in membranes and lipid monolayers, techniques which have been used by other groups to demonstrate pore formation by complement and by this group to confirm the existence of such molecules in the granules from cytotoxic T cells and natural killer cells[7-9] as well as to demonstrate similar pore-forming molecules in *Entamoeba histolytica*[10]. Marker release from liposomes can be demonstrated and molecular sieving is now being used to find the size of the functional lesion. The ultrastructural appearance of the lesions produced by the membrane attack complex of complement, the final pore-forming components, and by perforins, the leukocyte equivalents, has also been extremely helpful in elucidating their nature and it will be of interest to see what the eosinophil pore looks like when seen under the electron microscope.

That the eosinophil can form pores is of particular interest because, like other granulocytes, the eosinophil has another major killing mechanism available to it — the production of oxygen metabolites producing what may be termed 'burns'. Oxygen metabolites formed by the 'superoxide burst' are known to be the principal intraphagosomal killing mechanism for microorganisms[11]. Oxygen metabolites are also implicated in extracellular cytotoxicity brought about by neutrophils and by macrophages[12]. These reactions produce their membrane damage finally by lipid peroxidation and can characteristically be inhibited by catalase or superoxide dismutase or by iron chelators. Because the eosinophil contains a peroxidase in its granules and is capable of producing a superoxide burst, it is likely that it also uses oxygen metabolites for cytotoxicity in some circumstances. It is therefore a clear example of a cell that has, and seems to use, two of the major cytotoxic mechanisms.

The third major cytotoxic mechanism of eukaryotic cells involves the production of soluble cytotoxic factors, of which tumour necrosis factor and lymphotoxin are the best described. It is clear that monocytes use tumour necrosis factor when they kill nucleated cells by antibody-dependent cellular cytotoxicity[13-15] and although the roles of lymphotoxins in killing by T cells (or B cells) remain to be clearly defined, these cells can certainly produce lymphotoxin, which presumably does function *in vivo*.

It is therefore now becoming clear that these three major mechanisms — plugs, burns and poisons — are used in various combinations by different cell types and in different circumstances. Young *et al.* show that eosinophils can use plugs as well as burns. Lymphocytes use plugs as well as poisons and macrophages certainly use burns as well as poisons. It will be interesting to see if any cell uses all three mechanisms. □

Physics

Low-dimensional electron movement in a magnetic field

from Paul Chaikin

ELECTRONS in two dimensions in a perpendicular magnetic field move in circular orbits. Quantization of these orbits is responsible for the quantum Hall effect as well as a wealth of oscillatory phenomena in metals. But electrons in one dimension in a magnetic field cannot form such orbits. The discovery of a series of magnetic field-induced phase transitions, oscillations and behaviour like the quantum Hall effect in Bechgaard salts, which act as quasi-one-dimensional organic conductors, has stimulated a flurry of recent experimental[1-5] and theoretical[6-9] work and the discovery of a new form of instability in a two-dimensional system[10,11], as well as many unanswered questions.

The crystal potential has two interesting effects on the states of a two-dimensional system in the field. If the potential is reasonably isotropic (as in a square lattice) the electron orbits are distorted but closed and periodic. The wavefunctions must satisfy both orbital quantization and crystalline symmetry, conditions which are usually incommensurate. The result is a complex hierarchical self-similar energy spectrum with gaps on all energy scales[12,13] (Fig. 1). If the potential is highly anisotropic the motion of the electron may form a zigzag pattern which goes off in the easiest direction and never closes — an open orbit (Fig. 2).

The Bechgaard salts provide a unique system for the study of an interacting two-dimensional electron gas in a magnetic field. They have the formula $(TMTSF)_2X$ where X is PF_6, ClO_4, ReO_4 and so on[1-5], and are variously regarded as quasi-one- or quasi-two-dimensional. They are better known as the first organic superconductors, but they can also have insulating spin-density wave (SDW) ground states depending on the pressure and on the anion X. The band structure has been calculated and measured: the anisotropy in bandwidths in the highly conducting plane is about 10:1, whereas between the planes the bandwith is smaller by a factor of 30.

It is well known that one-dimensional metals are unstable against a Peierl's distortion or SDW which leads to an insulating ground state. For the Bechgaard salts under consideration the band-

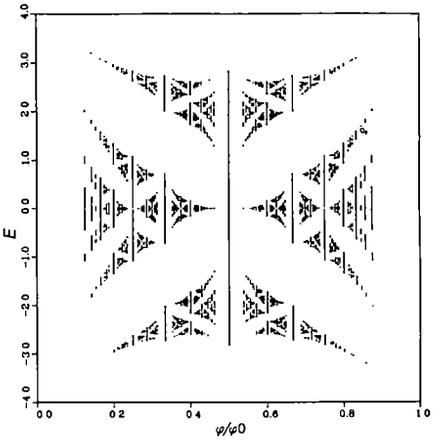

Fig. 1 Energy spectrum of an electron in a square tight binding model in the presence of a magnetic field measured in flux quanta per unit cell (ϕ/ϕ_0). Dark regions, allowed states.

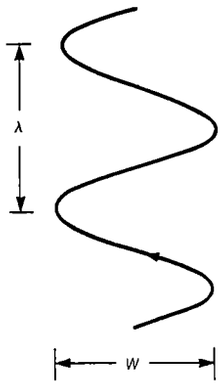

Fig. 2 Electron motion in a magnetic field for an open orbit. w and λ are proportional to the reciprocal of the magnetic field.

width in the second most conducting direction is large, the systems are effectively two-dimensional and they remain metallic to low temperatures. But the anisotropy is sufficient to make all the orbits open at the Fermi surface. In the presence of a magnetic field the electrons undergo the motion illustrated in Fig. 2. As the magnetic field increases the width w of the motion along the x direction and the period λ along the y direction decrease. The effect is to make the electrons more one-dimensional and thus increasingly susceptible to an SDW transition. Strictly speaking, the electron motion and the spectrum of the open-orbit electrons in a magnetic field is always one-dimensional (limited excursions along x and infinite along y). Thus, two-dimensional open-orbit metals cannot exist at zero temperature. An infinitesimal magnetic field will drive them to an insulating Peierl's or SDW state[12,14].

The basic instability leading to the field-induced transition is therefore well established. There are several quasi-classical models that seek to explain the series of phase transitions which allow the wavevector of the SDW distortion to change both continuously and discontinuously to take advantage of the magnetic quantization of carrier pockets which result from the distortion[6-9].

In the usual treatment of the one-dimensional instability a single length is considered — the reciprocal of the Fermi momentum (P_f) — and this sets the wavelength of the distortion at $\hbar/2\ P_f$. In the field-induced phase there at least three lengths, $\hbar/2\ P_f$, the magnetic length λ (Fig. 2), which varies reciprocally with the magnetic field, and the lattice period. In general the lengths are incommensurate with one another. The distortion wavevector results from the competition of the interactions represented by these lengths. The spectrum resulting from incommensurate potentials is often quite complex, as illustrated for a particular case in Fig. 1.

One might expect that the existence of the small gaps in the spectrum are inconsequential, as they are usually smeared out by finite temperature or scattering. The gaps have a profound effect on the Hall conductance, with the most dramatic effects involving large changes in magnitude and sign of the Hall conductance resulting from the smallest gaps[14]. More perfect crystals show an increasing number of field-induced transitions with abrupt sign changes in the Hall voltage[15], suggesting that in these salts an incommensurate spectrum is involved[3]. The existence of oscillations with a different magnetic frequency at high fields also points to a complex spectrum[2].

There are still basic questions left to be answered. The eventual state at high field should be insulating, but so far only semimetallic behaviour has been observed. And what of the quantum Hall effect? Hall measurements indicate steplike structure, but it is temperature dependent and has other dissimilarities[15-17]. The interplane bandwidth is small enough to allow the two-dimensional instability to occur, but is the system two-dimensional enough for the quantum Hall effect? The roles of incommensurability and dimensionality need further investigation. □

Desert ecosystems

Desertification or xerification?

from N.E. West

'DESERTIFICATION' has become a common term to describe the impoverishment of terrestrial ecosystems induced by man. But the word is much abused, often preventing the realization that deserts occur naturally in certain ecological contexts. Although the impression that deserts are produced by man helps to generate interest, and therefore money, to investigate problems of vegetation diminishment and soil degradation, particularly in regions of semi-arid climates[1,2], it encourages emphasis on treating the symptoms of abuse rather than the causes of the problems.

Deserts vary enormously around the world, with only some of those under the most arid conditions having escaped severe alteration by man[3,4]. Le Hourerou[5] proposed the term 'desertization' to imply the expansion of desert-like landforms and landscapes in arid to semi-arid environments. This word is supposed to avoid issues such as ecological degradation of tropical forests into savanna of forest into maquis, which can still be described as 'desertification'. But the distinction is probably missed by most and, in any case, degradation of terrestrial ecosystems usually does involve drying-out of the previous environment. Water typically enters the biological phases less easily, yet moves through an ecosystem more rapidly, following disturbance introduced by man. If soils are more compacted and organic matter lower, less water can infiltrate and be stored. Accelerated erosion of the soil surface may reduce the depth of the rooting profile as well as removing the most nutrient-rich portions. More xerophytic (drought-tolerant and less water-demanding) plants typically replace the preceding comparatively less xerophytic ones removed by excessive livestock grazing, wood harvest, fire and mechanical damage. This gives the impression that macroclimates must have changed when the major alterations in climate have occurred at soil level. Kovda[6], therefore, proposed the term 'aridization' to describe the drying-out process. The disadvantage of this word is that it can be confused with a permanent change in macroclimate.

I have recently used the term 'xerification' to describe the concomitant diminishment of vegetation and degradation of soils under unsustainable levels of land use in semi-arid areas in western North America[7]. This term could be used in more climatically favourable regions without the value-judgement implicit in

Albert L. Lehninger (1917–1986)

ALBERT LEHNINGER, who died on 4 March, is known to young and not so young biochemists all over the world as the sole author of the widely used textbook, simply called *Biochemistry*, the first edition of which appeared in 1970. To the older biochemist and to all those engaged in the study of the branch of biochemistry and biophysics called bioenergetics, he is known as one of the founders of their field. He was one of the first to publicize the word bioenergetics in his monograph bearing that name, published in 1965. His first book, *The Mitochondrion*, had appeared a year earlier.

It was his work on this sub-cellular organelle in the late 1940s and the 1950s that first brought him fame. Together with E.P. Kennedy, he showed in 1948 that a particulate fraction of rat liver, identified as mitochondria, catalyses all the reactions of the Krebs cycle and fatty acid oxidation. For this work Kennedy and Lehninger are co-recipients of the 1986 Passano Foundation Award.

Lehninger is perhaps best known for his second classical paper, also published in 1948. In that paper, together with his student Morris Friedkin, he described phosphorylation of adenosine diphosphate by inorganic phosphate, coupled to electron transfer between reduced nicotinamide nucleotide and oxygen (catalysed by the so-called respiratory chain). The phenomenon of oxidate phosphorylation itself had already been established by Engelhardt and Kalckar in the 1930s and before the Second World War Ochoa and Belitzer had made it likely that it was of a fundamentally different type from the only known phosphorylation reaction, linked with anaerobic processes. But the direct demonstration of what became known as respiratory-chain phosphorylation had proved elusive. Lehninger succeeded in two types of experiments, one with reduced nicotinamide-adenine dinucleotide as substrate and the other with 3-hydroxybutyrate, which reduces the nucleotide in a reaction that could not conceivably be associated with phosphorylation.

With the hindsight of nearly 40 years, we now know that the results of the first type of experiment were not as unambiguous as they at first appeared, but the second type remain valid and were sufficient to establish the concept of respiratory-chain phosphorylation. Lehninger was also the first to demonstrate phosphorylation in the terminal reaction of the respiratory chain — the oxidation of reduced cytochrome *c* — once again after failures by others. He was also one of the first to observe the energy-linked uptake of calcium by mitochondria and the first to make a thorough study of its characteristics.

Lehninger was one of a vanishing type: the highly successful research worker who is also a prolific writer. Also unusual is that all his books are monographs. How he was able to face up to the tremendous chore of regularly bringing out new editions of his monumental textbook was a source of wonder to many. Surely the explanation is that he enjoyed writing. That he was a such a lucid writer was no surprise to those of us who used to listen spellbound to his lectures at international meetings, delivered without any notes. The polish of these performances could only have been achieved with meticulous preparation.

Lehninger's early work was done at the University of Chicago where he moved in 1945 after obtaining his Ph.D. at that nursery of American biochemists at that time, the University of Wisconsin. He spent the academic year 1951–1952 at the University of Cambridge, England, and in 1952 was appointed Professor of Physiological Chemistry at Johns Hopkins University, Baltimore, where he stayed until his death. His colleagues at Johns Hopkins had planned a symposium, appropriately called *The Mitochondrion, 1986*, to be held in his honour on 5–7 June. The symposium will still be held, now sadly to his memory as well as in his honour. E.C. Slater

words such as desertification, desertization and aridization.

Irrigated lands in arid to semi-arid climates which have increased water tables and/or direct salt input from the irrigation water eventually support lowered crop production. Even some originally forested lands in southern Australia develop such problems when the high transpiration draw-downs affected by the forest are eliminated after tree removal. The only plants that can grow on some of the most heavily salinized former farm- or forestlands are shrubs normally found in desert regions. The soil moisture is excessive, but the soils are physiologically dry to non-desert species. The term xerification would more usefully describe these processes than the narrow word salinization.

Clearly it will be difficult to distinguish natural xerification from that induced by man. But palaeoecological evidence shows that deserts are relatively young ecosystems on all continents, and thus have arisen naturally. Therefore it is important to elucidate natural, as well as man-made, mechanisms. □

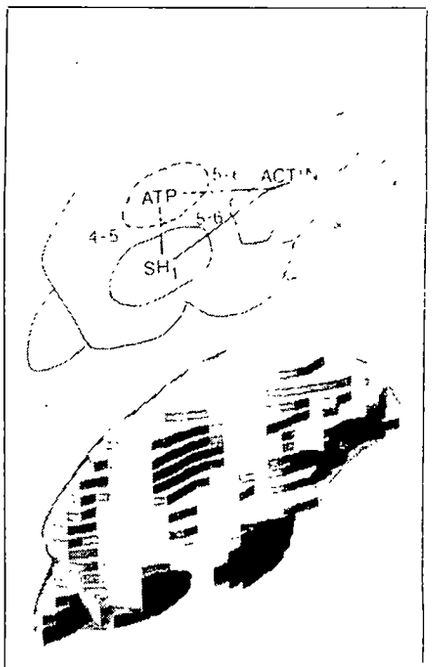
Muscle contraction

Crossbridges, force and motion

from Richard T. Tregear

THE basic question that concerns those interested in crossbridges is 'what makes muscle pull?'. Many different answers have been suggested over the years. Some simple and elegant experiments described at a recent workshop* exclude several of them. Other experiments place constraints on the part of the myosin head (or crossbridge) responsible for the generation of force consequent on ATP hydrolysis. The picture which emerges is of a crossbridge (which projects from the thick filament of muscle fibres) that can easily attach and detach from actin (in the thin filament) in the first part of the enzymatic cycle and then 'harden' its attachment and produce force in the later part of the cycle. The contractile process occurs in the middle of the myosin head, does not need the other head of the myosin molecule, much of the tail region of the molecule or even, perhaps, the light chains of the head itself. The process probably involves only a small change in the shape of the head, is reversible and can sometimes couple to a huge interfilament movement. Altogether this picture is not very like the usual undergraduate idea of crossbridge rotation and force production.



The evidence for these statements comes from a wide variety of approaches. The idea of the rapidly attaching weak-binding crossbridge comes from enzymatic studies (E. Eisenberg, NIH), and fits both with the way in which measurements of crossbridge attachment by X-ray diffraction (H. Huxley, Cambridge; K. Wakabayashi, Osaka) and mechanical stiffness (R. Simmons, London) are seen to rise before tension during activation and with the large number of disorganized myosin heads still seen by electron proton resonance (EPR) when a muscle is contracting strongly (D. Thomas, Minneapolis). On the other hand, the strong-binding, tension-generating state may be best seen by electron microscopy of muscle in rigor (M. Reedy, Duke); at any rate, no regular crossbridge angle other than that of rigor (thought to represent the maximal force-producing state) has been detected by EPR or polarized fluorescence in actively contracting muscle.

The resolution of immuno-electron microscopy is now good enough to divide the myosin head into a regulatory neck and an operative body, and within that body to locate the three regions most likely to transfer energy across it: the nucleotide- and actin-binding regions and the interlinking part close to the active thiol residue (T. Wakabayashi, Tokyo; see figure). Furthermore, both the sequence near the thiol and the purine-binding sequence have turned out to be highly conserved, being invariant from slime mould to rabbit, as if they perform an essential function (J. Spudich, Stanford).

Optical microscopy has now improved to such an extent that one can see the motion of unrestrained actin filaments over myosin, or of particles coated with myosin over actin (Spudich; T. Yanagida, Osaka). Such motion occurs even when the myosin is single-headed or its tail is greatly reduced in length. These experiments appear to eliminate contractile mechanisms dependent on either head–head interaction[1] or a change in tail structure[2].

Chemists have managed to attach a photolysable group to ATP (caged ATP) that can be diffused into muscle before lysis releases the ATP itself[3]. The resultant synchronized events indicate that phosphate release and tension generation occur together and that both processes are reversible (Y. Goldman, Philadelphia). It follows that tension can be regenerated without coupled ATP hydrolysis, which was not envisaged in earlier ideas of the crossbridge cycle[4].

An ingenious argument was presented from a couple of conceptually simple experiments. If actin is proteolytically cut loose in a myofibril or if myosin heads are floated into a brush of actin filaments, they remain still until ATP is added and then they move, quite rapidly. Yanagida measured the speed of motion and the rate of ATP hyrolysis and deduced that each crossbridge stroke using ATP moves the myosin molecule by at least 60 nm, which is too far for the crossbridge to stretch[5,6]. Is there something wrong with Yanagida's logic, or with the crossbridge theory itself? □

Neuroscience

Optical mapping of activity in primate visual cortex

from D. Van Essen and H. S. Orbach

MUCH of our current understanding of cortical function has been gained by analysing how different types of information are represented in a systematic fashion within the three-dimensional architecture of the cortex. This is most evident in the case of primary visual cortex (striate cortex) of primates, where cortical architecture is specialized to a notably high degree and where many of these specializations have interesting neurophysiological correlates. In a report on page 579 of this issue, Blasdel and Salama[1] use a relatively new technique involving *in vivo* application of voltage-sensitive dyes to ascertain how selectivity for stimulus orientation is mapped across the surface of striate cortex in the macaque monkey. Their study provides an intriguing and unexpected hint about modular organization of the cortex. In addition, it emphasizes the feasibility of the optical approach for attacking a host of interesting issues concerning cortical function.

It is well known[2] that cells in the striate cortex are arranged in orientation columns, in which aggregates of cells aligned orthogonal to the cortical surface all respond best to the same stimulus orientation (except for cells completely lacking orientation selectivity). Parallel to the cortical surface, orientation preferences tend to shift gradually and smoothly, with only occasional discontinuities in the progression. A major unresolved issue has been the relationship of this orderly array of orientation columns to two other basic features of striate cortex: a system of ocular dominance stripes that is most clearly delineated by a sharp segregation of geniculocortical inputs from the two eyes within layer 4; and a patchwork array of cytochrome oxidase-rich 'blobs', which are aligned with ocular dominance stripes and whose constituent cells generally lack orientation selectivity[3].

What has clearly been needed to sort out these relationships is a means for monitoring the two-dimensional pattern of visually evoked cortical activity with high spatial resolution. The 2-deoxyglucose technique, in which activity-dependent metabolism is measured autoradiographically, has proven helpful in this respect[4]. But it suffers from being a one-shot approach, in which only a single stimulation condition can be tested in any given cortical region. The technique of *in vivo* optical monitoring of neural activity using voltage-sensitive dyes is in principle much more flexible, because it has vastly superior time resolution and allows repeated measurements using various stimuli. First developed and tested on invertebrate preparations by Cohen and collaborators[5], voltage-sensitive dyes have recently been successfully applied to the mammalian somatosensory and visual cortex [6,7].

Several methodological refinements introduced in the study of Blasdel and Salama[1] yield a spectacular increase in the spatial resolution of the technique. Most importantly, the authors used a video camera instead of the standard photodetector array, and monitored a very slow visually evoked response, thereby gaining spatial resolution in exchange for an affordable loss of temporal resolution. In addition, they used a clever combination of stimulation paradigms and image-processing techniques to generate detailed false-colour maps of how orientation preferences are mapped across the surface of the cortex. The basic validity of this analysis was confirmed by direct comparisons between optical and electrophysiological determinations of ocular dominance and preferred orientation at selected sites.

Blasdel and Salama find that regions of similar orientation preference generally occupy small patches in the orientation map. These patches range from nearly circular to highly elongated in shape, with a length typically less than 1 mm. The alignment of iso-orientation domains is not strongly correlated with ocular dominance stripes nor with cytochrome oxidase blobs, an outcome which is consistent with previous deoxyglucose-based results[4]. It runs counter to more organized patterns that have been hypothesized, such as an orthogonality between ocular dominance and orientation stripes[7] or a radial or circumferential arrangement of iso-orientation domains centred around cytochrome oxidase blobs[8].

A particularly striking feature of the orientation maps is a pattern of 'fractures', lines or narrow strips along which the preferred orientation changes very rapidly. The fracture lines form a tightly interlaced network containing numerous loops and rings that are variable in size and shape, but are generally much less than 1 mm across. Blasdel and Salama raise the intriguing suggestion that these fracture lines form the outlines of discrete 'modules' within the cortex. However, they also note several potential complications relating to the fracture lines, and these deserve careful evaluation.

One of the complications arises from the fact that the maps display a well-defined orientation at all points, even in regions which post-mortem histochemistry shows to be superimposed on the cytochrome oxidase blobs. This is surprising in view of the previously mentioned complete absence of electrophysiologically assessed orientation selectivity in most blobs[3]. One possibility is that orientation selectivity might indeed be present in the blobs, but restricted to the most superficial cells (say, in layer 2), which presumably dominate the optical signals. Alternatively, the apparent orientation selectivity within the blobs might arise from spatial blurring of the optical signal, for example, as a result of light scattering within the cortex or as a reflection of the extent of dendritic arborizations. By this hypothesis patches whose cells genuinely lack orientation selectivity would nonetheless show an apparent orientation preference throughout, by virtue of spatial averaging of the orientations of nearby sites within the blur circle. Fracture lines associated with blobs would then no longer represent an abrupt discontinuity in a parameter that has a well-defined value at each point, but rather a mismatch in the extrapolated orientation in going from one side of a blob to the other.

Another puzzling feature is that not all orientations are equally represented within either of the two orientation maps illustrated by Blasdel and Salama. In particular, one oblique orientation (light blue in their false-colour representations) appears to be notably sparse, generally occurring as very narrow strips. Non-linearities in the colour reproduction process may contribute to this impression but are unlikely to provide a complete explanation, because many of the fracture lines run directly along the thin strips associated with the under-represented orientation. There may be pronounced anisotropies in the cortical representation of orientation, analogous to those suggested from electrophysiological recordings[9]. Yet another possibility is that the apparent under-representation was a consequence of slightly reduced efficacy of a particular stimulus orientation, conceivably because of astigmatism of one or both eyes. A final complication to the fracture story is that some of the fracture lines (more than seems likely by chance association) appear by visual inspection to parallel closely the vascular pattern (including some of the smaller blood vessels) that is shown in a figure accompanying the study. This may reflect yet another way in which non-neural factors can subtly bias the orientation estimates derived from optical measurements.

The question of whether striate cortex contains well-defined modules is fundamental to our understanding of cortical organization. Hubel and Wiesel[2,4] laid the

groundwork for this notion with the suggestion that any small region of cortex, about 1–2 mm on a side, contains a set of 'hypercolumns', that is, all the neural machinery needed for the analysis of orientation and ocular dominance in any small portion of the visual field. The idea received a major boost with the discovery of the cytochrome oxidase blobs, which clearly denote an anatomically distinctive two-dimensional repetitive pattern, but which leave open the question of whether hypercolumns have well-defined starting and stopping points.

The orientation fracture lines described by Blasdel and Salama are attractive candidates for hypercolumn boundaries. But the relationship is not entirely straightforward, as most of the modules delineated by fractures fail to enclose a complete set of orientations, and do not all contain a representation of both ocular dominance stripes. A more precise understanding of this relationship must await resolution of the technically based concerns described above about the origins and interpretations of some of the orientation fracture lines.

These concerns are amenable to experimental analysis, and clarification of the key issues should not be long in coming. Further refinements may also be anticipated for dealing with various technical limitations of the optical technique relating to signal-to-noise problems, image blur and the analysis of signal distribution within the third dimension (depth) of the target tissue.

In the meantime there is good reason to celebrate the successful application of voltage-sensitive dyes to basic questions of cortical organization. Blasdel and Salama have made clear that optically based activity monitoring techniques will become a powerful component in the ever-expanding repertoire available to neuroscientists interested in structure–function relationships within the brain. Application of this approach to questions of information processing, development and plasticity in sensory and motor areas of the cortex will keep many laboratories busy for years to come. □

Molecular biology

Why do disused proteins become genetically lost or repressed?

from Jared M. Diamond

ARTICLES in these columns typically focus on recent discoveries. But progress also depends on exposing areas of ignorance. Hence this article concerns our failure so far to resolve a fundamental problem of biology: why disused proteins become phenotypically repressed and are eventually genetically eliminated[1–5].

Evolution consists of the acquisition and loss of traits. Most biologists since Darwin have agreed that the acquisition of functionally significant traits is caused by natural selection. But why do disused, formerly significant traits become lost? (Think of the loss of eyes in cave animals, or the loss of flight in birds on predator-free islands.) Two answers have been suggested, both stemming from Darwin's work: disuse or natural selection. Most mutations destroy a function rather than improve it. Thus, if a character becomes selectively neutral through disuse, mutations will gradually remove the character even in the absence of positive selection to eliminate it. On the other hand, any character costs something to build and maintain. Thus, a disused character may be selectively disadvantageous, not merely neutral; selection may eliminate the character to recoup the wasted costs. The cost most often mentioned in this context is biosynthetic energy.

The traits whose costs could be measured most easily are single enzymes or biosynthetic pathways. Consider auxotrophic mutants, which have lost the ability to synthesize some essential solute and can grow only if that solute is provided exogenously. Lwoff[6] proposed that there should be positive selection for such mutants in the presence of the solute because the mutants save unnecessary biosynthetic costs incurred by the wild strain. Zamenhof and Eichhorn[7] confirmed that His^- and Trp^- auxotrophs of *Bacillus subtilis* are selected over the wild-type strain in the presence of His and Trp, respectively. Similar findings apply to Tyr^- and Trp^- auxotrophs of *Escherichia coli*[1,8]. Few attempts have been made to compare the saved biosynthetic costs of the auxotroph at the molecular level with its selective advantage at the population level, and thereby to decide whether the wasted energy hypothesis suffices to explain this genetic loss of a disused trait. The rare attempts that have been made cast doubt on the energy hypothesis[1,2].

The most detailed comparison is one in which Dykhuizen[1] used a chemostat to study *E. coli* mutants differing from the wild type only in their inability to synthesize tryptophan (Trp). Dykhuizen first calculated the energy needed by wild-type *E. coli* to synthesize various amino acids, assuming maintenance costs to be negligible compared with the costs of growth[9]. Amino-acid synthesis was estimated to cost 40 per cent of the total energy budget, Trp, in particular, 1.25 per cent. In a Trp-containing medium, the synthesis of this amino acid is repressed to a level where it costs only 0.01 per cent of the energy budget. The energy to synthesize the Trp-synthesizing enzymes themselves (in the absence of turnover) was estimated as only 17 per cent of this cost of Trp synthesis. Thus, if the sole advantage of the auxotrophs over the wild type in a Trp-containing medium were the saved synthetic energy, the auxotrophs should have had an insignificantly higher growth rate, by 0.01 per cent per generation (independent of generation time). In fact, their growth rate advantage was far greater — around 10 per cent per generation — and it increased with generation time.

Because these calculations of saved energy involve many assumptions, Dykhuizen next compared the selective advantage (over the wild type) of a mis-sense mutant that makes Trp-synthesizing enzymes but not the protein against a polar nonsense mutant that makes neither the enzymes nor Trp. By the saved energy hypothesis the polar nonsense mutant should have had a 17 per cent greater selective advantage than the mis-sense mutant (because energy savings are 17 per cent greater), but the two mutants were found to have the same advantage. Furthermore, mutants can still synthesize Trp from anthranilate via indole, although at some biosynthetic cost. Hence the selective advantage of the mutants over the wild type should decrease from a Trp to an indole to an anthranilate medium, and Dykhuizen, from the biosynthetic costs of each step, predicted relative advantages of 1.00:0.83:0.67. The actual relative advantages were the same for indole and anthranilate, and were lower than predicted (1.00:0.50:0.50).

Most puzzling of all, the advantage of mutants over the wild type was apparent only when they were grown together; the mutants and wild type had the same growth rates when grown separately. One can think of many uncertainties in these cost estimates: assumptions in the energy calculations that would affect the numbers; features of cell physiology that could

amplify a biosynthetic energy difference; and factors other than biosynthetic energy that should also be considered costs of Trp synthesis (for example, the space that Trp synthesis preempts in the already crowded cytoplasm or membrane[3,10]). But all these considerations still predict incorrectly that the mutants should grow faster than the wild type when grown separately. Thus, the advantage of mutants must instead involve some interaction with the wild type when grown together, such as competition for glucose, the limiting substrate.

Similar doubts concerning the energy hypothesis emerge from experiments on *lac* operon proteins[3,11,12]. For example, Andrews and Hegeman[12] compared five strains of *E. coli* differing in production of *lac* operon proteins (from 0.6 to 3.6 per cent of total cellular protein) growing in media with a substrate other than lactose. The authors observed no significant correlation between selective advantage and percentage of wasted protein.

The traditional explanation in terms of saved biosynthetic energy appears to fail. The familiar observation that synthesis of specific proteins becomes phenotypically repressed in the absence of requirement for the protein is also usually attributed to saved energy. Experiments are needed in which the selective disadvantage of a mutant that cannot repress an enzyme in the absence of its substrate is measured and compared with the saved energy or other postulated costs. □

Earth sciences

Magnetotelluric evidence for subduction of seafloor sediments

from D. Ian Gough

NEW results from magnetotelluric soundings across Vancouver Island reported by R.D. Kurtz, J.M. DeLaurier and J.C. Gupta elsewhere in this issue (*Nature* **321**, 596; 1986) provide the first correlation of high electrical conductivity with a seismic reflector at the top of a subducted plate. The good conductor, at depths of 20–50 km down the sloping plate, is best understood as composed of seafloor sediments and volcanic rocks that contain brine in their pore spaces, and carried on the Juan de Fuca plate as it subducted beneath Vancouver Island. If saline water is thus subducted at many convergent plate boundaries, the implications for the continental crust and the tectonic processes in it are important.

The magnetotelluric profile reported by Kurtz *et al.* forms part of the first of a series of transects across major structures in LITHOPROBE, the Canadian national programme of deep crustal studies. The central discipline of the programme is seismology, supported by other geophysical and geological techniques. In southern Vancouver Island three seismic reflection sections of outstanding clarity have been secured, showing both the subducting plate and much detail in the layered rocks above it (Green, A.G. *et al. Nature* **319**, 210; 1986). The magnetotelluric stations in the study of Kurtz *et al.* were sited along two of the three seismic profiles. At three stations, the top of the good conductor is correlated with a seismic reflector within 10 per cent of depths in the range 23–28 km. The results from all 18 stations in the study can be fitted to a two-dimensional model in which a sloping conductive layer correlates well with a seismic reflector interpreted as the top of the downgoing plate throughout the depth range 23–34 km. Such correlations facilitate recognition and interpretation of structures located in different physical parameters (such as elastic moduli and electrical conductivity). It is planned to obtain magnetotelluric profiles at high station density along future seismic reflection sections of LITHOPROBE on land.

Fluids in the crust are attracting increasing attention. Crustal water is of critical importance in the response of rocks to stress, in particular in the thrusting of rock sheets a few kilometres thick over areas of several thousands of square kilometres in continental collison zones such as the Himalayan, Alpine and Appalachian mountain systems. Crustal water has great economic importance in relation to metallic ore genesis and to maturation and migration of hydrocarbons. Such water is generally a brine (Fyfe, W.S. *et al. Fluids in the Earth's Crust* Elsevier, Amsterdam, 1978); the effects of the chemical reactions of this water with silicate minerals in the lower crust are being explored. A brine is a very good electrolytic conductor, and provided that it fills interconnected pore spaces or fractures it will give high bulk conductivity in the rock (Shankland, T.J. & Ander, M.E. *J. geophys. Res.* **88**, 9475; 1983). This is the interpretation of the conductive layer beneath Vancouver Island offered by Kurtz *et al.*

Saline water probably exists in crustal rocks of all ages. In tectonically active regions close to ocean ridges and subductions the silicate mineral of lowest melting point may provide another fluid that fills cavities between the other silicate crystals, both in the upper mantle and locally in the crust. Such partial melt is generally a good electrolytic conductor, and will produce high bulk conductivity if it is in interconnected spaces (Shankland, T.J. & Waff, H.S. *J. geophys. Res.* **82**, 5409; 1977).

In the interior of British Columbia, 200–600 km north-east of Vancouver Island, a large regional conductive layer is known to exist in the lower crust and uppermost mantle. I have suggested (*J. geophys. Res.* **91**, 1909; 1986) that this Canadian cordilleran regional conductor is caused by partial melt at upper mantle depths and saline water in the crust above. The evidence for subduction of seafloor rocks containing brine presented by Kurtz *et al.* gives one reasonable explanation of the accumulation of brine in the crust of the hinterland of the subduction. If similar evidence is found in other zones of subduction, the new result may lead to better understanding of the mechanisms responsible for the transfer of water into other regions of the continental crust.

It is to be hoped that magnetotelluric soundings will be added to the collection of seismic reflection profiles in other regions so that structures can be sensed in terms both of electrical conductivity and of seismic-wave parameters. Either saline water or partial melt produces contrasts of one to two orders of magnitude in electrical conductivity, whereas the corresponding effects on seismic-wave velocities and attenuations are of the order of 10 per cent. Magnetotelluric soundings should therefore detect fluids of both kinds with much greater sensitivity than can be achieved by seismology. On the other hand, seismology gives better location of velocity interfaces and faults. The two methods are complementary, and much more powerful together than either alone, as demonstrated in recent studies of the crust beneath the Rhenish Massif in Germany (Meissner, R. & Wever, T. *Am. Geophys. Union Geodynamics Ser.* **13**, 31; 1986, and Jödicke, H. *et al.* in *Plateau Uplift* ed. Fuchs, K. Springer, Berlin, 1983), as well as in the Vancouver Island studies of Kurtz *et al.* and of Green *et al.* □

Weather forecasts still tricky

SIR—The recent paper on 'Fractal characterization of inhomogeneous geophysical measuring networks' by Lovejoy *et al.*[1] and a discussion in *News and Views*[2] address the important problem of detectability of sparse atmospheric phenomena and, therefore, of the very feasibility of useful weather forecasting. Now, whatever the difficulty of its detection might be, a sparse phenomenon will exert an influence on the *time course* of a multitude of more systematic phenomena occurring over a wide range of space scales. The main reason for this is the fundamental instability of the atmospheric system[3]: a perturbation arising from an uncontrollable localized event and acting on a larger scale phenomenon pertaining to atmospheric circulation may give rise to an (exponentially) divergent history and to an altogether different regime, or to an aperiodic sequence of regimes perceived by an unaware observer as 'noise'.

Let γ be the precision with which the initial state of the system can be determined in phase space. Assuming that the atmosphere behaves as an unstable dynamical system we obtain the following estimate for the error growth after time t:

$$\gamma(t) = \gamma e^{tK} \qquad (1)$$

where K is the largest positive Lyapounov exponent (or more generally the Kolmogorov entropy).

Since our variables are distributed in physical space, an inadequate spatial resolution l will clearly induce an error in the estimate of the variables. Conversely, if for some reason their values are subject to uncertainty, it will be difficult to locate with precision the region of space from which these variables had initially emanated. We may therefore substitute, in our crude estimate, the phase space uncertainty γ by the precision l with which the initial state of the atmosphere can be determined in the physical space and write, instead of (1)

$$l(t) = le^{tK} \qquad (2)$$

When the size $l(t)$ will reach a value of the order of the dimensions of the entire system, L, predictions concerning individual histories will become meaningless and should be replaced by statistical considerations. The time τ_m for which this will happen is[4]:

$$\tau_m \simeq \frac{1}{K} \ln \frac{L}{l} \qquad (3)$$

This gives a quantitative measure of the limits of predictability of the system. A significant feature of τ_m is its logarithmic dependence on the parameter l, and thus its relative insensitivity to space resolution. Going from a quasi-uniform to a fractal distribution of l or vice versa is not going to change this picture drastically.

So although detection of sparse phenomena is important in its own right, it is worth stressing that even with a considerable improvement of the world detection network the problem of forecasting of the global state of the atmosphere is likely to remain as acute as ever.

Activation of cellular calcium entry

SIR—A recent *News and Views* piece by Baker[1] discusses the mechanisms of intracellular calcium ion (Ca^{2+}) release from the endoplasmic reticulum (ER) but refers briefly to cellular calcium entry from the extracellular fluid as being mediated by Ca^{2+} channels gated either chemically or by voltage. Voltage-activated Ca^{2+} channels that can be modulated by intracellular messengers have been characterized in many systems[2], but are unlikely to be present in a number of different epithelial tissues such as exocrine glands and liver simply because they are unable to fire action potentials and many activating hormones or neurotransmitters evoke membrane hyperpolarization rather than depolarization in these cells[3]. Nevertheless there is clear evidence that hormones and neurotransmitters can increase unidirectional Ca^{2+} flux into, for example, pancreatic acinar cells[4].

The mechanisms underlying this receptor operated Ca^{2+} entry are at present obscure although a link with the increased turnover of phospholipids after stimulation has been suspected for more than ten years[5] with evidence for such a link being particularly clear in relation to Ca^{2+} entry in blowfly salivary glands[6]. A recently formulated hypothesis[7] suggests that receptor operated Ca^{2+} entry is secondary to the emptying of an intracellular Ca^{2+} pool mediated by the action of inositol trisphosphate (IP_3) on an electrogenic Ca^{2+} pathway (channel) in the ER[8,9]. The well-established biphasic nature of agonist-activated Ca^{2+} mobilization is, according to the new hypothesis, explained by an initial emptying of the intracellular (ER) Ca^{2+} pool by IP_3 followed by entry of extracellular Ca^{2+} into the pool and, in the continued presence of IP_3, into the cytosol. On removal of the stimulant, IP_3 is rapidly broken down closing the Ca^{2+} channel in the ER and Ca^{2+} entry from the outside continues only until the content of the ER pool has reached a level that prevents further entry.

In this model[7] intracellular Ca^{2+} release and Ca^{2+} entry are both controlled by the same messenger, IP_3. Ca^{2+} entry is therefore not directly linked to the hormone receptor, but is messenger-mediated. A recent patch-clamp study on pancreatic acinar cells[10] demonstrating an external Ca^{2+} requirement for sustained K^+ channel (Ca^{2+}-activated) opening evoked by a peptide belonging to the cholecystokinin-gastrin group may be relevant in this context since the Ca^{2+}-requirement could be localized at a site separated from the hormone-receptor interaction indicating messenger-mediated rather than receptor-mediated Ca^{2+} uptake. These recent findings[10] appear to be compatible with the hypothesis forwarded by Putney[7].

Beam balance test of weak equivalence principle

SIR—In the recent article by Fischbach *et al.*[1], commenting on a *News and Views* piece[2], a new hypercharge force is postulated as being responsible for various apparently anomalous effects in physics. Although there may not be unanimity in the interpretation of the Eötvös data in terms of this new force[3], its existence would have such far reaching consequences in physics that further experiments are clearly required. As suggested by Fischbach *et al.*, further Eötvös-type or galilean experiments come to mind. Here we propose an experiment using a common balance which would allow the force, if it exists, to be measured with good precision. The experiment would be as follows.

The weights of the two test masses made of materials having different values of (B/μ) (see ref. 1 for notation) are compared using a beam balance at two different sites. The first site is in a tunnel deep inside a mountain where it can be assured that there are some kilometres of solid rock in all directions. Here, in the absence of any net hypercharge force, the test masses are adjusted to have apparently equal masses as measured using the balance. The balance and test masses are then moved out of the tunnel to a second site on the surface of the Earth, preferably

at the same altitude and not too distant. According to Fischbach *et al.* we would expect to find at this second site a difference in apparent weight ΔW:

$$\Delta W = a\,Mg\left(\frac{B_1}{\mu_1} - \frac{B_2}{\mu_2}\right) \qquad (1)$$

Taking a value for a derived from the Eötvös data as given in ref. 1 and masses of one kilogram, the largest value of ΔW that could reasonably be obtained would be for masses of an appropriate stainless steel and lithium hydride (^{6}LiH) respectively, for which $\Delta W \approx 2.5 \times 10^{-7}$ N, equivalent to a 25 μg difference in apparent mass. Replacing the ^{6}LiH by beryllium would reduce the apparent mass difference to 14 μg but would avoid possible dangers involved in the handling of kilogram quantities of ^{6}LiH. If, instead, we take the value of a deduced from the geophysical measurements of G, we find a value of ΔW equivalent to 1.5 μg and 0.9 μg for ^{6}LiH and Be respectively.

The practicality of carrying out such an experiment with a worthwhile accuracy requires first a transportable balance having a reproducibility better than 1 part in 10^9 (equivalent to 1 μg for a 1kg mass). Traditional knife-edge balances, although there are at least two which achieve such reproducibility[4,5], are certainly not transportable so would not be suitable. Such balances are much too delicate and require extreme care in the mounting, handling, and adjustment of the beam and knife edges. However, a flexure-strip balance has recently been described[6] that is much less subject to these constraints. The beam and flexure elements are designed to be assembled without any adjustment and to be relatively robust. Preliminary results indicate that a reproducibility of 5 parts in 10^{10} can be achieved in the comparison of 1 kg masses. A similar performance may eventually also be possible using a hydrostatic balance[7]. Second, we need to be able to construct pairs of appropriate test masses that are not subject to significant differences in air buoyancy or sorption effects. Adequate test masses could be made by enclosing up to about 1.5 kg of the test material (^{6}LiH, Be and stainless steel) in stainless-steel vessels made to have nearly identical external volumes and surface finishes. The stainless steel should be chosen to be one of those already used for stainless-steel mass standards, such as Immaculate V, Nicral D or an equivalent AISI 310 steel, whose magnetic and other properties are suitable. Provided that the external volumes of the test masses differ by only a few parts in 10^4, the differences in their respective air-buoyancy corrections are sufficiently small to be measurable without significant error. Vacuum weighing would of course remove this problem altogether but would, perhaps, introduce further problems due to desorption. It is not difficult to ensure that the values of the masses themselves and the heights of their centres of mass are sufficiently close for the demands placed on the knowledge of g and its vertical gradient to be modest.

Although the quickest tests of the ideas of Fischbach *et al.* could probably be made by repeating the Eötvös experiment using already existing equipment[3], we think it worth while pointing out that an experiment made using a beam balance could give results of ample precision. Indeed, if the force predicted is shown to exist its presence would, among many other things, lead to modifications in high-precision weighing procedures, to say nothing of its implications for the present definition of the kilogram.

Blym clone could be contaminant

SIR—In their reply to my recent paper[1] Cooper and Diamond[2] raise two points — first, that some of the clones I describe are contaminated by the original *HuBlym*-1 clone and, second, that the results of a single transfection assay, not described in my paper, conflict with other assays reported in the paper.

The original clone described in the paper is one of several isolated and designated as non-transforming (using the transfection assay) and reported by Diamond *et al.*[3]. There has never been any suggestion that this clone, which has the same sequence as *HuBlym*-1, is a contaminant.

It is not possible to exclude the possibility raised by Cooper and Diamond that the other clones described in this paper are indeed contaminants. Unfortunately, the clones, which I left in the laboratory, were disposed after my departure and before the issue of contamination was raised with me. These clones had, however, been designated as transforming or non-transforming in transfection assays read by Cooper and it was precisely because of this classification that they were subsequently selected for sequencing.

Cooper and Diamond cite a transfection assay performed by me in May 1984, when the sequencing of the Burkitt's clones was 90 per cent complete and the cloning and selection of the gene from normal human embryo fibroblast DNA had just started. This particular transfection was carried out at a time when the assay was not working reproducibly and was an exercise in trying to find out what the problem might be. Therefore this result, which conflicted with several other assays carried out previously and read by Cooper, cannot be considered in any way accurate or meaningful.

It is gratifying that Cooper and Diamond confirm my conclusion regarding the nucleotide sequences of *HuBlym*-1.

Writing enzyme units in the correct way

SIR—There seems to be a great deal of ambiguity and a frequent scientific error in the literature when the specific activity of enzymes is reported. Very often, it is expressed as "nmol/min/mg", as "nmol/min per mg" or as "nmol per min per mg". (See, as examples, refs 1–7, but many others could be cited.) Phonetically it seems correct but I believe it to be mathematically incorrect. It should be expressed as "nmol × min^{-1} × mg^{-1}".

The expression "*a*/*b*/*c*" is indeed ambiguous, because

$$(a/b)/c = \frac{a/b}{c} = \frac{a}{b\times c}$$

and

$$a/(b/c) = \frac{a}{b/c} = \frac{a\times c}{b}$$

therefore, in the linear form "*a*/*b*/*c*", the use of parentheses is obligatory.

To express the term

$$\frac{a}{b\times c}$$

it is necessary to write $a\times b^{-1}\times c^{-1}$ or $a/(b\times c)$.

And similarly, to express the term

$$\frac{a\times c}{b}$$

we must write $a\times c\times b^{-1}$ or $a/(b/c)$.

The formula that is derived for enzyme activity is defined correctly as "nmol × min^{-1} × mg^{-1}" or as "nmol/(min × mg)". The common expression "nmol/min/mg" is therefore ambiguous.

The same holds true for other units expressed in a similar formal way, such as mutations/cell/hour and disintegrations/min/tube. I urge the adoption of the correct designation for specific activity of enzymes, and similar units.

Gamma-ray spectrum of Chernobyl fallout

SIR—The activity in Oxfordshire due to the plume of radioactive material released from the Chernobyl reactor reached a peak on 2 May[1]. On 8 May we examined the 'Polyfoam' air filters routinely used in our laboratory air supply system and monitored a small but distinct amount of β- and γ-radiation activity. We have measured the γ-ray energy spectrum from the filters using a high-efficiency (40%) germanium detector, shielded from room background.

Figure 1 shows the complex γ-ray spectrum from the filters. The background is due to Compton-scattered γ-rays, which do not deposit their full energy in the detector. An analysis of the full-energy peaks yields a definite identification of 16 radioisotopes, with a further three (weaker) tentatively identified radioisotopes. The activity of each radioisotope is categorized as strong or weak in Table 1. The relative activities for the most prominent isotopes vary significantly from those deduced by Fry *et al.*[1], which serves to emphasise that these coarse filters were not designed to collect fallout products. The measured activity of ~ 2,000 Bq m^{-2} of ^{131}I on each 0.1m^2 filter suggests that ~ 1% of the local iodine activity[1] was deposited by the air flow of 2×10^4 m^3 per day.

Table 1 Relative γ-ray activities of radioisotopes measured in laboratory air filters

Isotope	Relative activity*	Half-life
^{131}I	S	8 d†
^{137}Cs	S	30 yr
^{132}Te	S	3 d
^{132}I	S	2 h
^{103}Ru	S	39 d
^{134}Cs	S	32 yr
^{106}Ru	S	367 d
^{140}Ba – ^{140}La	S	13 d–40 h
^{136}Cs	W	13 d
^{95}Zr – ^{95}Nb	W	64–35 d
^{141}Ce	W	33 d
^{99}Mo	W	3 d
^{144}Ce	W	284 d
^{129}Te^m	W	33 d
[^{127}Sb]	[W]	4 d
[^{105}Rh]	[W]	1.5 d
[^{143}Ce]	[W]	1.5 d

*Identified radioisotopes are listed in order of activity. Isotopes with activities greater than 10% that of ^{131}I are labelled strong (S) and those with activities less than 5% are labelled weak (W). † Days.

All of the identified radioisotopes are ^{235}U fission decay products. The criteria for observing a particular fission product in such a simple γ-decay experiment are: (1) the feeding mass chain should have a lifetime ≥ 1 day and ≤ 500 yr; (2) the fission yield should be ≥ 0.5% for the mass chain; (3) the β-decays should significantly populate excited nuclear states which subsequently γ-decay. Using these simple criteria, we find that all of the expected mass chains are accounted for, except masses 133 and 147, whose identifications are made difficult by the complexity of the spectrum.

Most of the activity (70%) will decay over the next month and the levels will approach those measured normally from the natural thorium and radium background. Air-supply filters with greater air flows or greater capture efficiency will have proportionally greater activity.

Q1146+111B,C quasar pair: illusion or delusion?

SIR—The quasar pair Q1146+111B,C has been re-observed by Turner *et al.* who argue that it comprises two gravitationally lensed images of a single source. In this letter, we show that we are probably observing two distinct though neighbouring quasars.

Were quasars placed randomly on the sky, the probability of finding another quasar of apparent magnitude m within an angle θ of a given quasar would be $P(\theta, m) \simeq n\pi\theta^2$, where $n(m)$ is the sky density of quasars brighter than magnitude m. For Q1146+111B,C, $\theta = 157$ arc s, $n(18.5) \sim 1$ per deg^2 (ref. 4), giving $P_c \sim 6 \times 10^{-4}$. However, quasars are probably not distributed uniformly throughout the Universe, and there is evidence that they are clustered in much the same way as are galaxies[5,6] (but see ref. 7), so their two-point correlation function is $\xi(r) = (r/r_0)^{-1.8}$, where $r_0 = 5(1+z)^{-1}h^{-1}$ Mpc, h = the Hubble constant $H_0/100$ km s^{-1} Mpc^{-1} and the cosmological density parameter $\Omega_0 = 1$. The probability associated with this excess for a given quasar to have a companion within angle θ brighter than magnitude m is then

$$P_c(\theta,m,z) = 2\pi(1+z)^3 \int_0^m db\, b \times \int_z^\infty dl\, \Phi\, \xi(b^2 + l^2) \qquad (1)$$

where $D(z)$ is the angular diameter distance of the quasar, and $\Phi(L,z)$ is the integral luminosity function for quasars with luminosity $L(m,z)$. Now, $\Phi(L,z) = (dn/dz)/D^2(1+z)^{1.2}$ (ref. 8) and observations[4] indicate that for $0.5 < z < 2$, quasars of a given magnitude are uniformly distributed in redshift with $dn/dz = 0.5n$. Substitution in equation (1) then gives $P_c(\theta,m,z) = 38(1+z)(\sqrt{1+z}-1)\theta^3\xi(\theta D)dn/dz$ for $D\theta \leq 2r_0$, where n is per steradian and θ in radians. Numerically, $P_c \sim 2 \times 10^{-4}$.

Published quasar catalogues[9,10] contain $N(19) \sim 2{,}000$ quasars brighter than $B = 19$. Unpublished surveys probably treble this number. The expected number of random associations with the separation and magnitude of Q1146+111B,C is $NP_r(157 \text{ arc s}, 18.5)/2 \sim 20$, which is roughly what is observed[5,9]. The expected number of closely clustered companions is $NP_c(157 \text{ arc s}, 18.5, 1.0)/2 \sim 1$. Hence we would expect by now to have discovered of the order of one physically associated pair of magnitude 18.5 quasars separated in angle by less than 157 arc s and in velocity by the velocity dispersion of small groups which dominate the correlation function, $\sim 300 \text{ km s}^{-1}$. We should not be unduly surprised if Q1146+111B,C fails tests of the lensing hypothesis[11] — it may be that expected pair.

In conclusion, we suggest that the necessity for lensing in some of the other gravitational lens candidates should be re-examined. This is especially important for faint quasars when there is no independent evidence for lensing (for example, an intervening giant galaxy or distortion of background galaxies) and no sign of common spectroscopic or morphological peculiarities. (Overall spectral dissimilarity need not rule out lensing because quasars can very significantly in the time delay between two images.) The quasar pairs Q2345+007A,B (ref. 12) and Q1635+267A,B (ref. 13) in which the fainter quasars are both roughly magnitude 21 both give $P_c \simeq P_r \sim 2 \times 10^{-4}$, if we assume that the correlation function is valid for proper distances ~ 20 kpc (as it is for the galaxy–galaxy correlation[14]; it has been suggested that the quasar–galaxy correlation function is even higher[15,16]). It is therefore not unreasonable that these two pairs comprise distinct objects; since $P_r \sim P_c$ we should expect to find a few similarly separated quasars with discrepant redshifts, for example, Q1548+114A,B (ref. 17).

We thank Ramesh Narayan for helpful suggestions. We acknowledge support by NSF Presidential Young Investigator grant AST84–51725 and grants from the Exxon Education Foundation and Boeing Company (E.S.P.) and NSF grant AST84–15355 (R.D.B.).

Beware the cups that cheer

SIR—Aluminium toxicity, intoxication or accumulation is associated (not necessarily causally) with several conditions including dialysis encephalopathy[1] and osteomalacia[2], the amyotrophic lateral sclerosis of Guam, and Alzheimer's disease[3] (believed to account for some one third of a million UK sufferers from senile dementia and said to affect over two million people in the United States). Edwardson and his colleagues have recently shown[4] the presence of aluminosilicates in senile plaques in Alzheimer's disease. Dietary intake of aluminium has not generally been regarded as a hazard, though one Swedish study[5] showed that cooking rhubarb in aluminium saucepans mobilized a significant amount of aluminium, presumably complexed by oxalate (ethanedi-oate). We would like to suggest that attention is paid to the high aluminium content of tea leaves and their infusion.

The tea bush (formerly *Thea sinensis*, now *Camellia sinensis*) is grown on acid soil, and tolerates high levels of aluminium, accumulating great quantities[6] of it. Indeed, potassium alum is used as a fertilizer[7]. The only other food plant which tolerates such high aluminium levels is the cranberry. The tea bush accumulates aluminium in the leaves to enable it to overcome a high level of aluminium in the leached acid soils in which it thrives.

We have examined samples of Chinese, Indian and Russian tea bought as packets from a local supermarket. The X-ray powder picture of each dry ash (all of surprisingly good quality) was essentially that of α-alumina (Al_2O_3). Other weak lines were present. The aluminium content (by gravimetric analysis) of these dry ashes varied from 8,700 p.p.m. to 23,000 p.p.m., in line with several reported analyses; up to 20,000 p.p.m. Al/dry weight have been reported in mature leaves[8].

We infused the teas in a teapot for up to 30 minutes using Cardiff tap-water (very soft), then analysed the infused liquids for aluminium with gravimetric references to underpin routine atomic absorption measurements. A typical finding was that the infusion of Russian tea had about 100 p.p.m. aluminium (100 mg dm^{-3}), and the Indian and Chinese typically had 40 and 60 p.p.m. aluminium, respectively.

Since many Britons drink a litre of tea a day, tea is likely to be as great a source of aluminium as any other in the British diet. (The aluminium foil often used for lining tea chests seems unlikely to exacerbate the problem).

Assuming (in the absence of information on the transfer of aluminium from diet into organs) that any source of aluminium is to be avoided at least for those suffering from conditions related to high aluminium levels, the belief that tea is a sovereign remedy under all circumstances may need revision. "The cups that cheer but not inebriate", may not be as true as William Cowper thought in 1785.

Frequency of dizygotic twinning

SIR—I am puzzled by a calculation in J.M. Diamond's article "Variation in human testis size" (*Nature* **320**, 488; 1986). In it he states that a single ovulation with intercourse will result in a live birth with probability ¼ and therefore a double ovulation will result in dizygotic twins with probability 1/16. He concludes that the double ovulation frequency must be 16 times the observed dizygotic twinning rate among births.

This conclusion is incorrect since a large fraction of the double ovulations will not lead to any birth at all. A double ovulation will yield zero births with probability 9/16, one birth with probability 9/16 and two births with probability 1/16. Hence the probability that a double ovulation will yield twins conditioned on there being any birth at all is $(1/16)/(1/16+9/16)=1/7$. Therefore Diamond should conclude that the double ovulation frequency is 7 times the observed twinning rate. Thus, for example, the Yoruba women would have a double ovulation frequency of 34.3% rather than 78%, as stated.

CAMBRIDGE *Journals*

Established titles from two leading societies . .

The Journal of Physiology

Chairman of the Editorial Board: **E.S. Petersen**

Published for The Physiological Society, each hardbound monthly volume is concerned with all aspects of research in physiology, especially vertebrate. This includes respiration, circulation, excretion, reproduction, digestion, homeostasis, and particulary neurophysiology and muscular contraction.
Volumes 370-381 (1986) **£410.00** per year in U.K. only; **£435.00/$1030** elsewhere; Airmail **£200.00** extra
ISSN 0022-3751

Quarterly Journal of Experimental Physiology

Chairman of the Editorial Board: **C.R. House**
University of Edinburgh

QJEP was founded in 1908 and has been published by The Physiological Society since 1979.
Volume 71: January, April, July and October 1986
£60.00/$130. Airmail **£20.00** extra
ISSN 0144-8757

Journal of Anatomy

Editor: **Prof. D.B. Moffat** *University College, Cardiff*

Published for the Anatomical Society of Great Britain and Ireland, the journal presents original work and book reviews in anatomy, embryology and histology in six casebound issues each year. Its scope, which includes human and comparative anatomy (functional aspects, neurology, embryology, histology, histochemistry, and electron microscopy), has made Journal of Anatomy the leader in its field.

Forthcoming articles include: Current developments and future directions in autonomic neuromuscular junctions; The granular peripolar cell of the human glomerulus; A Golgi study of the sixth layer of the cerebral cortex; Freeze-fracture observations on human peripheral nerve; Ultrastructural evidence for fibril-to-fibril associations in articular cartilage and their functional implications.
Volumes 144-149: February, April, June, August, October and December 1986 **£188/$440** per year; Airmail **£42.50** extra

Aims and Scope

The journal provides a medium for the rapid publication of full-length articles as well as short communications on various aspects of biotechnology. Information on new or potential applications of biotechnological relevance in the following areas will be considered for publication:

- molecular biology
- genetics
- biochemical aspects of metabolism and its control, including viral, microbial, plant and animal cell systems
- process development and its control, including computer applications automation and the development of (bio)-sensors as applied to biosystems.

The overriding criteria for publication are originality, high scientific quality and interest to a multidisciplinary audience.

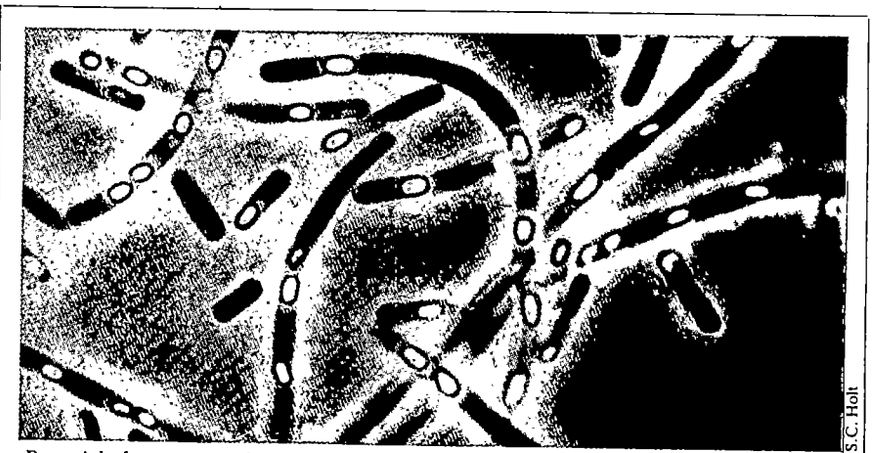
All around biotechnology

A.N. Emery and A. Lyddiatt

Comprehensive Biotechnology: The Principles, Applications and Regulations of Biotechnology in Industry, Agriculture and Medicine.
Editor-in-chief Murray Moo-Young.
Pergamon:1985. Four volumes, pp.3,764. £695, $995.

BIOTECHNOLOGY feeds upon many disciplines, and is dependent upon the cross-fertilization of ideas and information from a wide variety of sources. Ready access to the relevant literature is frequently inhibited by its style and format, and it is this drawback that is addressed by *Comprehensive Biotechnology*.

The work has been promoted as an integrated presentation of the basic principles, methods and applications of biotechnology. This is a formidable claim, and the fact that four volumes totalling over 3,500 pages were found to be necessary is a measure of the difficulty of the task that the editors set themselves. Moreover, the editorial board, under the direction of Murray Moo-Young, set out to assemble the work under several self-imposed constraints: they had to coordinate successfully an international team of 150 writers, combine intellectual appeal with comprehensive coverage *and* publish all four volumes at the same time. Such testing goals have been largely met in a work which lives up to its billing.



The four volumes are respectively entitled *Scientific Fundamentals, Engineering Considerations, Current Commodity Products* and *Speciality Products and Service Activities*, and each of them is in turn subdivided into either two or three sections. Volume 1, Section 1 covers genetic and biological fundamentals (including isolation methods, nutrition, growth and death of microorganisms as well as their genetic manipulation), while the regulation of cellular metabolism and enzyme evolution, mechanisms and kinetics are dealt with in Section 2. The introduction rightly describes this as a "pedagogic academic coverage" of the scientific disciplines underpinning the field as a whole, but the absence of stuffiness in the prose or inhibitory jargon is a strong incentive for the reader to explore the text rather than merely use it for reference. The relatively low-key coverage of animal and plant cell culture (combined in one lone chapter), however, reflects an emphasis out of keeping with the rapid increase of activity in these areas.

Volume 2 contains sections on bioreactor design, operation and control, and on upstream and downstream processing, written by a varied group of academic and industrial authors. This mix is not wholly successful, because some of the contributors have been allowed to reflect rather too strongly their commercial affiliations. Also, a stricter editorial hand would have avoided the repetition found, for example, in all four chapters on instrumentation, data handling and control, as well as in four chapters on aspects of membrane-based processes. Cross-referencing both between operations described within Vol. 2, and with applications in Vol. 3, would have greatly added to the value of these two components of the work.

Volumes 3 and 4 are described in their introductions as "utilitarian practical account[s] of commercial processes and products". The authorship is truly international (except for Soviet and Eastern European representation), and is largely drawn from industry. Volume 3 gives good accounts of present practices in the development and manufacture of health-care products, food and beverage products, and industrial chemicals, biochemicals and fuels. Volume 4 is much more ill-assorted: the first section, in particular, while aiming to introduce potential applications in biomedicine and chemotherapy, agriculture and other areas, is also left to pick up pieces of instrumentation, detection and containment of biohazards, and even surface thermodynamics. The remaining two sections give, first, an interesting and helpful international comparison of governmental approaches to both support and regulation of biotechnology, and lastly a useful blend of the theory and practice of waste management and pollution control.

It would need a football team of specialists to provide a detailed evaluation of the diverse contents of these four volumes. Instead, we sought to assess *Comprehensive Biotechnology* by making it available in our laboratories for anyone who cared to consult it — academic and research staff, students and industrial collaborators with interests across a wide range of subjects. By and large, their response has been enthusiastic. Specialists have generally judged the treatments of their own areas to be thorough, well illustrated, topical and generously referenced (up to about mid-1983). Venturing into less-familiar areas, we and our colleagues have found ourselves neither patronized by too shallow a text nor left floundering, bereft of explanation or definition. Each volume includes a glossary of terms and is individually indexed, though only Vol. 4 contains a cumulative index to the work as a whole — indeed, a general lack of inter-volume cross-referencing is a weakness. There is surely a strong case for producing a separate cumulative index.

Our personal expertise is in biochemical engineering, so it is inevitable that our more detailed criticisms arise with Vol. 2, and particularly the section on upstream and downstream processing. Here there are some surprising omissions, for example protein precipitation, non-specific adsorption, evaporation and drying. Such operations are now widely used in biochemical recovery, and absence of discussion of them is puzzling. This, however, could well be rectified in the subsequent, "update" volumes which the editors promise will appear at intervals to chronicle the scientific and technical developments of the future. Inclusion of an overview of the integration of unit processes in production and recovery operations would be beneficial, as would coverage of topics such as multiphase mixing,

Bacterial change — a phase-contrast photomicrograph of spores and vegetative cells of Bacillus fastidiosus. *The picture is reproduced from* Developmental Biology of the Bacteria, *by Martin Dworkin, published by Benjamin/Cummings. Price is $31.95, £24.95.*

biosensors, product polishing and quality control.

Finally, we have doubts about the grouping of certain topics and (more importantly) the physical robustness of the volumes. This is unquestionably a work of reference which will have to endure the rigours of usage in both library and laboratory. Two of the books contain over 1,100 pages in bindings likely to surrender to heavy patronage. Division into eight volumes might have inflated production costs but would have guaranteed a prolonged physical life — surely something to be expected from a work costing nearly £700. It would also have permitted a more rational allocation of material, avoiding the uneasy juxtapositions of topics in Vols 2 and 4, and consolidating individual volumes as entities in their own right.

For all that, Murray Moo-Young and his colleagues have brought off a notable success in producing this work and our limited criticism does not diminish this overall view. *Comprehensive Biotechnology* will be an essential purchase for all departments and institutions, academic or industrial, that claim an interest in any aspect of the ill-defined field popularly known as biotechnology. □

Controlling disease in the valleys

G. Webbe

Schistosomiasis: The St Lucia Project. By Peter Jordan. *Cambridge University Press: 1985. Pp. 442. £35, $49.50.*

THE aim of the St Lucia schistosomiasis project was to compare the effects of control of the snail intermediate host, chemotherapy (that is, drug treatment) and improving water supplies in reducing transmission of *Schistosoma mansoni*, and thus the incidence, prevalence and intensity of the infection. The project ran from 1966 to 1981. It was based upon an epidemiological model which predicted the relative importance of the three approaches to control, and the experimental programmes were therefore designed for maximum impact in separate valleys which had similar epidemiological characteristics. These programmes are described in Part I of Peter Jordan's book.

In one valley, area-wide molluscicide was directed against snail colonies, detailed research into the dynamics of transmission having been undertaken as a basis for an appropriate snail control strategy. In a second valley, the contamination with schistosome ova was reduced by chemotherapy; treatment was offered to anyone found to be infected at any of the four annual surveys. Water supplies were provided in part of a third valley to reduce exposure to infection in rivers and streams. Piped water was introduced to individual houses in five valleys, together with communal laundries with shower units, and simple pools for recreational purposes.

After four years the effects on transmission of *S. mansoni* through snail control and the improvement of water supplies had been assessed, and chemotherapy was offered to people found to be infected. At this time, too, the area-wide strategy of snail control was changed to one of focal control. Over the next four years different consolidation strategies after therapy were tried out in each of the valleys. Further control schemes (through the provision of latrines or chemotherapy) were also initiated to compare the effect on transmission of reduced contamination with *S. mansoni* ova.

Comparison of the control strategies, based on parasitological findings, showed that the chemotherapy programme resulted in the cheapest, quickest and greatest fall in incidence, prevalence and contamination potential (cost $1.00 per person per year). In the snail control schemes, where area-wide molluscicide and focal control were applied, the overall declines in incidence and prevalence were similar, with intensity being reduced more with area-wide control (cost $3.24 and $2.87 per person per year, respectively). There was substantial reduction in all indices of infection in the water supplies programme (cost $2.99 per person per year). The results of additional chemotherapy were disappointing, however, while the effect of the provision of latrines remained inconclusive because of sporadic water supplies. In the maintenance phase, after chemotherapy in all areas, the best results came from focal snail control or the provision of individual household water supplies and communal laundries and showers.

The overall results of the St Lucia project confirmed the predicted relationship between morbidity and intensity of infection, and it seems that, for rapid disease prevention, chemotherapy will now be the main component of schistosomiasis control. The effectiveness of any drug delivery system must, however, determine the level of residual infection after treatment in a particular area. Moreover, in global terms, the transmission of schistosomiasis is characterized by its variability. While patterns of human contact with water, as well as human–parasite–disease relationships, are similar around the world, the transmission patterns differ greatly according to the ecology of the species of snail concerned. Thus, while it highlighted the relative cost-effectiveness of different control approaches over a limited period, the St Lucia project does not provide a basic protocol which can be applied in all situations. Further, more information is required about different chemotherapy regimens and even about the effects of treatment on acquired immunity, before formulating treatment policy. With such a limited number of effective compounds available, the problem of drug resistance must also be considered when developing long-term maintenance strategies requiring periodic re-treatment campaigns.

Part II of the book contains details of several related studies that were carried out in St Lucia. Among these, the accounts of epidemiological research on human exposure, morbidity and the longevity of adult worms, and of the immunological work, are of special interest.

The book is well illustrated and the data are very clearly presented. Altogether it is an important contribution to the literature on schistosomiasis; it strongly reflects the multidisciplinary nature of the St Lucia project, and it contains a unique wealth of information for parasitologists and all who are concerned with control of this disease. □

G. Webbe is Professor of Applied Parasitology at the London School of Hygiene and Tropical Medicine, Keppel Street (Gower Street), London WC1E 7HT, UK, and was a member of the Rockefeller Foundation Advisory Panel for the St Lucia Project.

Issues of analysis

Paul H. Harvey

Ecology and Natural History of Desert Lizards. By Eric R. Pianka. *Princeton University Press:1986. Pp.208. Hbk $45, £30; pbk $19.95, £13.30.*

FOR the past 20 years Eric Pianka has compared desert lizard communities in America, Africa and Australia, using standardized methods to allow comparisons among study sites within and between continents. The main results of his work are now brought together in a book which is not short on data; in addition to 31 pages of appendices, over 60 pages of the 150-page text are taken up by tables and figures.

Most of the book describes differences in reproductive tactics, activity and feeding habits of the various species, anatomical correlates of ecology, and community structure. The discussions are frequently based on statistical and multivariate summaries of the data. Such analyses can be dangerous, because hidden assumptions often lead to incorrect conclusions. Over the past ten years, there has been particular focus on this issue and Pianka is acutely aware of the pitfalls involved. Indeed, he devotes a full chapter to describing and assessing the methods used in the analysis of community structure. Most of his conclusions seem sound; for example, using a carefully designed "computer transplant experiment" Pianka and Larry Lawlor show that diets of particular species tend to change from site to site in a way that complements the diets of other species with which they are found.

Not all the analyses are as careful as this, however. At one point Pianka identifies what he terms a "transcendent" relationship. Some lizard species thermoregulate more effectively than others. The extent to which lizards thermoregulate can be described by their change in body temperature over a set range of air temperatures. But, at a set air temperature, some lizards are warmer than others. Pianka believes that these two components of the relationship between body and air temperature are not independent of each other, and plots the slopes relating body temperature to air temperature against their respective regression intercepts for a sample of 82 lizard species. He claims that the resulting highly significant negative relationship "represents an innate design constraint imposed by lizard physiology and metabolism". But, for given air and body temperatures, slopes and intercepts are not *expected* to be independent values: if we change the slope, we also change the intercept.

We clearly need to compare Pianka's data with a model in which slopes are independent of the air and body temperatures measured. To set up such a model, I randomly shuffled the empirical slopes among the different species and then calculated new intercepts using the mean external and body temperatures for each species. I repeated this procedure ten times and the correlation between slope and intercept ranged between –0.87 and –0.90, which to some extent describes Pianka's "transcendent" relationship. Pianka's relationship between slope and intercept may be tighter than expected, but he has not demonstrated that it is under a clearly defined null hypothesis. Indeed, his description leads the reader to assume that the expected correlation between slope and intercept is zero.

One chapter deals with reproductive tactics and, here again, I suspect that statistical analyses have missed their mark. Body size effects are either ignored or "removed" by taking simple weight ratios. Since larger species of most vertebrate groups are known to lay disproportionately small eggs (the relationship is one of negative allometry), Pianka's techniques are probably inappropriate and his analyses need to be repeated correctly

Nonetheless, the book has considerable strengths. It is a rich source of unique data; it highlights our ignorance of factors influencing the structure of even relatively simple communities; and it documents excellent natural history observations of particular species. In addition, the text is enlivened by a delightful collection of superbly reproduced colour photographs illustrating the variety of species studied □

Paul Harvey is in the Department of Zoology, University of Oxford, South Parks Road, Oxford OX1 3PS, UK.

Technique in time

D.J. Huntley

Thermoluminescence Dating. By M.J. Aitken. *Academic: 1985. Pp. 359. Hbk £50, $59; pbk £30, $34.95.*

MARTIN Aitken's first book, *Physics and Archaeology*, published in 1961, contained only a page on thermoluminescence dating. This new book presents a stunning contrast.

In 1961 it was thought that thermoluminescence (TL) resulted from radiation damage due to α-particles emitted by naturally occurring uranium and thorium; we know now that it results from electrons becoming trapped at crystal defects as a consequence of their liberation by various kinds of radiation. The general idea of using TL to determine past radiation doses, and hence the ages of samples (using separate measurements of the dose rates), has been around for several decades. It was not, however, until Aitken took up the subject that real progress was made and reliable dates of practical value to archaeologists were obtained. Most advances in the technique originated in Aitken's own laboratory at Oxford, but description of them is spread over such a wide literature that we all welcome having them brought together in a single book.

In the first two chapters the basic principles and methods are outlined in language that anyone with a scientific training should be able to follow. Thereafter the reader will learn that the subject is riddled with complications. The archaeologist who has studied ^{14}C dating knows that here one has to measure only the $^{14}C/^{12}C$ ratio in order to calculate a date. In TL dating, on the other hand, the number and complexity of the problems that have to be taken into account is extraordinary. Non-linear TL response, differing TL sensitivities, inhomogeneous samples, varying water contents, radon escape and a host of other factors have to be coped with, and all of them are discussed in detail by Aitken Some of these complexities can, however, be thought of as simply reflecting the great richness of TL dating, which now subsumes several different techniques (fine-grain, quartz inclusion, subtraction, predose, zircon, etc.). Again, all are described thoroughly. Each chapter includes a page or more of "Technical Notes", where many useful details are given without interrupting the main text, while the book itself ends with 13 appendices, taking up 90 pages. These are an invaluable reference source which TL workers will often have cause to consult.

The shortcomings of the book are minor. Aitken admits to being biased towards research done at Oxford; here the book is naturally strong, but in consequence work done elsewhere receives less thorough treatment. My main criticism, however, is reserved for a lack of rigour at some points and for Aitken's use of units. An "ionized electron" (p.42) is not part of my vocabulary, and reference to the activity of potassium as 89.5 per cent beta and 10.5 per cent gamma will confuse the unwary. "Annual dose" is used where "dose-rate" is meant, R is used for α-particle range in units of length on p.299 and units of mass per unit area on p.300, and a sievert can no more equal a gray than a digested apple can equal a fresh one. These and others like them are not too serious, though they will puzzle those not sure of their science.

This is a book by a physicist for physicists, and an essential acquisition for any TL dating laboratory and library. It will be the standard reference for many years. □

Ways to dispose of radioactive waste

J.L. Knill

Geology and Radwaste. By A.G. Milnes. *Academic: 1985. Pp.328. Hbk £50, $60; pbk £36.95, $39.95.*

EVENTS during the first months of 1986 have placed the nuclear industry in Britain at the centre of public attention. A series of minor incidents at the Sellafield nuclear fuel reprocessing plant, the identification of four possible sites for the shallow disposal of low-level radioactive waste, the publication of the Environment Select Committee's critical report on radioactive waste — all have been greeted with outcries from the various groups opposed to all forms of nuclear proliferation. Now, of course, we have had Chernobyl, and the attacks on the nuclear industry will intensify. The consistent reply from the industry has been that its critics are over-reacting, that technical improvements will continue to be made and that the risks associated with release of nuclides into the environment are overstated. These differences of opinion will not be resolved easily, and will fuel the continuing debate on the sources, and disposal methods, of radioactive waste.

Such waste is traditionally subdivided into four classes: very low, low, intermediate and high-level/heat-generating. However, this classification can be over-simple in that short-lived, intermediate-level waste may be disposed of together with low-level waste, and some argue that α-emitting low-level waste should be grouped with intermediate-level waste.

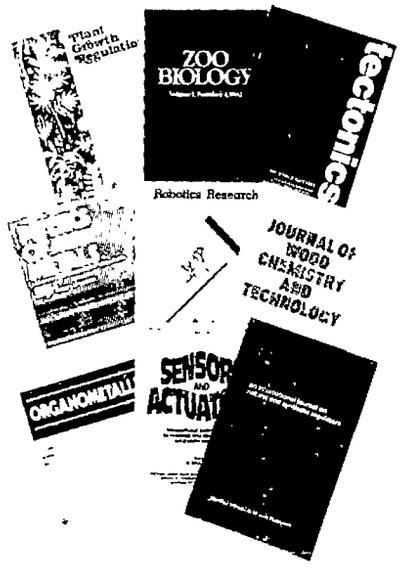
Because of the long half-lives of the radionuclides it contains, and the daughter products, high-level/heat-generating material will be an environmental hazard for hundreds of thousands of years. For this reason, disposal must be at depth in a geologically stable environment. A British research programme into deep disposal was stopped by the government in 1981, and for the next 50 years high-level waste will be stored on the surface as a fluid, and progressively encapsulated in glass, in order to maximize dissipation of the heat which is less easy to control underground. Deep disposal will then follow.

Since 1981 the responsibility for finding, proving and developing low- and intermediate-level waste disposal sites has rested with UK NIREX Ltd, a company controlled by the energy and nuclear industry. Selection of a deep site for intermediate-level waste in an anhydrite mine at Billingham led to local opposition, and then withdrawal of the site by the government. The choice of Elstow for an engineered low-level disposal site in clay met a similar reaction but, now, three further shallow sites in clay have been named; after detailed investigation, one of them will be selected and the case for development put to a public enquiry.

Against this background, the appearance of *Geology and Radwaste* is timely. Milnes defines his reasons for writing the book in the preface. He notes that the geological uncertainties are inherent, that simple solutions rarely exist and that this field offers much scope for conflict, as did the classic geological controversies of the past. Despite his conviction that the nuclear road is not the one we should take, he recognizes that here is a problem that will not go away, and that radioactive waste disposal is no more of an environmental hazard than the uncontrolled emission of (for example) carbon dioxide, sulphur dioxide and heavy metals.

The book is divided into three parts, the opening chapter of Part I providing a summary of radioactive waste types. As in the remainder of the book, the text here is exceptionally clearly written and well illustrated, meeting the author's objective of being accessible to a wider audience than the specialists involved. Also notable is Milnes's impressive grasp of the literature; much that is published on this subject is unrefereed, and is available only in rather obscure reports and conference proceedings. Each chapter ends with a summary of selected literature, with full references at the back of the book.

The second chapter of Part I covers the alternative methods of disposal of low-level liquid wastes, and the disposal of low- and intermediate-level solid wastes at sea, by shallow burial and in deep, mined cavities. The particular problems of high-level waste are highlighted, attention being drawn to some of the more exotic solutions that have been offered in the past.



Part II, occupying about two-thirds of the text, gives the geological perspective to radioactive waste disposal by describing the subsurface and surface processes operating through geological time. Much of the material here is familiar, but the author skilfully draws in case histories and examples to illuminate particular points; for instance, rates of denudation are illustrated by reference to the Texas Panhandle and to a mine test site at Mol, in Belgium. The eleven chapters systematically cover the relevant rock-forming, tectonic, geomorphological and fluid processes which provide the potential environments for storage and disposal. These processes are discussed in the context of the time-scale within which hazardous disruption of a repository could occur.

The two final chapters review predictive methods for identifying the disposal system most likely to guarantee that any release to the environment will not exceed regulatory limits. Safety assessment of potential sites demands expertise well beyond geology, and the book does not provide a guide to methods of site selection, site specific investigation or the geological aspects of safety assessment. Within his chosen compass, however, Milnes has produced a lucid and thorough book which should be read by all of those who have involvement with, or interest in, the geological disposal of radioactive waste. In the aftermath of Chernobyl, that is likely to be very many people indeed. □

J.L. Knill is Professor of Engineering Geology in the Department of Geology, Imperial College, University of London, London SW7 2BP, UK, and is a member of the UK Radioactive Waste Management Advisory Committee.

• *Management of Toxic and Hazardous Wastes*, published by Lewis Inc., Chelsea, Michigan, contains the (updated) proceedings of a conference on the subject held in Columbus, Ohio, in 1983. Price is $49.95, £45.95.

New journals review

On 25 September *Nature* will publish the sixth annual review supplement devoted to science journals.

Criteria for inclusion of a journal in the 1986 issue are that:

(i) the first number appeared, or the journal was retitled, *between June 1984 and May 1985* (the second cut-off date allows at least three issues of a journal to have been published, the minimum number on which a reasonable judgement can be based);

(ii) it is published at least three times a year;

(iii) the main language used is English.

Publishers and learned societies are invited to send *four different issues of each suitable periodical, including the first and most recent numbers* (if from outside the United Kingdom, by air mail) to: The Review Editor, *Nature*, 4 Little Essex Street, London WC2R 3LF, England. Subscription details, for both 1986 and 1987 should be included.

Galaxy formation by mock gravity

C. J. Hogan & S. D. M. White

Steward Observatory, University of Arizona, Tucson, Arizona 85721, USA

Absorbing particles in an isotropic radiation field experience an attractive force due to their mutual shadowing. If the pre-galactic universe contained suitable sources of radiation and absorbing material, an instability caused by this effect may have led to the formation of galaxies and galaxy clusters. Other consequences include the segregation of galaxies from dark matter and a strong anisotropic far-infrared background.

RADIATION pressure can have a significant effect in structuring the interstellar medium, dominating gravity for some species and environments by many orders of magnitude[1-5]. As first pointed out by Spitzer[2], absorbing particles in an isotropic radiation field experience 'mock gravity', an inverse-square attraction due to their mutual shadowing. Gamow[6] originally suggested that mock gravity resulting from Compton absorption of the microwave background by free electrons might provide a source of cosmological instability. However, as demonstrated by Field[7], this effect is negligible, both because matter and radiation are very close to thermodynamic equilibrium, and because the temperature is so low at epochs of interest that scattering exceeds absorption by a very large factor. On the other hand, it is possible that conditions in the pre-galactic universe might resemble those in the interstellar medium today, with stars emitting ultraviolet radiation and dust providing significant continuum opacity[8-15]. In this situation, mock gravity can drive a rapidly growing instability which might extend up to scales comparable to those observed in galaxy clustering.

Several non-gravitational mechanisms have been investigated which could, in principle, generate large-scale structure[16,17]. Mock gravity provides another such mechanism, but is unique in several respects. No true instability has previously been demonstrated to occur on such large scales. The gravitational instability usually invoked to explain large-scale structure is just a reflection of energy conservation in pre-existing fluctuations which are left behind as the universe expands around them. Mock gravity can behave like a true instability in that a wide range of scales can grow to nonlinearity in much less than an expansion time. It has a natural scale-length (the photon interaction length) which limits the size of structures, and a natural scale of binding energy determined by the radiation field. Together these scales determine the mass and density of the largest structures produced. Segregation of light and dark matter, and of enriched and unenriched gas, are also natural consequences of mock-gravitational instability. Within this theoretical framework, the development of structures qualitatively like those observed is a natural consequence of certain general conditions in the pre-galactic medium, and has little dependence on the previous large-scale mass distribution.

Our analysis differs from previous discussions[2,3] of mock gravity. Instead of presupposing an isotropic, externally generated radiation field, we introduce a homogeneous density of radiation sources. In linear theory, we are then able to treat the growth of optically thick perturbations. Our analysis includes the expansion of the universe, which was omitted from discussions focusing on the interstellar medium. We make the usual assumptions that the absorbing particles are continuum absorbers such as dust grains, that scattering can be neglected, and that the re-emitted radiation has a negligible interaction with the grains.

Mock gravitational instability

Consider a uniformly radiating background medium with luminosity density l. Within this medium are distributed dust grains with number density n, and frequency-averaged absorption cross-section σ. The sky brightness in a direction $\mathbf{i}$ seen from the origin is

$$S(\mathbf{i}) = \int_0^\infty \mathrm{d}r\, r^2 (l/4\pi r^2) \exp\left[-\int_0^r \mathrm{d}r'\, n(r'\mathbf{i})\sigma\right] \qquad (1)$$

Decomposing n into a uniform and a perturbed part $n_0 + \delta n$, we find the perturbation in brightness

$$\delta S(\mathbf{i}) = (-l/4\pi) \int_0^\infty \mathrm{d}\tau\, \mathrm{e}^{-\tau} \int_0^{\tau/n_0\sigma} \mathrm{d}r'[\delta n(r'\mathbf{i})/n_0] \qquad (2)$$

The net force exerted by radiation pressure on a grain at the origin is then

$$\mathbf{F} = -\frac{\sigma}{c}\int \mathrm{d}\Omega\, \delta S(\mathbf{i})\mathbf{i} = -\frac{l\sigma}{4\pi c}\int_0^\infty \mathrm{d}\tau\, e^{-\tau}\int_0^{\tau/n_0\sigma} \mathrm{d}\Omega \frac{\delta n(r'\mathbf{i})}{n_0}\mathbf{i} \qquad (3)$$

Let us consider the force due to a plane-wave perturbation $\delta n/n_0 = \delta_k\, \mathrm{e}^{i\mathbf{k}\cdot\mathbf{x}}$. Then $\mathbf{F} = F_k\, \mathrm{e}^{i\mathbf{k}\cdot\mathbf{x}}\mathbf{k}/|\mathbf{k}|$ with

$$F_k = -\frac{l\sigma}{c}\frac{\delta_k}{ik}[1 - p^{-1}\tan^{-1} p] \qquad (4)$$

where $p = k/n_0\sigma$. For a static medium the equation of motion of such a linearized plane wave is $\ddot{\delta}_k = -ikF_k/m$, where m is the effectively coupled mass per dust grain. Hence

$$\ddot{\delta}_k = \frac{l\sigma}{mc}[1 - p^{-1}\tan^{-1} p]\delta_k \equiv \omega_k^2 \delta_k \qquad (5)$$

and the fluctuation grows exponentially with growth rate ω_k. For optically thin perturbations ($p \gg 1$) ω_k is independent of wavelength. In the opposite limit, the growth rate decreases with $\omega_k \propto p$.

In an expanding universe filled with well-coupled dust and gas, the equation of motion becomes

$$\ddot{\delta}_k + (2\dot{a}/a)\dot{\delta}_k = (l\sigma/mc)[1 - p^{-1}\tan^{-1} p]\delta_k \qquad (6)$$

where $a(t)$ is the expansion factor, k is a co-moving wavenumber defined so that $p \equiv k/a(t)n_0(t)\sigma$, and gravitational effects have been neglected. The growth rate of the fluctuation relative to the expansion depends on the dimensionless parameter

$$A \equiv (2\omega_k(t)/3H)^2 \equiv A_0[1 - p^{-1}\tan^{-1} p];\ H \equiv \dot{a}/a$$

defined by the coefficients in this equation. For optically thin perturbations in an approximately Einstein–de Sitter universe, $A \cong A_0 = 4l\sigma/9mcH^2$ is independent of time provided the properties of the dust and the sources do not evolve. In this situation, the fluctuations grow as

$$\delta_k \propto t^\alpha, \qquad \alpha = (A_0 + \tfrac{1}{36})^{1/2} - \tfrac{1}{6} \qquad (7)$$

For large A_0, $\delta_k \propto t^{\sqrt{A_0}}$ and growth is rapid. For a given perturbation $p \propto a^2$, and even for large A_0, rapid growth can occur only after a characteristic time $t_c(k)$ defined by $p(t_c, k) = 1$. The equation for δ_k can be written

$$\ddot{\delta}_k + 4\dot{\delta}_k/3t = (A_0/t^2)[1 - (t/t_c)^{-4/3}\tan^{-1}(t/t_c)^{4/3}]\delta_k \qquad (8)$$

The solutions of this equation are shown in Fig. 1 for several values of the parameter A_0. The gravitational mode $\delta_k \propto t^{2/3}$ is also shown for comparison. Rapid growth occurs only after $t = t_c$ and only for $A_0 > 1$. The transition at $t = t_c$ is quite sharp. Note that the initial amplitude of the fluctuation need not result from an enhancement in physical density. Inhomogeneities in the distribution of luminosity sources and of dust production sites will introduce initial white noise fluctuations on all scales greater than those characteristic of these processes. If, however, real density fluctuations are dominant on large scales, mock gravity will take over from normal gravity as soon as the slope of the appropriate curve in Fig. 1 exceeds 2/3.

Astrophysical context

For this instability to be cosmologically interesting, A_0 must be >1 and at the same time fairly large scales must be optically thin. We now investigate the range of astrophysical parameters where this may occur.

It is useful to write the luminosity density in units of the Eddington limit[15]:

$$l_E \equiv \rho c^2 / t_{Sal} \tag{9}$$

where

$$t_{Sal} = c\sigma_T / 4\pi G m' \simeq 4 \times 10^8 \text{ yr} \tag{10}$$

is the Salpeter time, $\sigma_T \simeq 6 \times 10^{-25}$ cm^2 is the Thomson cross-section, and m' is the mean mass of cosmic atoms. Once again ignoring curvature terms in the expansion law, $H^2 = 8\pi G\rho/3$, we obtain

$$A_0 = \frac{t^2 l \sigma}{mc} = \frac{2}{3}\frac{l}{l_E}\frac{\sigma}{\sigma_T}\frac{m'}{m} \tag{11}$$

If the radiation sources are Eddington-limited, it is apparent that the effective cross-section per gas atom $\sigma m'/m$ must exceed the Thompson value in order for rapid growth to occur.

This requirement is found to be generously satisfied in the interstellar medium (ISM) of our own galaxy. Spitzer (ref. 5, p. 162) finds empirically that the sky coverage per gas atom is

$$\frac{\langle n_{dust}\sigma_{dust}\rangle}{\langle n_H \rangle} \simeq 10^{-21} \text{ cm}^2 \tag{12}$$

based on measured selective extinction at 1,000 Å. In Spitzer's model, the corresponding dust-to-gas mass ratio is $X_d = 6 \times 10^{-3}$. In what follows we therefore adopt $\sigma m'/m \equiv f_{ISM}\ 10^{-21}$ cm^2. Because $\sigma \propto \lambda^{-1}$ for wavelengths larger than the typical grain size, the value of f_{ISM} is sensitive to the mass in dust grains but not to their size distribution, provided they are small compared with the characteristic wavelength of the radiation. f_{ISM} is also sensitive to the value of this wavelength. A similar opacity per mass would be expected for large molecules[11–13,18].

In our discussion of mock gravity, we focus exclusively on grain opacity. Although atomic continuum cross-sections in the ultraviolet are large enough to be interesting ($f_{ISM} \simeq 6000$ for Lyman continuum absorption), atoms are quickly ionized in ultraviolet radiation fields strong enough to produce instability unless the gas is concentrated in small, very dense lumps. Line opacity is ineffective both because line widths are less than the systematic Hubble velocity across the structures that interest us, and because only a small fraction of the radiation participates in the instability. Dust grains or large molecules absorb ultraviolet continuum radiation efficiently but are large enough to survive the absorption of an ultraviolet photon. Grains and molecules tend to survive more easily at earlier epochs than they do now, because the dominant destructive process—sputtering by collisions with energetic ions—is suppressed. Gas at redshift $z > 7$ is cooled by Compton interaction of electrons with the microwave background, and does not reach the high temperatures needed for sputtering[5].

Formation of structures

If the effective opacity is too high, scales of interest will be optically thick and structure will not grow. Let us require that the instability operates up to a fiducial wavelength $\Lambda_c = 32\Lambda_{32}h^{-1}$ Mpc. A value of $\Lambda_{32} \simeq 1$ seems necessary to produce galaxy density fluctuations of order unity in spheres of radius $8h^{-1}$ Mpc, as inferred from the observed galaxy autocorrelation function. The optical depth parameter across this characteristic scale is

$$p_c = 2\pi/\Lambda_c n\sigma = 6.5 f_{ISM}^{-1}\Omega_g^{-1}h^{-1}(1+z)^{-2}\Lambda_{32}^{-1} \tag{13}$$

where we have set the gas density to $n_H = 10^{-5}\Omega_g h^2(1+z)^3$ cm^{-3} and the current value of $H = 100h$ km s^{-1} Mpc^{-1}. For the instability to operate efficiently, p_c must exceed unity. Thus for significant growth across Λ_c by $z = 20$, we require $\Omega_g < 0.016 f_{ISM}^{-1}h^{-1}\Lambda_{32}^{-1}$.

Although individual sources might be expected to radiate at the Eddington limit, the mean luminosity density at $t > \varepsilon t_{Sal}$ is likely to be limited by the total efficiency, ε, with which rest mass is converted into radiation (this constraint could be avoided, in principle, by having an intense burst of radiation). For a population of sources which forms at $t = 0$ and burns uniformly until time t_b,

$$l/l_E = \varepsilon(t_{Sal}/t_b) = 6 \times 10^{-4}\varepsilon_{-2}(\Omega h^2)^{1/2}(1+z_b)^{3/2}(\rho_s/\rho) \tag{14}$$

where ρ_s is the density of sources and z_b is the redshift corresponding to t_b, ρ is the total density, and $\varepsilon_{-2} = \varepsilon/10^{-2}$ for the sources. For such a population of sources, the optically thin growth parameter is

$$A_0 = 0.9\varepsilon_{-2}(\Omega h^2)^{1/2}(\rho_s/\rho)(1+z_b)^{3/2} f_{ISM} \tag{15}$$

To obtain rapid growth, structure formation and burn-out must occur at $z_b > 10$. We can eliminate the explicit dependence on the opacity parameter f_{ISM} by requiring $p_c \geq 1$. Then

$$A_0 \leq 6\varepsilon_{-2}\Omega^{1/2}\Omega_g^{-1}(\rho_s/\rho)(1+z_b)^{-1/2}\Lambda_{32}^{-1} \tag{16}$$

where the density parameters Ω and Ω_g refer to the present. This bound is saturated if we identify Λ_c as the wavelength for which $t_c = t_b$. Equation (16) shows that plausible situations exist in which rapid fluctuation growth at $z > 10$ would occur on all scales up to those of galaxy clusters.

What is the efficiency of converting luminous energy to binding energy? Let u_k denote the Fourier coefficient of peculiar

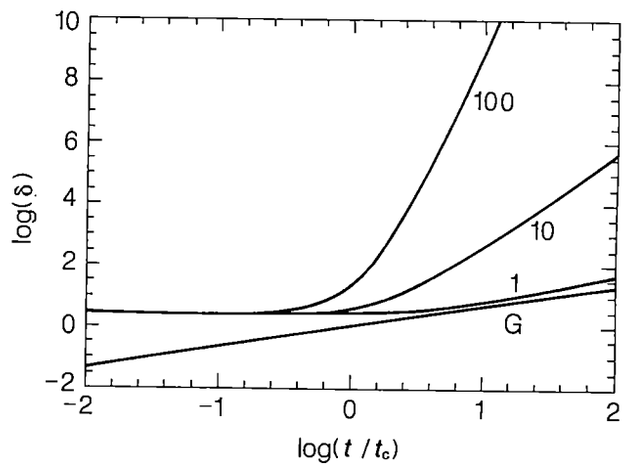


Fig. 1 Growth of perturbations due to mock gravity in the linear approximation. Density perturbation amplitude in arbitrary units is plotted as a function of time, which is expressed in terms of the time t_c when a scale becomes optically thin. The models shown here assume constant opacity and luminosity per mass, and are labelled by the value of their growth parameter A_0. The curve labelled G represents growth by ordinary gravitational instability.

velocity in the gas. Neglecting the expansion, equation (4) gives us the typical velocity attained in an expansion time:

$$v_{\rm gas} \cong |u_k/H| \simeq |F_k/mH| = \frac{l\sigma\delta_k}{kmcH}[1-p^{-1}\tan^{-1}p] \quad (17)$$

From equations (9) and (14), the luminosity density at t_b is given by

$$l = \varepsilon\rho_s c^2/t_b \quad (18)$$

and thus the gas velocity is

$$v_{\rm gas} \simeq 3/2\varepsilon c\delta_k(\rho_s/\rho)p^{-1}[1-p^{-1}\tan^{-1}{\rm p}] \quad (19)$$

Hence, radiation energy is converted to gas motion with maximum efficiency if the scale with $p=1$ goes nonlinear; in this case $v_{\rm gas} \simeq \varepsilon c(\rho_s/\rho_g)$. This corresponds roughly to all the momentum of unidirectional radiation $\varepsilon\rho_s/c$ being imparted to the gas; if $\delta_k = 1$ and $p=1$, the radiation field indeed becomes highly anisotropic (see equation (2)). It is interesting that this degree of coherent structuring of the radiation field occurs spontaneously.

If the evolution after t_b is purely gravitational, the binding energy density is $\sim v_{\rm gas}^2\rho_{\rm gas}$. While the maximum mass scale of structure is determined by the opacity ($f_{\rm ISM}$), the specific binding energy is therefore determined by the radiative efficiency (ε). It is encouraging that we can obtain reasonable results for both simultaneously.

Even during the nonlinear evolution of the instability, radiation pressure acts on optically thin systems exactly like ordinary gravity, but with an effective gravitational constant $3A_0/2\Omega_g$ times larger[2]. As a result, we expect the gas and dust to be swept quickly into a hierarchy of structures. For optically thick systems, the details of the nonlinear evolution driven by mock gravity are complex. Once a system is optically thick, it inhibits the action of mock gravity on both larger and smaller scales. As a result, the growth of structure is coupled on widely disparate scales and is very difficult to treat. Here we discuss two aspects of the optically thin hierarchy: the characteristic masses that emerge and the specific angular momentum generated by mock-tidal torquing.

A characteristic mass scale for nonlinear evolution is defined by the requirements that a contracting clump should become optically thick at the same time as the gas density within it comes to dominate the total background density. Mock gravity then begins to switch off just as normal gravitational effects become nonlinear. This mass M_1 satisfies

$$M_1/\pi r_1^2 = m/\sigma;\ 3M_1/4\pi r_1^3 = \rho_0(1+z)^3 \quad (20)$$

and hence

$$M_1 \cong 2\times10^{16} f_{\rm ISM}^{-3}(\Omega h^2)^{-2}(1+z)^{-6}M_\odot$$
$$r_1 \simeq 30 f_{\rm ISM}^{-1}(\Omega h^2)^{-1}(1+z)^{-3}\ {\rm Mpc} \quad (22)$$

For the plausible parameters $\Omega h^2 = 0.25$, $z=20$, $f_{\rm ISM}=0.5$, these give $M_1 = 4\times10^{10}M_\odot$, $r_1 = 30$ kpc. Thus this mass scale might be identified with individual galaxies.

A consequence of the rapid growth rate is that the specific angular momentum acquired by gas clumps as they form is typically a factor $\frac{3}{2}(\dot\delta/\delta) = \frac{3}{2}\sqrt{A}$ larger than that which similar clumps would acquire if they turned around at the same epoch under the action of normal gravity alone. As a result, the rotational kinetic energy of a gas clump becomes comparable to its normal gravitational binding energy when it is $(9A/4)$ times larger than in the familiar normal-gravity case[19,20]. Thus a system which has virialized at size r from maximum expansion size r_m has typical dimensionless spin parameter $\lambda = |E|^{1/2}J/GM^{5/2} \simeq 0.06\ (9A\Omega r_m/8\Omega_g r)^{1/2}$ if it is gas-dominated. It appears that with little or no collapse, mock gravity can make rotationally supported systems with the parameters of spiral galaxies at a redshift of $\sim$20.

The maximum gas mass over which the instability can operate effectively is larger than M_1 (equation (22)) by a factor Ω_g^{-2}:

$$M_{\rm max} = \frac{4\pi}{3}\bar\rho_g\left(\frac{m^3}{\bar\rho_g\sigma}\right)$$
$$= 4\times10^{16}\Omega_g^{-2}(1+z)^{-6}(\Omega h^2)^{-2}f_{\rm ISM}^{-3}M_\odot \quad (23)$$

This mass is naturally identified with galaxy clusters. For the parameters suggested above together with $\Omega_g = 0.02$, $M_{\rm max} = 2\times10^{14}\ M_\odot$, which is comparable to the total mass of gas and galaxies seen in the largest nonlinear systems known. If the instability is able to drive perturbations on this scale mildly nonlinear ($\delta\rho_{\rm gas}/\rho_{\rm gas}\sim5$) at $z=20$, then systems of total mass $\sim10^{15}M_\odot$ will collapse as a result of normal gravitational instability at $z\simeq1$ and will contain $\sim$10 times as much 'dark' matter as gas and visible stars.

We have made several arbitrary assumptions about the time evolution of luminosity and opacity. If l remained high while the gas density were gradually depleted, the remaining gas would be swept up into ever larger structures, limited by the current optical depth in the remaining gas. Thus, a small fraction of galaxies—those which formed last—might appear in nonlinear structures with a very large coherence length. It might be possible to explain in this way the observed superclustering of Abell clusters, which appears to be coherent over $>50h^{-1}$Mpc. As we have demonstrated, the gravitational binding of these very large-scale structures is not expected to be large. Large-scale peculiar velocities in the gas of order HR occur while the structure is forming but decay thereafter like $a(t)^{-1}$. The coherence length should scale roughly as the inverse fraction of gas remaining.

Astrophysical implications

The notion that gas clustered first by non-gravitational processes and that dark matter followed its gravitational influence leads to several predictions about galaxy–mass segregation. First, the structure of haloes might be expected to correspond to spherical infall models[21,22]. Second, the mass-to-light ratio of many-galaxy systems is expected to be simply related to their crossing times. When mock gravity switches off, a highly clumped gas and galaxy distribution will remain superposed on a relatively uniform background of dark matter. A region where the gas density is $(j+1)\bar\rho_g$ at this time will later collapse to a system with virialized gas density, $\rho_{fg}\sim(j+1)\bar\rho_g(j\Omega_g)^3$, and with a gas-to-total mass ratio, $\rho_{fg}/\rho_f \sim (j+1)\Omega_g$. The crossing time, t_c, of such a system is proportional to $\rho_f^{-1/2}$, and so objects that form at late times should obey the scaling relation $M/L \propto t_c^{2/3}$. If, in addition, we assume that the hierarchical clustering induced by mock gravity leads to a present distribution obeying $\rho_{fg} \propto r^{-2} \propto M_g^{-2}$ as inferred from observed galaxy correlations, we can derive the scaling relations, $M/L \propto L^{1/2}$ and $L \propto V^{1/4}$, where V is the characteristic virial velocity. These relations are in reasonable agreement with observations of galaxy systems.

The stellar population required in our model cannot have the same mass function as that in our Galaxy; normal stars with a large ultraviolet flux and lifetimes $<10^8$ yr eject too large a fraction of their mass in metals to produce the needed light without over-enriching the remaining gas. One promising type of radiation source for our purposes would be a 'very massive object'[8,9] ($M \gtrsim 200M_\odot$), which sends nearly all its metals into a black hole and blows off an envelope of hydrogen and helium. Radiative efficiencies for such objects typically[8,9] exceed 10^{-3}. The effects of the explosions from such objects could possibly dominate over their mock-gravity effects if they formed at sufficiently low redshift ($z<6$). Accreting black holes could also match our luminosity requirements without creating an enrichment problem, and could reach even higher efficiencies.

On the other hand, an appreciable metal abundance ($\lesssim10^{-3}$, depending on luminosity), is necessary in the protogalactic gas to provide sufficient dust opacity for the instability to operate. In this model, it is possible that a significant portion of present galactic dust originated at high redshift; this is a desirable feature

as present dust formation rates seem inadequate[23]. The high metallicity of the intergalactic gas in galaxy clusters may result from sputtering of pre-galactic grains once Compton cooling has turned off at $z \simeq 7$. Observed objects with low metallicity are not a serious embarrassment because mock gravity segregates gas according to its dust content. Initial chemical inhomogeneities thus tend to get amplified, highly enriched regions being brought together while metal-poor gas is left behind. This segregation can occur even though dust and gas may be locally well coupled, because enriched clouds are compressed by radiation pressure and can pass through the unenriched gas with little interaction: some such segregation would be expected even on scales as large as $M_{\max}$, provided the enriched clouds are compressed to $\tau \gtrsim 1$. Thus, the existence of metal-poor systems such as IIZw40 may not be in conflict with our model. We would, however expect such systems to be less strongly clustered than normal galaxies. There are physical reasons why globular clusters may form preferentially from low-abundance clouds in protogalaxies[24], and there is some observational support for just such selective cluster formation[25]. The low metal abundance of clusters in the galactic halo may, therefore, be compatible with the substantial pre-galactic metal formation our model requires. Such relations between metallicity and structure may also explain why Lyman-α absorption systems in quasars are less strongly clustered than metal-line systems, and indeed why there should be a correlation between column density and metallicity.

Perhaps the cleanest prediction of our model—because it is a direct by-product of the fundamental mechanism—is the intensity and anisotropy of the re-radiated emission from the grains. This is expected to produce a cosmic far-infrared background peaked at $200\,\mu\text{m} \lesssim \lambda \lesssim 600\,\mu\text{m}$ (ref. 10). The total present energy density parameter in radiation from sources which burned from $z=\infty$ to $z=z_b$ is

$$\Omega_R = \tfrac{3}{5}(\rho_s/\rho)10^{-2}\varepsilon_{-2}(1+z_b)^{-1}\Omega \qquad (24)$$

Using equation (16) and requiring $A_0 > 6$ so that the instability can operate, we find

$$\Omega_R > 0.6\times 10^{-2}\Omega^{1/2}\Omega_g\Lambda_{32}(1+z_b)^{-1/2} \qquad (25)$$

which should be compared with the total energy density of the cosmic microwave background, $\Omega_R = 2.4\times 10^{-5}h^{-2}$. Even for $z > 10$ and $\Omega_g \simeq 0.01$, the two fluxes are comparable. Such a strong far-infrared background should be easily detectable by the Cosmic Background Explorer Satellite (COBE).

The anisotropy in this background may be estimated as follows[10]. Suppose that the re-radiated infrared luminosity density has variance $(\delta I/I)_{IR} \cong 1$ on the co-moving scale $\Lambda \simeq 32h^{-1}\,\Lambda_{32}$ Mpc of observed clustering. Roughly $N \simeq 100\,\Lambda_{32}^{-1}h^{-1}(1+z_b)^{-1/2}$ such regions contribute to the dust emission integral in any direction, so the r.m.s. variation in observed brightness will be

$$\frac{\delta I}{I} \cong N^{-1/2} \simeq 0.1\Lambda_{32}h^{1/2}(1+z_b)^{1/4}(\theta/\theta_c)^{-1} \qquad (26)$$

for angular scales θ larger than that subtended by Λ_c.

$$\theta_c \simeq 16\Lambda_{32}\Omega \text{ arc min} \qquad (27)$$

Anisotropy with these characteristics should be detectable by the Space Infrared Telescope Facility (SIRTF). The techniques for calculating small-scale anisotropy, and the observational issues, are discussed in ref. 10.

These fluctuations in the dust radiation can generate further inhomogeneities in the matter distribution as a result of coupling by Thomson drag[17]. This effect is negligible for the parameters we prefer here, but it could be significant on large scales if dust and radiation sources were present at $z \gtrsim 200$ in sufficient quantities to generate a small-scale mock gravitational instability. If the mock-gravity instability occurs at high enough redshift or gas density, the Thomson optical depth may exceed unity, suppressing anisotropy on angular scales less than a few degrees[17]. This does not occur, however, for parameters which produce large-scale structure.

Discussion

The model we have presented is radically different from conventional models for galaxy formation. In view of this, it is surprising that many observed facts fall into place quite 'naturally' and that no fatal flaw has appeared. Apparently, the model deserves serious consideration. Unfortunately, however, there is considerable difficulty in sharpening many of its predictions. The nonlinear evolution of the structure in mock gravity is particularly difficult to analyse rigorously, and even numerical simulations are difficult because the force between two gas elements in optically thick systems depends on the global configuration of the system. It may be possible to construct an apparatus in which mock gravity between many particles could be observed directly. This would offer the advantage of representing most aspects of the phenomena in question with a very large number of particles and with high spatial resolution and dynamic range. The acceleration of a grain in an evacuated chamber with $\sigma = 10^{-8}\,r_\mu^2$ cm^2 and $m = 10^{-12}\rho_g r_\mu^3$ g due to a beam of radiation with an energy flux of $100F_{100}$ W cm^{-2} is

$$a = 300 \text{ cm s}^{-2}F_{100}r_\mu^{-1}\rho_g^{-1} \qquad (28)$$

Thus, it may be possible to build an apparatus in which the mock gravitational acceleration exceeds normal terrestrial gravity ($g = 981$ cm s^{-2}), or the mock-gravity instability proceeds so rapidly that the entire apparatus can be dropped briefly to eliminate normal gravity during the experiment. It would be amusing to build an analog computer in the laboratory that might allow us to study the formation of galaxies and galaxy clusters in the real Universe.

Voltage-sensitive dyes reveal a modular organization in monkey striate cortex

Gary G. Blasdel & Guy Salama

Departments of Ophthalmology and Physiology and the Centre for Neuroscience, University of Pittsburgh, Pittsburgh, Pennsylvania 15261, USA

Voltage-sensitive dyes allow neuronal activity to be studied by non-invasive optical techniques. They provide an attractive means of investigating striate cortex, where important response properties are organized in two dimensions. In the present study, patterns of ocular dominance and orientation selectivity were obtained repeatedly from the same patch of cortex using the dye merocyanine oxazolone, together with current image-processing techniques. The patterns observed agree with most established features of monkey striate cortex and suggest a new unit of cortical organization; one that is modular in structure and which appears to link the organization of orientation selectivity with that of ocular dominance.

NEURONES in the striate cortex perform several important transformations using visual information[1-8]. They combine inputs from both eyes so that retinal images appear fused, yet they retain information on ocular disparity, so that objects may be viewed in relief. They also respond selectively to edges at certain orientations in visual space. The two response properties most related to depth and edge perception, ocularity and orientation selectivity, are organized systematically across the cortical surface.

The anatomical basis for ocular interaction in the cortex is better understood than that of orientation selectivity because it originates from patterns of terminating geniculate afferents and there are methods to visualize these afferents. The geniculate axon terminals establish a repeating sequence of right-eye/left-eye bands in lamina 4C (refs 5, 8, 9) which, when viewed from the cortical surface, display an average width of 0.5 mm and run vertically into the boundary of area 17 (striate cortex). As information flows radially out of lamina 4C (ref. 10), the monocular responses that these bands establish carry over into, and dominate, the responses of cells lying above and below, creating a system of slab-like columns that extend from pia to white matter.

Orientation selectivity, like ocular dominance, seems to be organized radially (vertically between pia and white matter)[1,2,6,8], but its precise anatomical substrate is unknown, and its organization has thus proved more difficult to define[11]. Using long tangential electrode penetrations, Hubel and Wiesel found that incremental steps through the cortex are accompanied by incremental shifts in preferred orientation[6]. This led them to suggest that orientation selectivity, like ocular dominance, might be organized as a system of parallel slabs, and experiments with 2-deoxyglucose (2DG), a metabolic marker that labels active neurones, seemed to confirm this notion[12]. But these experiments suffer from the fact that 2DG can be used only once (the animal must be killed to visualize the result), and this makes it difficult to determine how the same piece of tissue might respond to a different stimulus (a different orientation, for example). The presence of cytochrome oxidase blobs (identified on the basis of their rich cytochrome oxidase content), at regular intervals in the superficial layers, complicates the issue further since cells within these blobs lack selectivity for orientation and label strongly with 2DG for any orientation that is used. On account of all these difficulties, the evidence for an overall slab-like organization has never seemed quite as compelling for orientation selectivity as it has for ocular dominance[13-15].

A technique that might perhaps allow repeated mapping of cortical activity patterns was reported by Cohen and co-workers, who showed that certain dye molecules function as optical transducers of membrane potential[16-19]. Squid axons stained with merocyanine 540 were found to emit a fluorescence signal that closely followed action potentials measured with an intracellular electrode[16]. The mechanism(s) responsible for these optical signals are not understood completely, but are thought to entail a voltage-dependent transition between monomer and dimer states of membrane-bound dye molecules[19]. Rotations of dye molecules within the membrane[20] or rotations of dipole moments during monomer to dimer transitions may also be involved[19,21].

While voltage-sensitive dyes may seem a complicated way to monitor membrane potentials, they offer great promise in the study of two-dimensional phenomena because surfaces are well suited to optical inspection. Although initially the small amplitude of voltage-dependent optical signals and the phototoxicity of the dyes restricted widespread application of the method[16,18,22], many of these problems have now been overcome[19-22] and it is possible to obtain optical signals from many different neural preparations, including mammalian cortex[23].

We report here results achieved with one such potentiometric dye, merocyanine oxazolone (NK2367)[24], on the organization of the monkey striate cortex. Our approach differed from that of previous investigators in that we used video imaging technology instead of photodiodes[23,25,26] to monitor activity. This sacrificed temporal resolution (which was not needed in the present study as ocular dominance and orientation are stable over time), but allowed us to achieve greater spatial resolution than previously possible. As a result, we observed patterns of activity not visualized before, including direct images of ocular dominance bands in living animals and the first detailed maps of orientation selectivity covering large areas of cortex. Analysis of these patterns revealed that orientation changes continuously within discrete domains, or modules, and that these modules overlie ocular dominance borders in such a way that ocular dominance varies continuously within them.

Monkeys

We used macaque monkeys for these studies because this species has contributed most to our understanding of the striate cortex. Macaque monkeys offer the additional advantage that large areas of striate cortex (corresponding to central and parafoveal parts of the visual field) lie in the relatively flat and exposed operculum directly under the cranium at the back of the head. Three animals that served as subjects in unrelated experiments were used to test and develop the chamber and optical apparatus. However, the results reported here were achieved with only two animals (one *Macaca nemestrina* and one *Macaca fascicularis*). Both were implanted with chronic chambers that allowed us to record from single patches of cortex on successive occasions over a period of eight weeks.

Monkeys were anaesthetized and paralysed according to established procedures[3,27]. Both eyes were refracted and fitted with contact lenses and 3-mm artificial pupils. Preliminary recordings with microelectrodes established visual field locations for the exposed cortex and allowed us to align each eye separately with the centre of a computer-driven 19-inch monitor.

Optical apparatus

Figure 1 shows the apparatus used. Light from a tungsten halogen lamp passes through a collimator, interference filter and diaphragm before being reflected onto the cortical surface. An objective lens (0.1–0.3 numerical aperture) collects the reflected light, passes it to a projection lens to focus an image of the cortex either onto a set of four photodiodes or to a Newvicon television camera (COHU Inc., Model 5300, San Diego, California). Outputs from the photodiodes were fed into conventional current-to-voltage converters, amplified and sampled by an A/D converter. The video signal was fed into an image processor (Imaging Technology Inc., Woburn, Massachusetts) which consisted of a digitizer with a flash 8-bit A/D converter (AP-512), four frame buffers (FB-512-Q) and an arithmetic unit processor (ALU-512-Q). Video images taken under different conditions of visual stimulation were accumulated in separate frame buffers for subsequent manipulation by the processor. Because of the small size of the expected signals (1 part in 1,000 or less) and the limited dynamic range of the A/D converter (256 grey levels), additional circuitry was required: (1) to flatten the signal (to shade the video image so that all parts had roughly equivalent values); (2) to boost the small signal gain (which contains most of the voltage-dependent information); and (3) to eliminate d.c. bias (reduce the apparent white level). This additional circuitry put radiant changes >0.01% within the range of the flash A/D converter; it also introduced and amplified noise which was removed through averaging. Tests with the calibrated emissions of a light-emitting diode indicate that this system detects radiant changes greater than 0.01% if they persist long enough (of the order of seconds) to be averaged. Improvements in the signal/noise ratio at the front end (for example, by cooling the image detector) should shorten the duration of required averaging.

Cortex staining

The dura was removed and the exposed cortex stained by circulating a 0.1% solution of NK2367 (Nippon, Kankoh-Shikiso, Kenkyusho, Ltd., Okayama, Japan) in balanced salt solution over the surface for 0.5–1 h. This solution was then washed out and the inlet and outlet tubes sealed to minimize cortical pulsations. Sections from freshly stained monkey cortex indicate that this procedure allows NK2367 to penetrate ~0.5 mm into the cortex. Because the observed signals strengthen steadily during the first 0.5–1 h after staining, it seems that dye in the more superficial layers (probably in the pia) must be bleached before optical signals from the deeper tissue become visible.

Observations

A set of four photodiodes were placed in the image plane of our optical apparatus (Fig. 1) to monitor optical signals simultaneously from separate patches of cortex (100 μm wide, separated by at least 400 μm). This arrangement allowed us to screen several membrane-permeable cyanine and impermeant merocyanine dyes known to exhibit voltage-dependent optical responses. Several dyes yielded signals, but those achieved with NK2367 stood out to such an extent that we concentrated all subsequent efforts on experiments with this dye.

Figure 1*b* shows the signal from one photodiode averaged over 10 presentations of vertical and horizontal gratings. Movement artefacts associated with heartbeat and respiration were eliminated from this trace by synchronizing each presentation to the animal's electrocardiogram and respiration[23]. In this trace, an increase in absorption (at 700–740 nm) corresponds to the appearance of a drifting vertical grating. A small glitch appears approximately at the time the vertical grating is replaced by a horizontal one, and the signal begins to decay back to baseline

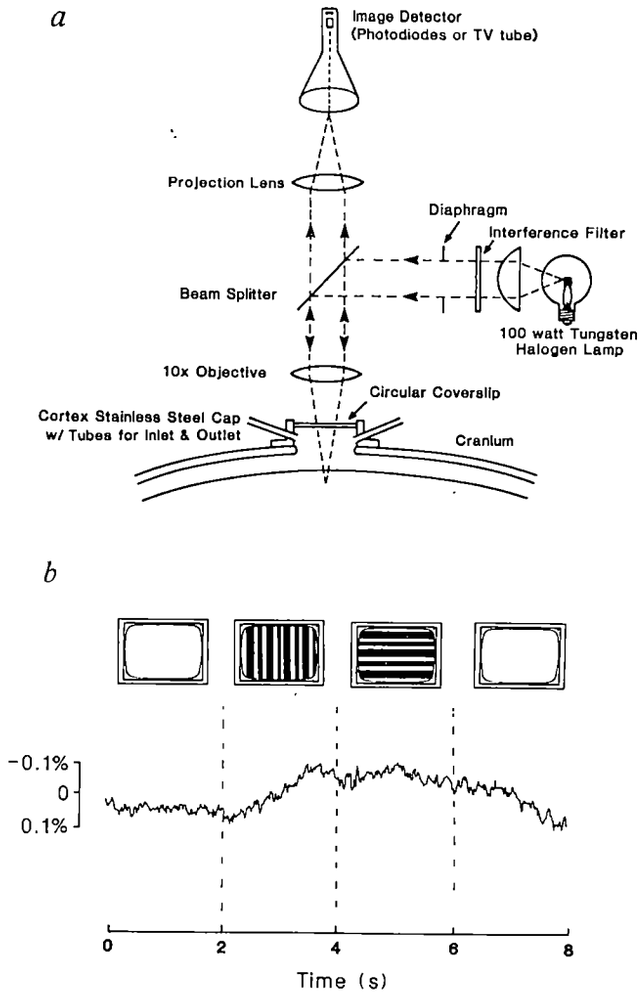

Fig. 1 *a*, Experimental arrangement for monitoring voltage-sensitive dyes in monkey striate cortex. A hole (25 mm diameter) was cut in the cranium, a stainless-steel ring cemented to the skull and the dura removed. The ring had stainless-steel inlet and outlet tubes to bathe the cortical surface with dye solution (0.1% in balanced salt solution). A second ring containing a round glass coverslip was screwed into the first ring to form a water-tight compartment. The position of the glass could be adjusted to dampen cortical pulsations and provide an optically smooth window for viewing the cortex. A condenser lens collimated light from a 100-W tungsten halogen lamp and directed it through an interference filter (720 ± 25 nm, Omega Optical, Brattleboro, Vermont), an aperture, then to the reflective surface of a beam splitter (a 50% half-silvered mirror). Reflected light passed through an objective lens and glass coverslip onto the cortex. Reflected and scattered light from the cortex passed through the coverslip, to the objective lens, through a projection lens, to the image detector (photodiodes or the TV camera). *b*, Averaged response to 10 successive presentations of vertical and horizontal gratings as seen by one photodiode that surveyed a 100-μm^2 patch of cortex. At the onset of a drifting vertical grating, there is a sudden increase in absorption for this part of cortex. A small glitch appears where the grating changes from vertical to horizontal, and the trace returns to baseline when the horizontal grating fades back again into a blank screen. Sequential presentations were synchronized to both the electrocardiogram and the respiration so that movement artefacts produced by these events could be subtracted, as previously described by Orbach *et al.*[23].

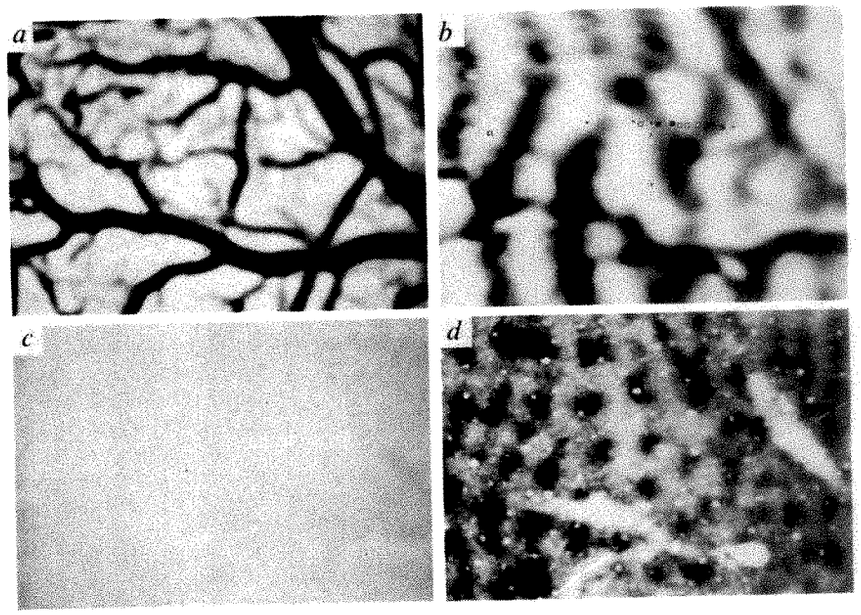

Fig. 2 *a*, Cortical blood vessels viewed under white light. Blood vessels appeared out of focus because the optical system was focused 300 μm below the pial surfaces. This patch of cortex was located just behind the lunate sulcus in the right hemisphere. Posterior, anterior, medial and lateral correspond to the top, bottom, right and left of the image frame, respectively. The border between areas 17 and 18 lies parallel to and just below the lower border of this frame. The height and width of this image corresponds to a 4×5-mm patch of cortex. *b*, The familiar pattern of ocular dominance bands is produced by subtracting images accumulated during visual stimulation of the contralateral eye from images accumulated during stimulation of the ipsilateral eye (all orientations). This produces an intensity difference of ~0.2% (amplified electronically) between the dark and light bands. The bands have an average width of 0.5 mm, run vertically into the area 17/18 border, and correspond to the rows of cytochrome oxidase 'blobs' which appear in *d*. The spots in *b* illustrate the location of 16 electrode penetrations conducted in this region of cortex before and after measurements with voltage-sensitive dyes. Small black dots indicate sites that yielded binocular responses, open squares indicate sites that were dominated by the contralateral eye, and closed squares indicate sites dominated by the ipsilateral eye. In agreement with the photodiode results, the correspondence between the dark bands and closed squares indicated that stained cortical tissue darkens with increased electrical activity (see text). *c*, The result of subtracting two time-averaged images while the monkey viewed a blank screen. The same algorithm was used as in *b*. *d*, At the end of the experiment, the same piece of cortex was sectioned tangentially and stained for cytochrome oxidase[36]. The section image shown here was aligned and expanded (necessary because of tissue shrinkage) according to the positions of blood vessels so that they laid in register with the images in *a*–*c*. Note that during examination of the histological preparations, no evidence was found of tissue damage attributable to repeated applications of the dye over more than eight weeks.

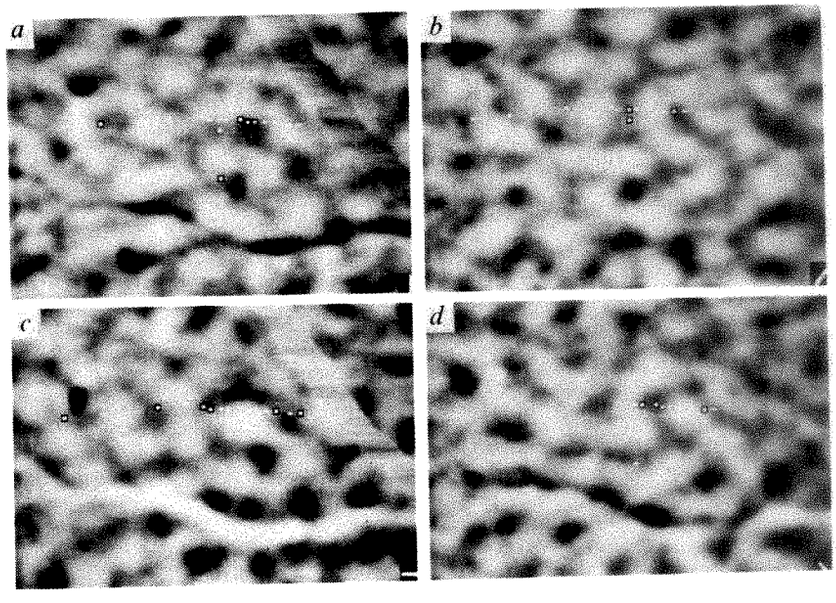

Fig. 3 Iso-orientation activity patterns produced by four separate orientations—vertical, right oblique, horizontal and left oblique. Each image was compiled separately and related to a reference image generated by the orthogonal orientation. This subtraction was necessary to minimize the effects of activity-dependent hyperaemia[28]. For example, images of cortex taken during horizontal presentations were subtracted from images taken during vertical presentations to produce the pattern in *a*. The observation that vertical and horizontal patterns shown in *a* and *c* are complementary merely underscores the consistency of the result. White dots indicate the positions of electrode recording sites. Those outlined in black denote locations where sampled cells preferred orientations within 22.5° of that presented. These correlate with the darker parts of each image and never overlap with the lighter ones. Major blood vessels, which sometimes produce shadows caused by uncontrollable dilation during image acquisition, have been blocked out to prevent unwanted influences on adjacent regions of the same image during subsequent normalization and image processing.

when the horizontal grating disappears. The occurrence of similar responses for horizontal and vertical gratings (increased aborbance in both cases) is probably due to the location and size of the cortical patch surveyed.

The large sizes, stability and long durations of these signals suggested that they might be monitored with higher spatial resolution using a TV camera. Stable signals over a long period made it possible to average many frames during each visual presentation; typically, 1,800 frames (30 frames per s) were summed during a set of 10 presentations. This led to a profound improvement in the signal to noise ratio; and further improvements were achieved through lateral averaging—that is, by dividing the image into squares 4 pixels high and 4 pixels wide, and averaging all the pixel values within each square. As noted above, the paradigm detects radiant changes greater than 0.01%.

Ocular dominance

Figure 2*a* shows a 4×5-mm patch of striate cortex as it appeared under white light. Blood vessels appear out of focus because the focal plane lies 300 μm beneath the pial surface. The lunate sulcus, as well as the accompanying border between areas 17 (striate cortex) and 18, lie parallel to and just below the lower boundary of the image. Blood vessels do not present a problem because they become virtually transparent to light at 720 nm (the wavelength at which we monitor the response of the dye), and disappear altogether (except for a couple of the largest

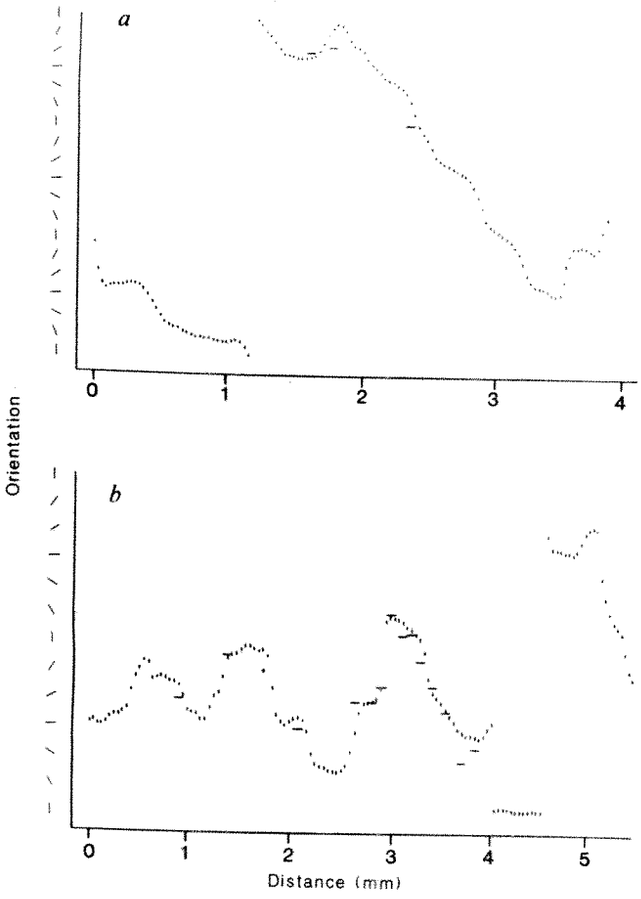

Fig. 4 Orientation values as they would appear along a single, tangential electrode penetration. This is done twice. *a*, Orientation values along a vertical scan line running through the three vertically aligned sites in the centre of Fig. 5*a*. *b*, Orientation values along a single horizontal scan line lying along the 14 horizontally aligned sites in Fig. 5*a*. Short horizontal lines indicate the actual orientation values that we determined (by averaging orientation preferences determined at three different depths) for each of the sites.

vessels) when one cortical image is subtracted from another (Fig. 2*c*). Because of the strong haemoglobin absorption at 430–610 nm it is unlikely that such controls could be obtained at wavelengths below 620 nm.

Figure 2*b* depicts the characteristic pattern of ocular dominance bands produced by subtracting cortical images accumulated during visual stimulation of the contralateral eye from images accumulated during stimulation of the ipsilateral eye. Because cortical tissue darkens with activity once it has been stained with NK2367, the dark bands in Fig. 2*b* correspond to ipsilateral dominance. Comparison of Fig. 2*a* and *b* shows that these bands have little in common with blood vessels. However, there is a tendency for the largest vessels to produce shadows (either light or dark), largely through uncontrollable changes in vascular perfusion during neuronal activity[28].

Besides resembling ocular dominance bands visualized with other techniques[5,8,9], the bands in Fig. 2*b* display several characteristic features: they have the same width as those observed with 2DG, they run vertically into the border of area 17, and every light and dark stripe straddles a row of cytochrome oxidase blobs, as would be expected[13]. The latter correlation is apparent from the aligned image (Fig. 2*d*) of a section from the same patch of cortex which was stained for cytochrome oxidase.

To confirm the identities of these bands independently, direct electrical measurements were made with microelectrode penetrations at 16 separate locations. The spots in Fig. 2*b* indicate ocular dominance values determined (on the basis of recordings at three separate depths) for each location. The round spots (indicating balanced binocular responses) predominate near the edges of bands while the open squares (contralateral dominance) align with the light bands and the closed squares (ipsilateral dominance) with the dark.

Orientation

Initial attempts to visualize orientation selectivity were made by subtracting images obtained during control conditions (equiluminant grey screen) from images obtained while the monkey viewed a drifting vertical grating. This approach was hampered by the previously mentioned vascular changes induced by neuronal activity[28], and by a diffuse, activity-dependent darkening of the cortex which may be the result of generally heightened activity within the stained cortical neuropil.

These problems can be avoided by comparing frames accumulated during stimulation with two orthogonal orientations. Activity remains high for both sets of frames such that perfusion and diffuse changes remain constant, and only events induced by a change in the stimulus orientation are detected.

We used this approach to produce the four images in Fig. 3, all of which resemble patterns achieved with 2DG[12]. The patterns produced by horizontal and vertical gratings complement one another, as do patterns produced with right and left oblique. Although this finding might appear self-evident given our subtraction protocol, the lack of overlap between the patterns reinforces their stimulus-relatedness and stability, and reduces possible concern about spontaneous fluctuations in neuronal activity. The image in Fig. 3*c*, for example, was obtained half an hour (and six intervening scans) after that in Fig. 3*a*.

Small white squares in Fig. 3 indicate the positions of our 16 electrode penetrations. Those revealing an orientation preference within 22.5° of the test stimulus are outlined in black. It is easy to see that the latter predominate within active (darkened) regions of cortex and avoid inactive (light) regions.

To improve our resolution of orientation selectivity, we obtained 12 separate activity patterns from the same patch of cortex taken at 12 separate orientations (that is, at 15° intervals). These allowed us to compare values at each pixel location (for every image) to determine the orientation responsible for the strongest response. Figure 5*a* depicts the colour-coded optimal orientation at each point, and shows that orientation values change continuously in most regions of cortex and that all orientations are represented within fairly small areas (<1 mm^2). It also allows the extraction of orientation values along single scan lines so that they may be plotted directly. This is done in Fig. 4*a* and *b*, which shows orientation values along two orthogonal axes that intersect the sites of electrode recordings (white squares in Fig. 3*a*). These plots resemble qualitatively those of Hubel and Wiesel's tangential electrode penetrations[6], and agree with the results of our own recordings (indicated by short horizontal lines).

Fractures

The colour-coded images in Figs 5*a* and 6*a* highlight the distribution of regions responsive to different orientations in one patch of cortex. This distribution is not one of parallel bands since the image does not have an overall rainbow appearance, but it is possible to find small regions where such an appearance is predominant; these regions are separated from one another by sudden shifts in preferred orientation which break the continuity.

To visualize the pattern of disruption more completely, we applied a gradient operator to the orientation values in Figs 5*a* and 6*a*. This is a simple operator which derives the rate of orientation shift (like a first derivative) in each part of the image. The results appear colour-coded in Figs 5*b* and 6*b*, where the colour sequence orange, yellow, green, blue, red and black

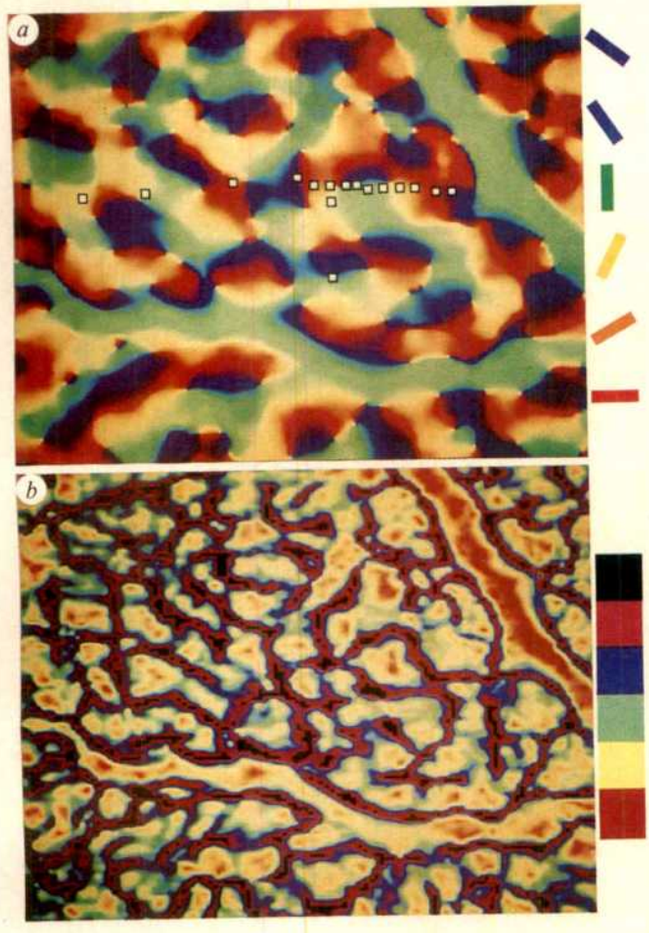

Fig. 5 *a*, Detailed orientation preferences mapped from the same patch of cortex using successive presentations of 12 separate orientations. Like the images in Fig. 3, these patterns were generated by collecting two sets of frames with orthogonal orientations, as the animal viewed bi-directionally moving gratings, and subtracting one from the other. The process was then repeated with different orthogonal pairs. Our computer (LSI 11/73) used the 12 resulting images to analyse orientation selectivity at every point in the image. Every pixel in each image was transformed into a vector; the magnitude of each vector was the pixel value (response intensity), and its angle was twice the orientation of the stimulus grating. This representation ensured that for each pixel, vectors representing equivalent responses at orthogonal orientations would cancel out. The 12 vectorial images were then summed to produce an output image consisting of two parts, one corresponding to vector magnitudes which reflects the degree of orientation selectivity for each part of cortex, and one corresponding to half the vector angle, reflecting orientation preferences. This figure shows colour-coded representations of optimal orientations. Actual orientation values appear graphically in Fig. 4. It is important not to overinterpret areas devoted to any particular orientation as most of the apparent differences derive from nonlinearities in colour processing (particularly with respect to blue). *b*, Gradient of the orientation values presented in *a*, taken so as to visualize the two-dimensional distribution of continuous regions and sudden breaks. The colours orange, yellow, green, blue and red indicate increasingly rapid rates of orientation change; black denotes regions where orientation preference jumps by 45° or more within a distance of 40 μm.

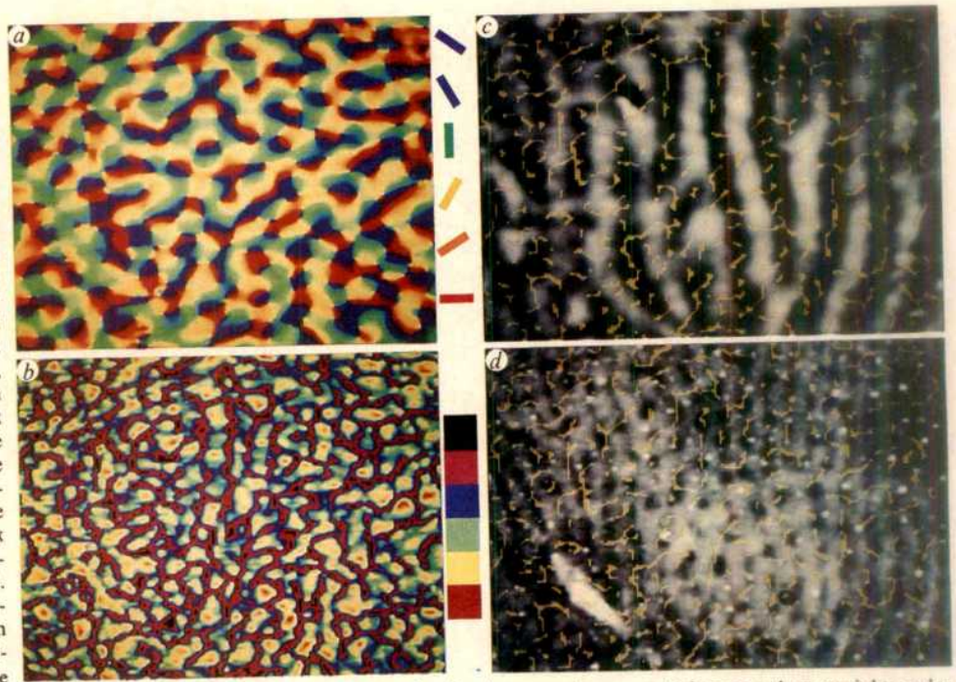

Fig. 6 Low-power view of the striate cortex. The horizontal width of this image corresponds to 8 mm on the cortical surface. As in Fig. 5, the area 17/18 border lies parallel to and just below the lower border of this image. *a*, Colour-coded distribution of orientation, similar to that shown in Fig. 5*a*. If orientation selectivity really were organized into parallel slabs, this image should look like a rainbow, or stacks of rainbows. Such colour distributions are present only on a small scale. *b*, Colour-coded representation of the orientation gradient. At this lower power, modules of continuous orientation domains are even more apparent than in Fig. 5*b*. As in Fig. 5*b*, the most abrupt transitions—those exceeding 45° in 40 μm—are indicated in black. *c*, Ocular dominance pattern for the same part of the cortex (obtained by alternate visual stimulation of the two eyes, as in Fig. 2*b*). Fine yellow lines indicate exceptionally radical shifts in orientation preference and correspond approximately to the black regions in *b*. Note the pronounced tendency for these lines to run down the centres of adjacent ocular dominance columns, or to intersect them at right angles. If we lower the fracture threshold to include slightly less radical jumps in preferred orientation, these lines elongate, becoming more modular in appearance, and eventually converge to form a pattern similar to that in *c*. The fracture-bounded modules are situated between the centres of adjacent ocular dominance columns, an opportune place for receiving balanced inputs from both eyes. This arrangement also establishes a continuous shift in ocular dominance across each module. *d*, Cytochrome oxidase-stained section from the same patch of cortex. Even a casual comparison between this image and that produced in *c* shows the close correspondence between cytochrome oxidase blobs and the centres of optically determined ocular dominance columns (both light and dark). As in *c*, yellow lines indicate the positions of fractures. Due to their pronounced tendency to align with the centres of ocular dominance columns, the fractures also overlap with the cytochrome oxidase blobs, an observation perhaps related to Livingstone and Hubel's finding that orientation tuning weakens and sometimes disappears near blobs[15]. Maps of orientation tuning (derived from the vector magnitude of the operation that produced the images in 5*a* and 6*a*) reveal a

indicates increasingly rapid changes (with respect to distance) in preferred orientation. It is clear from this representation that the most abrupt changes (indicated by red and black) travel along lines similar to fractures in a crystal, and circumscribe small (0.5–1 mm wide) regions of cortex. Within each region, orientation changes continuously along one axis, in a manner consistent with an organization of parallel slabs. Because these regions occupy most of the cortical surface area, and clearly are circumscribed by fractures, one can think of them as modules. The latter appear highly regular in area, and where larger areas are observed they take the form of elongated, module-wide strips, suggesting that smaller domains with mutually confluent maps have merged.

Fractures and ocular dominance

As both orientation selectivity and ocular dominance repeat their representation within short distances (<1 mm), it seems likely that they are related. One possibility, suggested by Hubel and Wiesel[6,7], but which they subsequently disproved[10], is that iso-orientation bands intersect ocular dominance columns at some consistent angle. Our results also reject this notion. But when we compare ocular dominance columns with sudden changes in preferred orientation (that is, with the fractures), we find a marked correlation. As can be seen from the superposition of ocular dominance columns and fracture segments in Fig. 6*c*, the fracture segments that are aligned with ocular dominance columns run down their centres and avoid the edges. Those that intersect the boundaries of two adjacent columns do so at right angles. Accordingly, disruptions in the gradient of preferred orientation tend to coincide with reversals in the gradient of ocular dominance; and orientation and ocular dominance both vary continuously along single but separate axes within each module.

Comments

Our results demonstrate the feasibility of using voltage-sensitive dyes in conjunction with video imaging techniques to study functional organization in the monkey striate cortex. They reveal for the first time a detailed map of cortical regions responsive to different orientations. We will discuss these two very different findings separately.

Dye technology. One important issue concerns the source of our optical signals. Although we have noticed a general, activity-dependent darkening of unstained cortex, we have not found this phenomenon useful in identifying cortical response properties. We believe that changes in dye absorbence underlie the generation of the patterns we see because: (1) these patterns do not become apparent until after the cortex has been stained; (2) they become weaker with exposure to light; and (3) they become stronger when the cortex is restained. These signals could be derived from dye-stained neurones and glia, and although it would be interesting to know the relative contributions of these two populations, this information is not critical as both neurones and glia exhibit preferences for orientation and ocular dominance[29].

A second issue concerns the observation that cortex stained with NK2367 exhibits an increased absorption at 700–740 nm associated with increased activity. The direction of the change is opposite to that reported for NK2367 in studies of invertebrate neurones[30], heart muscle[20], and skeletal muscle[31,32]. However, the voltage-dependent spectral changes of this dye are known to be species-dependent[30], and dye molecules bound to skeletal muscle sarcolemma and transverse-tubule membranes exhibit voltage-dependent absorption changes of opposite direction[32]. Finally, the prolonged staining period required to allow dye to percolate through the pia and upper layer of cortex may alter the dye–membrane interaction such that the action spectrum might invert[21]. In this regard, one reason NK2367 works better than other dyes tested lies in its ability to penetrate pia, which entails some degree of membrane permeability.

By visually inspecting cross-sections of freshly stained monkey cortex we determined that NK-2367 diffuses ~0.5 mm beneath the cortical surface. Cells lying any deeper than 0.5 mm do not stain and so presumably do not contribute to the optical signals. Although cells in the upper zone make some contribution, the amount is difficult to gauge, and vagaries of light scattering further complicate the issue. These uncertainties are not critical as long as the properties under investigation (ocular dominance and orientation selectivity) are aligned in depth and the optical results correlate with electrophysiological recordings.

Orientation selectivity and ocular dominance. Given the newness of the technique reported here it seems inevitable that technical limitations will become more apparent with future developments. It is possible, for example, that our results are affected more than we allow by small blood vessels and by blobs (where orientation selectivity is weak). More work is clearly needed on these issues; and for the moment we can only stress the close correlation between our optical, anatomical, and electrophysiological results. With these limitations in mind, therefore, we present here the best conclusions that we can reach with regard to cortical organization.

The model of Braitenberg and Braitenberg[33] suggests that cortical regions responsive to different orientations might be organized, clockwise and anticlockwise, in a pinwheel fashion about various distributed foci. Although there are many places where this is not seen, in those where it is, the rapid changes in preferred orientation (which we call fractures) might serve merely to make adjustments in the overall map. It is difficult to see, though, how this arrangement could produce the open-looped network of fractures apparent in Figs 5*b* and 6*b*. Given the prominence of these fractures, it seems likely that they would correlate with (and possibly be derived from) some anatomical constraint. Hubel and Wiesel[7] suggested that continuous shifts in orientation might provide an economic means of wiring up many cells with different orientation selectivity and overlapping receptive fields. Along these lines it is easy to envisage a developmental mechanism whereby neurones express some innate tendency to shift orientation preferences in their neighbours. If such a mechanism operated over ranges of 0.5–1 mm, it could lead to the condensation of stable aggregates, each with their own internally consistent map. The space constant of 0.5–1 mm could originate from local dendritic arborizations, which extend about this far.

As a slight variation of this theme, specific connections or neurones might organize the small ordered map wthin each module. These connections might then compete for territory and thereby produce the highly regular size that is apparent for the domains in Fig. 6*b*. This possibility is supported by a striking similarity between the fractures we observe and the lattice-like patterns that Rockland and Lund produced in monkey striate cortex by making large injections of horseradish peroxidase[34]. Given the overlap between fractures and blobs in Fig. 6*d*, this possibility is also suggested by the finding that horseradish peroxidase injected into blobs is transported, sometimes asymmetrically, to other blobs[35]. In this regard, it is perhaps significant that the blobs in macaque striate cortex are not usually circular and frequently extend, like fracture segments, down ocular dominance column centres.

Apart from their involvement in the anatomical and developmental constraints listed above, how might a modular design facilitate image analysis? One appealing notion is that it compartmentalizes visual space. Each module might examine a small part and reach some conclusion regarding depth and edges; the overlap between ocular dominance and orientation gradients within each module underscores this possibility. There is a problem, however, in that most modules are not large enough (by a factor of ~0.3) to accommodate all orientations. It is possible that the compartments either do not need complete sets of orientation, or, if such compartments do exist, that each may contain more than one module. On the basis of receptive field

sizes and scatter, Hubel and Wiesel[7] estimated that a point in visual space affects the firing of cells within a 1-2-mm block of cortex. Needless to say, a block of this size could include several of the continuous domains that are cell modules.

Within a module, orientation changes continuously (to a good approximation, linearly) along a single axis. The simplest explanation for this arrangement is that it satisfies some sort of packing constraint; that is, the need to represent all orientations evenly within a given distance. Given the relatively broad orientation tuning (20–60°) for most cells, it also ensures that cells responding to a particular edge will be grouped together, which might enable some sort of local averaging to improve the reliability of detection. But why should the orientation preference remain constant along the orthogonal axis? Is there really a need for such redundancy, or is there some other response parameter (such as position, edge length or spatial frequency) that varies along this axis? We cannot answer these questions yet, but they should influence the direction of future research and the answers should contribute significantly to our understanding of the striate cortex.

Test of the gravitational lens hypothesis for the quasar pair 1146+111B,C

P. A. Shaver & S. Cristiani

European Southern Observatory, Karl-Schwarzschild-Str. 2, D-8046 Garching bei München, FRG

It has recently been suggested[1] that the quasars 1146+111B,C, separated on the sky by 2.6 arc min, are actually two images of a single object produced by an extremely massive gravitational lens. The basis for this suggestion is the similarity in redshifts (within 100–200 km s^{-1}) and spectral features. Here we report differences between the two spectra in a hitherto unobserved range, suggesting that the two images are in fact distinct quasars located close together in space.

Close pairs of quasars are of interest in connection with both gravitational lensing, in which case the two images originate from the same object, and physical clustering, when the two images are due to distinct but spatially close quasars with similar redshifts. At separations of several arc seconds it is generally assumed that quasar pairs of similar redshifts and spectra are due to gravitational lenses, although even some of these could be physical pairs: the physical clustering of quasars may be similar to that of galaxies today[2], and separations of 5–10 arc s correspond to 30–60 kpc at redshifts of ~1–3 (for Hubble constant $H_0 = 100$ km s^{-1} Mpc^{-1} and deceleration parameter $q_0 = 0$), not uncommon in clusters and groups of galaxies. Pairs at arc-min separations have generally been thought to be distinct objects, although the possibility of gravitational lensing has occasionally been raised on these distance scales as well, particularly in the context of cosmic strings[3–6].

Distinguishing between the two effects can be difficult for several reasons: redshifts of broad emission lines are difficult to measure accurately and can differ substantially from the true systemic redshifts[7]; spectra of different quasars tend to be broadly similar; and some spectral differences can be present even in gravitationally lensed images, because of differential extinction by intervening material or intrinsic temporal variations combined with differential time delays along the two lines of sight[8]. However, definitive tests of gravitational lensing can be made, for example, by comparing the magnitude variations of the two images, or the redshifts of narrow forbidden lines arising in the host galaxies.

The quasars 1146+111B,C, separated by 2.6 arc min, have been known for several years to have similar redshifts[9] (ΔV = 100–200 km s^{-1}), and they have been included in lists of possible physical pairs[2]. Recently, on the basis of the similarity in redshifts and spectra, it has been suggested that this pair may be produced by a gravitational lens[1]. If so, it would be most unusual, as the large angular separation would imply an extremely large mass for the lensing object.

To test this interpretation, we have observed this pair in the red wavelength region, to look for similarities or differences between corresponding spectral lines in that unexplored range.

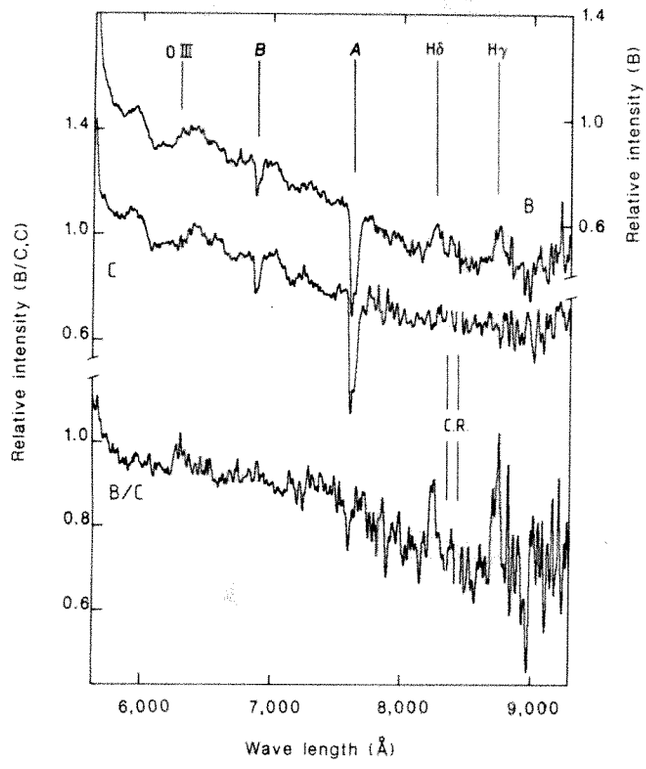

Fig. 1. Spectra of the quasars 1146+111B and C, and their ratio (B/C). The positions of the redshifted ($z = 1.0115 \pm 0.0003$) emission lines of Hγ, Hδ and O III in 1146+111B, the atmospheric *A* and *B* bands, and two cosmic-ray events (C.R.) are indicated.

The observations were made in the period 14–16 April 1986, using the European Southern Observatory faint object spectrograph and camera (EFOSC) on the 3.6-m telescope at La Silla. A red grism providing a dispersion of 270 Å mm^{-1} was used with a slit width of 1.5 arc s, resulting in a spectral resolution of 18 Å (full width at half-maximum) throughout the wavelength range 5,600–9,300 Å. Both objects were observed simultaneously. Standard flat-fielding, sky subtraction, and wavelength and intensity calibration techniques were applied, and the resulting spectra are shown in Fig. 1.

Many features are common to both spectra, particularly the ubiquitous Fe II multiplets[10]. There is, however, a significant difference: the Hγ 4,340 Å and Hδ 4,102 Å emission lines are prominent in the spectrum of B and not seen in that of C (Hγ equivalent widths of ~26 Å in B and <4 Å in C). The ratio of the two spectra reveals a third possible difference, an emission feature in the spectrum of B at 6,301 Å, probably the O III, 3,133 Å Bowen fluorescence line which is sometimes seen in quasar spectra.

In view of these spectral differences, it seems unlikely that the two objects are different images of one quasar. Even allowing for possible intrinsic variations and path-length differences, it is improbable that the hydrogen lines could have varied by a factor of 6–7 relative to both the continuum and the Mg II emission line over the suggested[1] delay time of $\sim 10^3$ yr. The spectra are different, and the most straightforward interpretation is that the objects are two different quasars. The similarity in redshift is not at all surprising for a physical pair: there are enough close pairs (in redshift and projected separation) in the Véron catalogue[11] that the probability of at least one of them having a redshift difference ≤ 100 km s^{-1} is essentially unity. There is another quasar pair, of separation 1 arc min, which was also suggested to be due to a gravitational lens[12], but closer scrutiny revealed significant spectral differences in that case also[13]. In the absence of any compelling evidence to the contrary, therefore, we conclude that 1146+111B,C are simply two separate quasars located close to each other.

We thank John Danziger, Bob Sanders and Joe Wampler for useful comments and discussions.

Natural ventilation of the Paintings Room in the Altamira cave

P. L. Fernández*, I. Gutierrez†, L. S. Quindós†, J. Soto† & E. Villar*

* Fundamental Physics Department, Science Faculty, and †Medical Physics Department, Medicine Faculty, University of Santander, 39005 Santander, Spain

The Altamira cave (Santillana del Mar, Santander, Spain) is famous for the ceiling of one of its chambers, the Paintings Room, which is decorated with palaeolithic paintings. However, the massive influx of visitors resulted in deterioration of these rupestrian paintings and the cave was closed in 1977 to determine both the causes and the maximum number of visitors that could visit the cave without putting the paintings at risk[1–3]. The natural ventilation of the Paintings Room is one of the most important factors in formulating the maximum occupational index for visitors to the cave. The emission of carbon dioxide and water vapour by visitors inside the chamber is directly proportional to the number of visitors and the time spent in the room. By ventilating the room, these components should be removed from the air within a short period of time, thus returning the chamber to the prevailing conditions before visitors were allowed in. We report here variations in the ^{222}Rn concentration in the air of the Paintings Room which we use as a quantitative index of the natural ventilation existing in this chamber. We carried out parallel studies of the temperature at different points in the cave and the evolution of the carbon dioxide concentration in the air of the Paintings Room, and hence established the maximum number of people per hour that should be allowed to visit this chamber.

Radon-222 is a noble gas of the radioactive series of ^{238}U, an element that occurs in rocks in the Earth's crust with a concentration between 2 and 5 p.p.m. (parts per 10^6). Because of its gaseous nature and its greater concentration within the Earth, radon escapes through the interstices of the soil to the atmosphere, with an exhalation rate of ~1 atom c^{-2} s^{-1}. When this exhalation occurs in places with little ventilation, the radon concentration of the air may be high.

The ^{222}Rn concentration of the air of the Altamira cave was measured by scintillation cells with a capacity of 500 cm^3, in which a vacuum had been created down to a pressure of 50 torr. These scintillation cells were made of transparent plastic and

Table 1 Mean monthly ^{222}Rn concentration in the air of the Hall and Paintings Room; and the natural ventilation rate in the Paintings Room

	Paintings Room	180 ± 9	
January 1984	Hall	177 ± 9	9.3 ± 1.2
	Paintings Room	181 ± 9	

their internal walls were covered with a film of SZn(Ag). The emission of α radiation by the radon ($t_{1/2} = 3.8$ days) contained in the air filling the cell leads to this radiation falling onto the film of SZn(Ag), where it produces fluorescence. The light thus emitted can be detected using a photomultiplier tube and the pulses produced can be recorded.

Because two of the short-lived radon daughters, ^{218}Po and ^{214}Po, are also α emitters, their contribution to the total counting supplied by an air sample increases with time until a radioactive equilibrium is reached between the radon and the two daughters. This equilibrium is reached 3 h after the sample is taken only if, initially, radon gas was present in the air sample. Therefore, to calculate the radon concentration, we carried out a 10-min counting 3 h after the collection of the air sample assuming that there was a radioactive equilibrium between the radon and its daughters. The number of counts obtained from the scintillation cell when empty was subtracted from each measurement resulting from fluorescence of the SZn(Ag).

The ^{222}Rn concentration was measured in two chambers within the cave: the Hall chamber, located at the entrance to the cave; and the Paintings Room (see Fig. 1). Measurements were made three times per week over a period of 1 yr between February 1983 and January 1984. From these results, we calculated the monthly average radon concentrations (Table 1).

To calculate the natural ventilation in the Paintings Room from the radon concentrations, we used the simplified model proposed by Wilkening[4], which is based on the fact that the temporal variation in the radon concentration (C) in the air of this chamber can be expressed as the sum of the production caused by radon exhalation from the rock surfaces, the radioactive decay and the radon loses resulting from the natural ventilation:

$$\frac{dC}{dt} = E\frac{S}{V} - \lambda C - \frac{Q}{V}(C - C_h) \quad (1)$$

where E is the radon exhalation rate, S and V the surface and volume of the Paintings Room, respectively, Q the ventilation rate in this chamber, λ the radon decay constant and C_h the radon concentration in the Hall chamber.

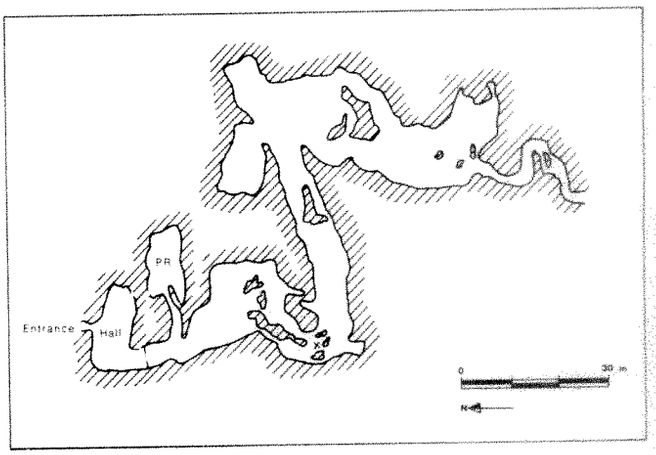

Fig. 1 Map of Altamira cave. PR, Paintings Room.

In stationary conditions, and assuming that $Q \simeq 0$ when the radon concentration reaches its maximum value C_{max} (in our case 196 pCi l^{-1}), then

$$E\frac{S}{V} = \lambda C_{max} \quad (2)$$

We can calculate the ventilation rate as

$$Q = \lambda V\frac{(C_{max} - C)}{(C - C_h)} \quad (3)$$

To apply this model to the experimental values obtained in the Altamira cave, we calculated the natural ventilation in the Paintings Room. Table 1 shows that values obtained for the ventilation rate are low throughout the whole year. Taking into account the volume of the Paintings Room, ~330 m^3, it would take ~16 h to totally renew the air in the chamber by natural ventilation in July, the period of maximum ventilation rate, and ~330 h in May, the period of minimum rate.

At the same time as measuring the radon concentration, we studied two variables that may be related to the ventilation rate: air-temperature differences between the Paintings Room and the Hall chamber and the carbon dioxide concentration in the air of the Paintings Room.

The Altamira cave has a single entrance. In such a static cave, ventilation currents are principally caused by convective air movements that basically depend on the temperature gradients between the different points into the cave. In the Altamira cave, the air temperature differences between the Paintings Room and the other chambers, with the exception of the Hall chamber, are always very small[5]. Temperature differences between the air in the Paintings Room and that in the Hall chamber are appreciably caused by the influence of the outside temperature on the latter so convective interchanges can be expected.

Figure 2 shows the monthly mean values obtained for the ventilation rate in the Paintings Room and the temperature differences between the air of the Paintings Room and the air of the Hall chamber throughout the measurement period. The correspondence can be observed between the annual variations in both ventilation in the Paintings Room is basically determined by convective processes between these two areas.

The carbon dioxide concentration in the air of the Paintings Room has its origin from the gas dissolved in the infiltration waters that flows into this enclosure. In the same way as the radon gas, the carbon dioxide concentration in the Paintings Room is eliminated by natural ventilation as the air interchanges with the outside atmosphere. The experimental measurement of the carbon dioxide concentration was carried out using an infrared analyser connected to a continuous trace graph plotter.

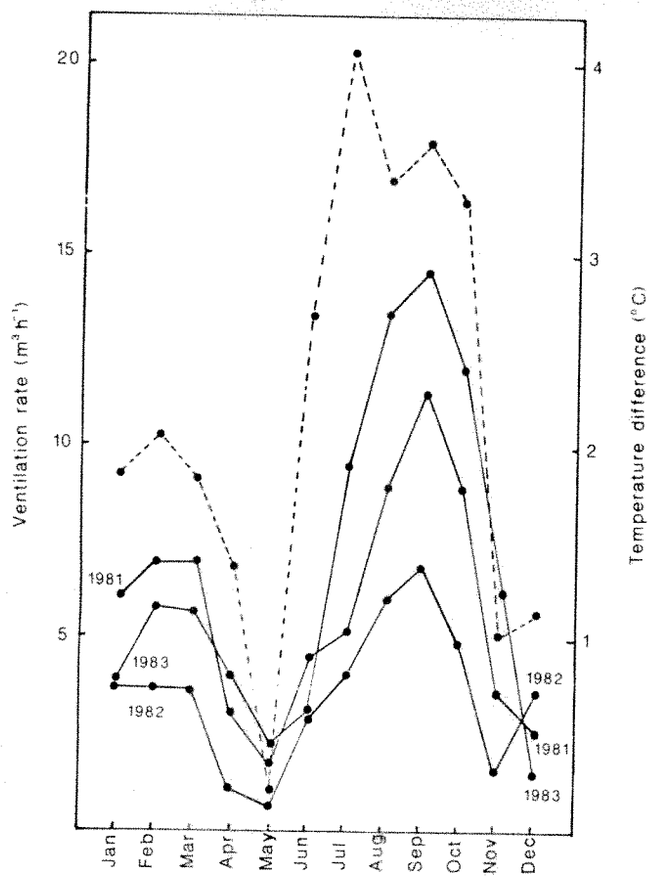

Fig. 2 Variations in the ventilation rate (dashed line) and the temperature differences (solid lines) between the Paintings Room and the Hall chamber.

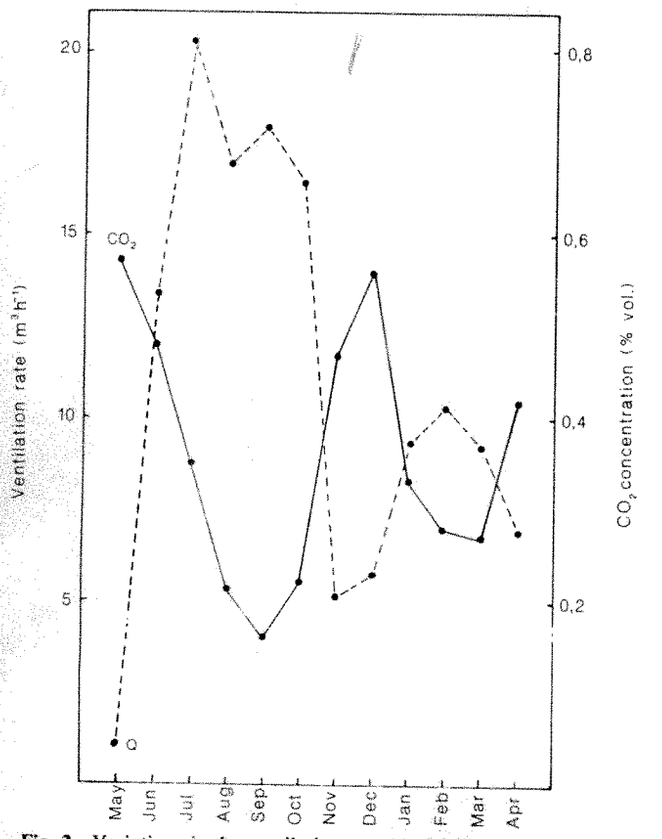

Fig. 3 Variations in the ventilation rate (dashed line) and carbon dioxide concentration (solid line) in the Paintings Room.

Figure 3 shows the ventilation rate calculated previously together with the monthly mean carbon dioxide concentrations measured in the Paintings Room. The inverse relationship between both variables consistent both with the variations in the temperature differences between the Hall chamber and the Paintings Room and with the fact that natural ventilation is the major factor affecting changes in the carbon dioxide concentration.

Taking into account that a person exhales an average carbon dioxide volume of $\sim 17\,l\,h^{-1}$ (ref. 6) our results show that the maximum number of people that could visit the Paintings Room for a period of one hour each day in the summer months without raising the carbon dioxide concentration higher than that seen in May are 43, 74 and 80 visitors in July, August and September, respectively.

Our results indicate a weak natural ventilation in the Paintings Room throughout the whole year. The ventilation rate shows minimum values in May and November and maximum values in the summer months. These results agree with the estimations obtained from the temperature differences between the air of the Paintings Room and that of the Hall chamber and of the carbon dioxide concentration in the air of the Paintings Room. The minimum radon concentration and maximum ventilation rate, found in July, match the maximum absolute value of the temperature difference between the Hall chamber and the Paintings Room and the minimum carbon dioxide content in the air of the latter, found in the same month. In the same way, the maximum radon concentration and minimum ventilation rate recorded in May match the minimum absolute value of the temperature difference between the Hall and the Paintings Room and the maximum carbon dioxide concentration measured in this month.

Global distribution of peroxyacetyl nitrate

Hanwant B. Singh*, Louis J. Salas† & William Viezee†

Nitrogen oxides (NO_x) have a central role in the chemistry of the atmosphere, especially in key processes relating to ozone, hydroxyl-radical (OH) and acid formation[1–7]. High reactivity of NO_x (lifetime of 0.5–2 days) precludes hemispheric-scale transport and it has been proposed that non-methane hydrocarbons present in the troposphere can transform NO_x into its organic forms principally as peroxyacetyl nitrate (PAN)[8,9]. PAN is highly stable in the colder regions of the middle and upper troposphere and can provide a mechanism for NO_x storage and transport. Once transported, PAN and its homologues can easily release free NO_x in warmer atmospheric conditions. PAN is probably ubiquitous and its concentrations could exceed those of NO_x in clean tropospheric conditions[10–12]. Here we present the first view of the global distribution of PAN based on extensive shipboard and aircraft measurements. PAN is more abundant in the Northern than in the Southern

Hemisphere and in the continental than in the marine troposphere. In contrast to its behaviour in polluted atmospheres, PAN mixing ratios in winter greatly exceed those in summer. These measurements provide a basis for assessing the significance of PAN as a reservoir of NO_x and for extending and validating reactive nitrogen chemistry theory in the troposphere.

Details of the measurement techniques for PAN and light hydrocarbons (LHC) used in the present observational program have been described elsewhere[13,14]. An overall accuracy of ±20% is estimated for the PAN measurements. We determined the hemispheric PAN distribution in surface air aboard the US Coast Guard vessel *Polar Star* while travelling from Seattle, Washington (48° N), southward to Puenta Arenas, Chile (48° S), between 11 November and 28 December 1984. All PAN and LHC measurements were made over the ocean 50 miles or more away from the coast on a daily hourly schedule from 08:00 to 22:00 local time. Figure 1*a* shows the inter-hemispheric PAN profile. PAN levels in the Northern Hemisphere are highly variable, ranging from <10 p.p.t.v. (parts per 10^{12} by volume) to some values >70 p.p.t.v. A sharp decrease towards the Equator is evident. Mean daily surface PAN levels in the Southern Hemisphere are only ~5 p.p.t.v., compared with the average Northern Hemisphere level of 38 p.p.t.v. The relatively high concentrations encountered at latitudes 28° N and 35° S are attributable to air masses of continental origin. Figure 1*b* shows the hemispheric profile of selected light hydrocarbons measured earlier on a similar North–South Pacific track[14]. Figure 1 shows that the PAN latitudinal distribution is similar to that of the alkanes, but is unlike the more uniformly distributed propene. The theoretical assertion that light alkanes (and NO_x) are probably the most important precursors of PAN, and therefore their hemispheric gradient is translatable into a PAN latitudinal gradient, is at least partially supported[8,9]. Although reliable NO_x data are not available, it is possible to conjecture that in the lower marine troposphere, NO_x levels are extremely low (10–30 p.p.t.v.), and probably of comparable magnitude in the two hemispheres[15,16] (also B. Ridley, unpublished data). Although PAN can hydrolyse relatively rapidly in sea water (half-life ≃15 min at $pH = 8.3$)[17], the extremely low partition coefficient suggests that oceans are, at best, a minor sink.

Aircraft measurements to an altitude of 10 km above sea level (~250 mbar) were made aboard the instrumented NCAR/NSF Beechcraft King Air research aircraft. Flights were conducted in the summer of 1984 over the Colorado–Wyoming area (19–28 July; 40° N) and over the eastern Pacific (12–22 August; 40° N); and in the winter of 1985 over the eastern Pacific (12 February to 4 March; 40° N). A total of 130 flight hours were logged. Each flight lasted 5–6 h to allow for reaching ceiling altitude and for collecting a maximum number of data points during ascent and descent. Figure 2 gives examples of typical vertical PAN profiles measured during day (~11:00–17:00) and night (~22:00–04:00) in fair weather conditions. The differences between the profiles measured during ascent (solid line) and descent (dashed line) are indicative of the variability associated with region and time of day. Figure 2 shows that PAN is preserved at night with concentrations that can be comparable to the daytime values. An important feature of these data is the indication that PAN concentrations in stable weather conditions tend to increase with height, which supports the proposed theory for *in situ* PAN synthesis[8]. PAN concentrations along the summer profile in Colorado (Fig. 2*a*) vary between 100 and 200 p.p.t.v., whereas those along the summer profile off the California coast (Fig. 2*b*) are much lower, varying between 20 and 50 p.p.t.v. Observations showed that during unsettled weather (for example, when a cold front passed through the region on 27 July), PAN values over Colorado temporarily approached those measured over the Pacific. There is a great deal of structure and variability in PAN concentration in the atmosphere, especially during winter (Fig. 2*c*). Aircraft observations of temperature and wind obtained during the February 1985 flights

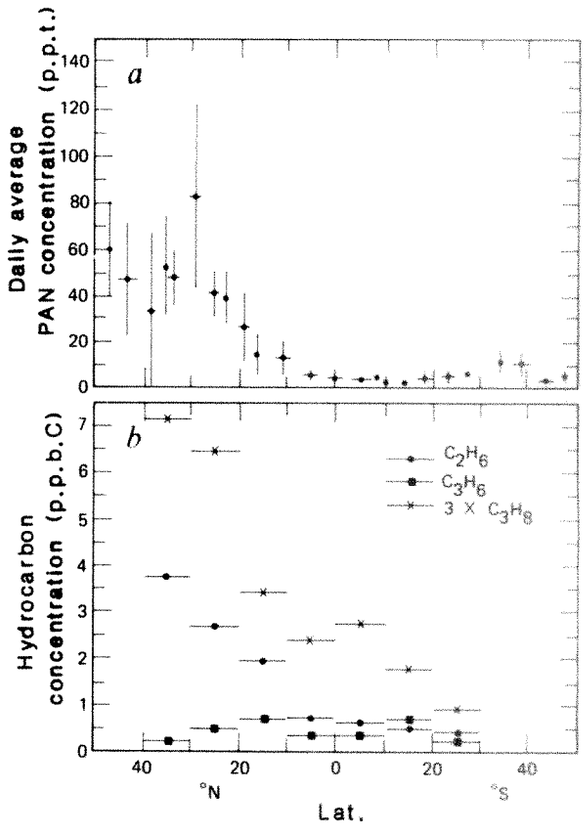

Fig. 1 Inter-hemispheric profile of surface-air concentrations for PAN and selected non-methane hydrocarbons. *a*, PAN data obtained from measurements aboard the US Coast Guard vessel *Polar Star*. The horizontal line segments represent the daily averaged PAN concentration in p.p.t.v. over the latitude (time) interval during which measurements were made. The standard deviation of the daily measurements ($\pm 1\sigma$) is indicated. *b*, Hydrocarbon data from ref. 14 obtained over the eastern Pacific Ocean during the period 30 November–21 December 1981 (p.p.b. C = 10^{-9} v/v carbon). ●, Ethane; ■, propene; ×, 3 × propane.

showed no significant variations in the vertical temperature profiles but did indicate a different wind direction and speed in the lower and middle troposphere for each of the five research flights. For the two profiles of Fig. 2*c*, the winds changed from north-north-west at 35–40 knots (21–22 February) to easterly at 25–30 knots (27 February). More research is needed to explain whether this is attributable to regional anthropogenic effects, to chemistry, meteorology or to all of the above.

Figure 3*a*,*b* shows composite vertical profiles of PAN concentration for the various time periods and geographical locations of the aircraft flights. Composite profiles are obtained by averaging the day and night measurements collected during stable, uniform air mass conditions. In Fig. 3*a*, three salient features of PAN abundance are evident: (1) in the Pacific during summer (August) and winter (February), PAN concentrations in the upper troposphere are higher than in the lower troposphere—this feature may be evident also in the summer (July) profile for Colorado except that the lower troposphere shows relatively large concentrations, possible because of continental or regional anthropogenic influences; (2) during summer, PAN concentrations throughout the continental troposphere are significantly larger than throughout the marine troposphere; and (3) PAN concentrations over the Pacific in winter are considerably higher than in summer.

The relatively high upper tropospheric PAN concentrations are consistent with PAN's extreme stability in this region, due

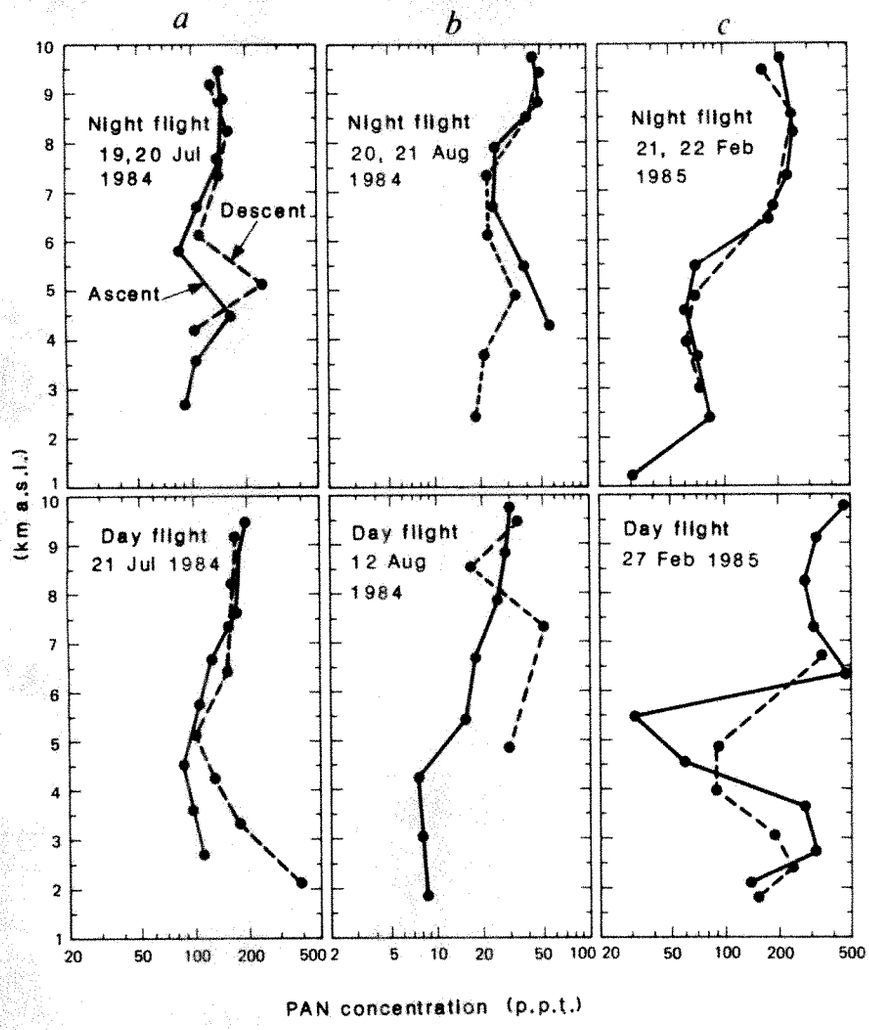

Fig. 2 Ascent (solid) and descent (dashed) vertical profiles of PAN to 10 km above sea level. Night and day profiles are shown for: *a*, the Colorado July 1984 flights; *b*, Pacific August 1984 flights; *c*, Pacific February 1985 flights.

principally to colder temperatures[8,9]. Also, there seems to be a greater free NO_x availability in the upper troposphere[16,18] and this would facilitate PAN formation. The continental PAN abundance of 100–200 p.p.t.v. is almost five times higher than its marine abundance during the same season (summer). This difference is even more significant when one considers that the continental troposphere was observed to be 2–4 K warmer than the marine troposphere. A 4 K increase in temperature can reduce PAN half-life by a factor of two because of the strong temperature dependence of the PAN dissociation rate [$K = 1.95 \times 10^{16} \exp(-13{,}543/T)$ s^{-1}]. A rational explanation must depend on the availability of non-methane hydrocarbons (NMHC) and NO_x precursors. The second feature of interest in Fig. 3*a* is the large increase in PAN concentration off the California coast between August 1984 and February 1985. If these profiles are representative of summer and winter, respectively, PAN levels in winter over the eastern Pacific Ocean could be nearly five times higher than in summer. This wintertime enhancement of PAN abundance is completely out of phase with what is normally encountered in polluted atmospheres, where highest values occur in summer[19]. The temperatures throughout the troposphere during the February 1985 aircraft flights were 8–10 K lower than those in August 1985. This temperature reduction alone could increase PAN stability by a factor of 5–6 and is likely to be an important part of this seasonal behaviour. Figure 3*b* shows measurements for the February 1985 California flights averaged for locations both over the ocean and ~50 km inland from the coastline. In the lower trophosphere, the PAN concentrations over land are consistently higher than over the ocean. In the upper troposphere, the differences are nominal.

In addition to PAN, measurements of PPN (peroxypropionyl nitrate) were also made. PPN was frequently below our detection limit because of its very low abundance. However, during the Colorado flights it was possible to measure PPN along with PAN. Figure 3*c* shows composite profiles for PAN and PPN based on the July 1984 Colorado flights. The shape of the vertical PPN profile is similar to that of PAN, but its abundance is only ~5% of PAN.

Figure 4 shows the composite profile of two surrogate hydrocarbons, propane and ethane, which were measured as part of a C_2–C_5 hydrocarbon analysis conducted during the same flights. Figure 4*a*,*b* shows that although the hydrocarbon abundance over the continental troposphere is greater than that over the marine troposphere, it is so by only a factor of two or less. No reliable NO_x data from these two regions have been published. A comparison of recent NO and NO_2 data from the Pacific troposphere (B. Ridley, unpublished data) and the earlier less reliable NO_x data from this continental tropospheric region[18] suggest that the latter NO_x levels are significantly higher. The concurrent higher abundance of both NO_x and NMHC precursors over the continental troposphere may be responsible for this large PAN gradient. Measurements of PAN along with NO_x and peroxyacetyl radical precursors (such as acetaldehyde and acetone) are required to reconcile adequately the observed PAN distributions. The winter NMHC abundance is also higher (Fig. 4*a*, *c*), probably because of reduced wintertime removal rates (lower OH). Global models which currently do not include NMHC–PAN chemistry point to the possibility of higher winter NO_x for the same reason[5]. However, a great deal of this extra winter NO_x seems to be contained in the form of PAN and is unavailable for photochemical participation[20]. Figure 4*d* shows

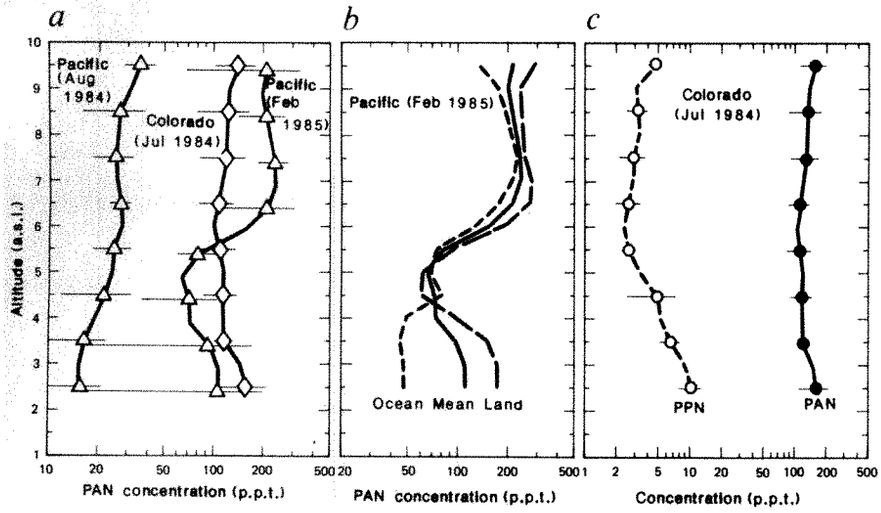

Fig. 3 Composite vertical profiles of PAN and PPN. *a*, Comparison between composite profiles ($\pm 1\sigma$) from Colorado for July 1984, and from the Pacific Ocean off the northern California coast for August 1984 and February 1985. The February profile is shifted slightly in the vertical for clarity. *b*, Mean PAN profiles observed over the ocean and 50 km inland during February 1985. *c*, PPN and PAN profile measured over Colorado.

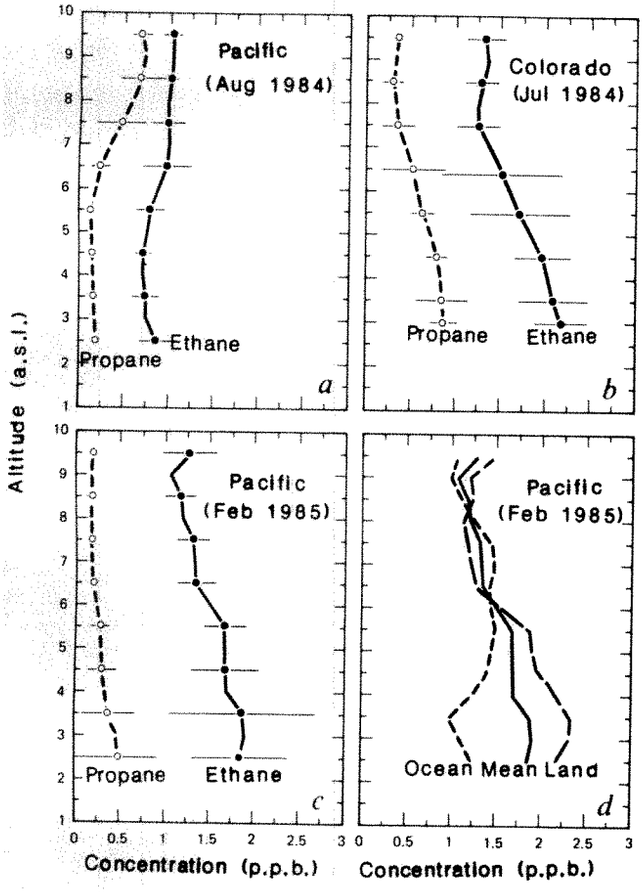

Fig. 4 *a–c*, Composite vertical profiles of ethane and propane. *d*, Ethane concentrations observed over the Pacific Ocean and 50 km inland during the February 1985 flights.

ethane data for the February 1985 California flights averaged for locations over the ocean and over land. These profiles can be compared with those for PAN in Fig. 3*b*. In the lower troposphere, both the ethane and PAN concentrations over land are consistently higher than over the ocean. In the upper troposphere, land/ocean differences are nominal.

Our free tropospheric PAN measurements point to the following important features: (1) PAN concentrations in the Northern Hemisphere are significantly greater and more variable than in the Southern Hemisphere; (2) PAN concentrations show evidence of increase with height; (3) PAN concentrations in winter are higher than in summer; (4) PAN is more abundant in the continental troposphere than in the marine troposphere, at least in the summer; (5) there is a reasonable association between PAN levels and its NMHC precursors; and (6) PAN concentrations in the free troposphere are large and may exceed those of free NO_x. All of these observations are in qualitative agreement with the theory that background NMHC/NO_x precursors can tie up significant quantities of NO_x as PAN, especially in the colder regions of the upper troposphere[8,20]. Preliminary modelling results suggest that photochemical models which do not include NMHC–PAN chemistry may significantly overpredict the availability of free NO_x and HNO_3 in the troposphere, with consequent important implications for tropospheric ozone production[20]. Simultaneous NO_x and carbonyl precursor data are needed to explain the PAN behaviour. Future increases in atmospheric NMHC and NO_x abundance, either due to increased emissions or falling hydroxyl radical concentrations[21], may enhance the role of PAN in the troposphere. Indeed, this may be one of nature's ways of regulating the photochemistry of the troposphere.

This research was funded by NSF grant ATM-8308816 to SRI International. We thank the US Coast Guard for making facilities available aboard the *Polar Star*. The support of the NCAR flight facility personnel is much appreciated.

Geometry of accretion and oceanic thrusting of the Spongtang Ophiolite, Ladakh-Himalaya

Ingrid Reuber

Greco Himalaya-Karakorum, CNRS,
Laboratoire de Geologie Stratigraphique et Structurale,
40, ave du Recteur Pinneau, 86022 Poitiers, France

Ductile mylonitic shear zones, which in ophiolitic peridotites overprint high-temperature ductile flow, have been commonly associated with intra-oceanic thrusting, if situated at the base of the peridotites[1,2]. In fewer cases, such shear zones have been related to the vicinity of transform faults cutting the spreading ridge[3–9]. In the Spongtang nappe, one of the few well preserved Himalayan ophiolite slabs, obducted southward from the Indus–Tsangpo suture zone, two successive mylonitic ductile shear events in the peridotites have been observed. The first can be related to a transform fault, the second to intra-oceanic thrusting, resulting in the superposition of two peridotite sheets[10,11]. Poor development of the crustal sequence also indicates the presence of a transform fault, and/or to a very slowly spreading ridge. Here a three-dimensional geometry of the accretional and successive oceanic environment in the context of the eastern Neo-Tethys is proposed.

The peridotites in the high Zanskar mountains[12–14] have been mapped and studied with increasing accuracy in the past decade[10,11,15–20]. The true ophiolitic units overlie tectonically a very heterogenous series of volcanosedimentary mélange[21]. The complete assemblage has been thrust over sedimentary series of the Zanskar unit (Fig. 1*a*)[15–19].

The peridotites are harzburgitic tectonites affected everywhere by high-temperature ductile flow (S1). Two tectonic units are superposed by a mylonitic shear zone. The upper unit consists of lherzolitic harzburgite, whereas the lower one represents more depleted facies expected originally at a higher level of the sub-oceanic upper mantle.

Few cumulates are present at the east end of the lower unit (Fig. 1*b*, *d*). Ultramafics (wherlites with pyroxenitic layers) predominate over gabbros. Two measurements of the magmatic layering show it to be rather flat (Fig. 1*c*).

Pegmatitic gabbro and pyroxenite dykes of decimetric to metric width in the harzburgites just west of the cumulates represent magma from the cumulate magmatic chamber injected into host rock that is still hot.

Dyke swarms with a NW-SE mean orientation for each of the four observed swarms (Fig. 1*b*, *c*) intrude the cumulates. They are the only sheeted dykes observed in the Spongtang nappe.

Isolated diabase dykes a few metres wide with chilled margins, indicating their intrusion into cold host rock (~400 °C, ref. 22) are common throughout the harzburgites of the lower unit (Fig. 1*c*).

The high-temperature plastic flow which is linked to the ascent of the upper mantle and consequent partial fusion below a spreading centre[21], is ubiquious in the peridotites. The kinked olivine grains indicate activation of the (0*kl*) (100) 'pencil glide' of olivine at 1,000–1,200 °C and relatively low deviatoric stress[23,24]. The orientation of measured S1 foliation planes shows a random distribution.

The dunitic banding, gabbroic schlieren as well as all ultrabasic dykelets are affected by this deformation, whereas the diabases, and the pegmatitic gabbro and pyroxenite dykes are not, showing their intrusion in the upper mantle later than the plastic flow.

The dispersion of the plastic flow structures may be explained by: (1) originally random orientation, indicating poorly-developed, slow or irregular mantle flow and the absence of a well defined spreading axis, at least locally; (2) frequent reorientation of the S1 structures by the following deformations, as observed at a small scale (see refs 10, 11 for details).

A second ductile deformation affected the harzburgitic tectonites in distinct shear zones. Mylonitization starts from the grain boundaries of the kinked olivine and lamellar orthopyroxene (Fig. 2*a*), and finally affects the whole rock, leaving only small relict islands of the high-temperature plastic flow (Fig. 2*b*). This mylonite forms under high deviatoric stress and at 700–1,000 °C, together with the amphibolite facies metamorphism frequently observed in the accompanying metamorphic sole[1]. It is also in accordance with the proposed oceanic environment[25].

In the Spongtang peridotites, the chronology of the two successive episodes of mylonitic shearing can be established according to the dykes they affect: the first (S2) deforms the pegmatitic gabbro dykes, coeval with the final crystallization of the cumulates, but not the isolated diabase dykes. In some cases, shear zones develop more intensely in and around these dykes, rather than in the adjacent harzburgite. This has been explained by shearing immediately following the injection of these dykes[4,5,10,11].

The second shear event also affects isolated diabase dykes within the shear zone, and transforms them to foliated green amphibolite, indicating a temperature of ~500 °C. It follows their intrusion into cold host rock, and thus postdates the first mylonitic shear event S2. Deformation textures in the two fine-grained olivine mylonites are very similar, but some serpentine is involved in the S2′ shear zones (Fig. 2*c*), indicating

Fig. 1 (Opposite and page 594) *a*, Location of the Spongtang Klippe in western Zanskar. *b*, Structural map of the Spongtang ophiolite, showing the four major vertical shear zones S2 (1–4) in the west and upper unit with the observed dominating shear sense, some of the minor shear zones in the lower unit (5–7), frequently associated with gabbro dykes, and the intra-peridotitic thrust. For each shear zone the total of the observed lamellar pyroxenes in the dominant direction and in the opposite one is indicated, following the method of Reuber *et al.*[28]. Z, Zanskar unit; VS, volcanosedimentary sole; hbs, serpentinized harzburgite in the mélange; hb1, harzburgites of the lower unit; dun, dunites; cum, cumulates; gab, gabbro dykes; dyk, diabase dyke swarms; hb2, harzburgites of the upper unit; S2′, intraperidotitic thrust; Φ1, thrust of peridotites over mélange series, Φ2, thrust of the whole Klippe over Zanskar units. *c*, Stereogram of the poles of diabase dykes; big dots, dyke swarms (four measurements); small dots, isolated dykes (23 measurements); squares, deformed isolated diabase dykes (two measurements) within the intra-peridotitic thrust, stars = cumulate layering (two measurements). *d*, Simplified cross-section along *a*–*b*, symbols are as in *a*. *e*, Stereograms of the poles of the mylonitic foliations and lineations associated showing the transform shear S2 in the upper unit (measurements of 60 foliations and 24 lineations), the intra-peridotitic thrust S2′ (measurements of 26 foliations and six lineations), and the transform shear in the lower unit (measurements of 47 foliations and 13 lineations). In the upper unit, the squares represent centrimetric zones of especially intense shear, in the lower unit they represent S2 shear associated to the gabbro dykes. *f*, Stereograms of the poles of the pegmatitic gabbro and pyroxenite dykes (gab, 46 measurements: A, six pematitic pyroxenites; B, eight pegmatitic pyroxenites with a gabbroic centre; C, 16 leuco-gabbro dykes; A to C from the section on the west bank of Photang; D, leuco-gabbro dykes from other places between Photang and Central Spong); of the foliations S1 (measurements of 50 foliation planes in the upper, 55 in the lower unit, 22 lineations in the upper, 26 in the lower unit); compare with the early ultrabasic dykes (dun, dunitic banding, nine measurements in the upper, 16 in the lower unit, opx, orthopyroxene dykelets, eight measurements in the upper, 12 in the lower unit; px, websterite dykelets, two measurements in each unit; gb, gabbroic schlieren, one measurement in the upper, four in the lower unit; large symbols, upper; small symbols, lower unit). Stereograms *c*, *e*, *f* are equal angle projections of the lower hemisphere. Localities may be differentiated as follows: 1, west of Spong; 2, central and upper Spong; 3, Spong/Photang ridge; 4, south-east, Photang.

Fig. 1*a/b/c*

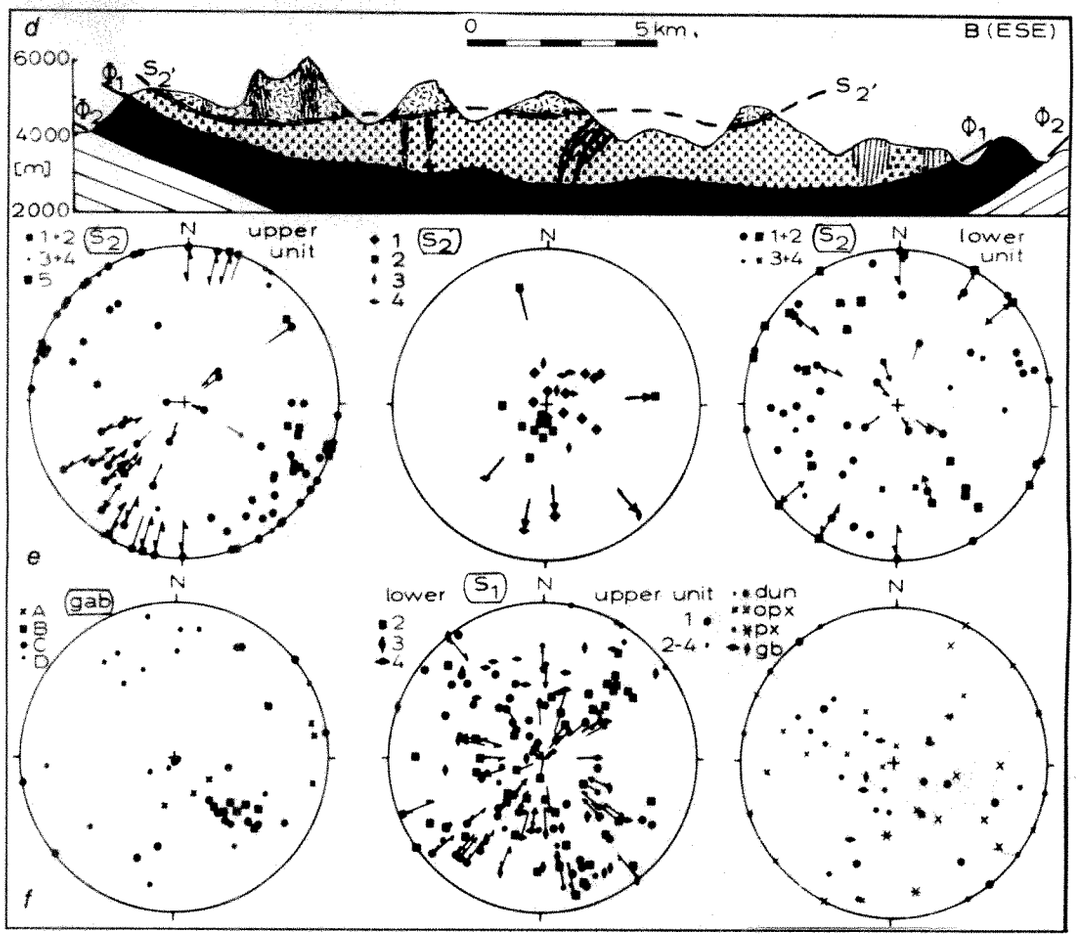

Fig. 1*d/e*

deformation at conditions proximate to the olivine-serpentine transformation, that is again at a temperature around 500 °C. The small temperature increase between dyke injection and shearing, can be produced by shear heating. However, this temperature is at least 200 °C too low for plastic creep in olivine[25], and the deformation involves olivine re-crystallization in a serpentine matrix, rather than olivine creep, a similar result to that obtained by E. Rutter (ref. 26 and personal communication).

The orientation of these shears is different. The first event, constitutes four main vertical shear zones between 50 and 600 m wide, totalling 1.6-km of sheared harzburgite within a 4-km wide zone west of the upper unit. Originally, this zone may have continued farther west beyond the actual outcrop. These main shear zones strike around N 40° E (Fig. 1*b*, *d*), and the associated ductile shear is predominantly sinistral, as shown by lamellar orthopyroxenes, interpreted directly in the field[27,28]. From west to east the sinistral shear is progressively accompanied by pure flattening, as the relative number of orthopyroxenes indicating dextral shear increases (Fig. 1*b*).

In the lower unit, several minor shear zones add up to an additional ~500 m width of sheared harzburgite dispersed over 5 km. Their orientation as well as the observed shear sense become progressively dispersed and less important towards the east (Fig. 1*e*), as expected at the edge of a mega-shear zone.

The second mylonitic shear S2′ is concentrated in one main shear zone of sub-horizontal orientation (Fig. 1*e*), and a width of 20–70 m. This zone, marking the limit between the upper and the lower peridotite units, can be followed throughout the Spongtang Klippe (Fig. 1*e*, *d*). It is most visible in the mountain north of Spong glacier, where a sheared diabase dyke is coated with white magnesite (Fig. 3). The few lineations and the little information available on the shear sense indicate, however, a predominance of south- to southeastward thrusting of the upper unit over the lower one (52: 11 lamellar orthopyroxenes, Fig. 1*e*).

The present data constrain the accretionary geometry of the Spongtang ophiolite. In the absence of palaeomagnetic data, rotation with respect to a vertical axis cannot be traced, and the data are treated as if no such rotation occurred during or after obduction. A small rotation with respect to an horizontal axis will improve the internal kinematic coherence of the model proposed as follows.

The dykes of the dyke complex are, in general, considered to be parallel to the ridge orientation[22]. In the absence of a true dyke complex, the mean orientation of the dyke swarms indicates a NW–SE orientation for a poorly developed ridge (N 140° E).

The S2 vertical shear zones may be linked to a transform fault zone continuing farther west beyond the actual outcrop. The transform fault should be parallel with the major shear zones, thus trending NE–SW (N 40° E).

The flat S2′ shear can be related to intra-oceanic thrusting in a NNW–SSE direction. Thus, for considerations of accretionary geometry, the upper unit can be restored towards the NNW of the lower one.

The proposed ridge and transform orientations are nearly perpendicular, and the predominantly sinistral shear of the transform zone results in a dextral offset of the ridge segments.

This idea is consistent with the poorly-developed cumulates in the vicinity of the transform fault, which limits the cumulate magmatic chamber in the west. This observation does not exclude a normal crustal section farther east beyond the Spongtang Klippe. Predominantly ultrabasic cumulates at the edge of

All are photomicrographs, cross-polarized light.

Fig. 3 At the Spong glacier the intra-peridotitic thrust is underlined by the white magnesite coating of a deformed diabase dyke.

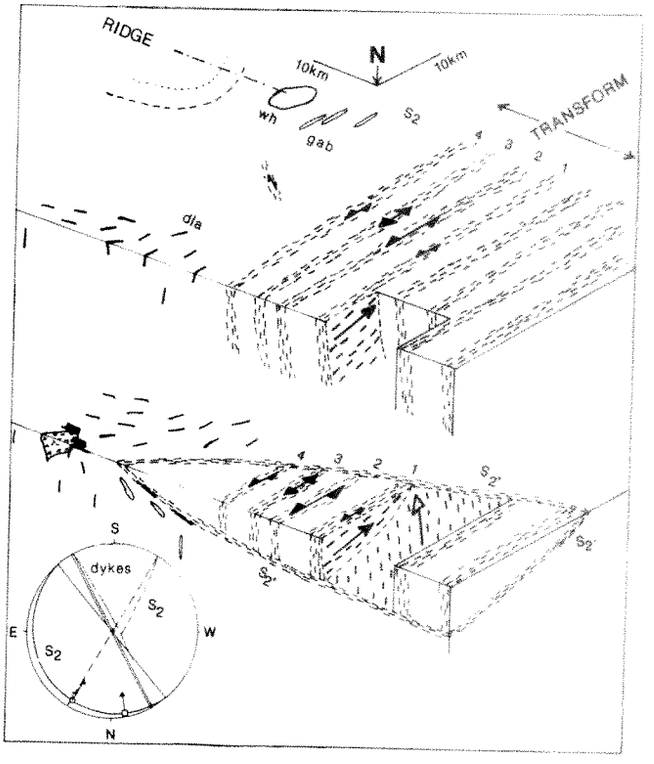

Fig. 4 *a*, Sketch of the oceanic accretion geometry before intra-oceanic thrusting, looking southward. Disposition of the ductile shear zones (1–4) at an approximately median level of the cumulate magmatic chamber (in white) possibly existing farther east of the transform fault. The observed cumulates rather originate in a small magmatic chamber (wh), nearer to the transform zone, where the pegmatitic dykes (gab) are also found, the intrusion of the isolated diabase dykes (dia) is drawn off-axis (not to scale). The true position of L2 is shown in the inset. *b*, Intra-oceanic southward thrusting of the transform zone over the block east of the transform, the inset shows position of L2 and L2′ lineations. *c*, Stereogram showing the circular trace of the mean position of the main planar structures and associated lineations after rotation to their proposed original position as explained in the text.

ransform fault have previously been described in a very similar t-up for the Antalyan ophiolite (Turkey[4,5]). The high content primary clinopyroxene in the harzburgites of the western part ıd the upper unit indicates again little partial fusion as would expected in a compressive transform zone[29].

A rotation of 20°, less than the dispersion of the measurements r S2′ foliation planes, with the azimuth of the mean S2′ plane the axis, is proposed to restore a thrust movement on the S2′ liation planes (Fig. 4*c*). At the same time, the normal com-ıent related to the transform shear S2 becomes inverse (Figs 1*e*, 4*c*), which is in better accordance with the compressive aspect of this transform zone.

This is the first ophiolitic example of intra-oceanic thrusting resulting in the superposition of two peridotite units. The absence of amphibolites of volcanosedimentary origin underly-

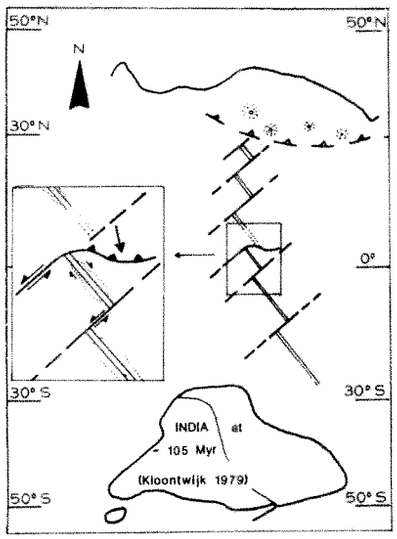

Fig. 5 Sketch of the possible geometric relations between the accretionary ridge, the transform fault and the intra-oceanic thrusting in the context of the beginning northward move of the Indian plate. Its northern boundary is stable at 30° south from the Permian to Middle Cretaceous[33], a time span which should include the phenomena described in the text.

ing the thrusted peridotites[10,11,20,21], can be explained by: the absence of volcanism in the transform zone; the scarcity of volcanosedimentary cover due to thrusting shortly after accretion; Spongtang representing a deep-seated part of the section.

This model, which is concerned with details of the accretionary geometry, does not decide the global geotectonic environment. However, there is a strong preference for the creation of Spongtang ophiolite in the open ocean, because: transform faults and intra-oceanic thrusts are not known in back arc basins; preliminary geochemical results show mid-ocean ridge basalt characteristics for more than half of the studied samples of volcanics of the sole of Spongtang as well as from the Dras area[30,31].

This does not exclude the possibility that such oceanic crust travelled into the arc environment through the combined effects of spreading and subduction, and eventually became overprinted by arc intrusives, volcanics, and associated sediments[32].

Applying this model to the eastern Neo-Tethys, shows us the possibility of maintaining extension along NW-SE oriented ridge segments, associated with minor dextral shear, even under the beginning of NNW-SSE compression. The latter is concordant with sinistral shear on the NE-SW oriented transform faults, possibly even beyond their true transform segment, and may initiate the first intra-oceanic thrusts (Fig. 5).

I thank M. Colchen, E. Gilbert and A. Nicolas for discussions and critical comments, as well as P. Nehlig, E. Reuber, G. Reibel, D. Perret, M. Dabas for company in the field. Financial support from the Greco Himalaya-Karakorum, CNRS is gratefully acknowledged.

A magnetotelluric sounding across Vancouver Island detects the subducting Juan de Fuca plate

R. D. Kurtz*, J. M. DeLaurier† & J. C. Gupta*

Magnetotelluric[1] (MT) and geomagnetic[2] depth-sounding measurements have been made at 18 sites (7 with remote reference[3]) across Vancouver Island (Fig. 1), beneath which the Juan de Fuca plate is underthrusting[4,5]. Vancouver Island is part of the old accretionary Wrangellia terrane[6] and is located in the central portion of a 350-km forearc region that extends from the sediment-filled trench[7] to the Garibaldi volcanic belt[8]. Gravity[9] and seismic refraction studies[10] suggest that the descending plate has a shallow northeasterly dip of 8°–16° with perhaps higher dips beneath northeastern Vancouver Island. A high-resolution seismic reflection survey[11] along lines 1 and 3 (Fig. 1) located a zone of strong acoustic reflections (the E-horizon[11]) near the top of the subducting Juan de Fuca plate at depths of 23–34 km. Our model of the broad-band MT data defines a sloping, highly conducting zone also near the top of the subducting plate at the same depths as the seismic E-horizon. The high electrical conductivity in this zone (the E-conductor) is the result of saline fluid within the pore spaces of sedimentary and mafic materials of the upper oceanic crust that have been subducted to those depths beneath Vancouver Island. These are the first data which clearly define a dipping conductive layer associated with the boundary region between converging plates; they have significant implications for thrust earthquakes and metamorphic reactions that occur in subduction zones.

The MT data were processed at each field site in real time, to evaluate data quality and, where possible, to maintain standard deviations of $<5\%$ for apparent resistivity and $<\pm1°$ for impedance phase. The upper panels of Fig. 2 show the suite of apparent resistivity curves spanning six decades from 384 Hz to 1,820 s determined in the major and minor axes of anisotropy and grouped for the electric field measured approximately perpendicular (B-polarization mode) or parallel (E-polarization mode) to the strike of the continental margin. The curves in each group are similar in shape and display a decrease in amplitude at periods longer than 1 s, an indication of increasing conductivity at depth. The apparent resistivities for these two modes diverge at the longer periods (>30 s), which is charac-

teristic of data from stations on the resistive side (the crust beneath Vancouver Island) of a boundary adjacent to a more conductive structure (the seawater and oceanic crust). The vertical displacements of up to two decades along the ordinate are caused by near-surface resistive[12] or conductive[12,13] anomalies. The average phase curves, however, have small standard deviations at periods >10 s, indicating a generally laterally uniform resistivity distribution in lower crust beneath southwestern Vancouver Island.

At site 12, the two orthogonal resistivity curves (highlighted in Fig. 2) and phases (not shown) are nearly isotropic for periods <10 s while at sites 10 and 14 the isotropy is moderate for periods <1 s. We have used an inversion procedure[14,15] on the data for these three sites to obtain one-dimensional layered models (Fig. 3). The sedimentary materials covering the valley beneath site 14 are more conductive than the resistive bed rock with little overburden beneath sites 10 and 12. Below depths of several kilometres the crust is moderately resistive, in the range 5,000–15,000 Ωm. All models are characterized by a low-resistivity layer (the E-conductor) at depths of 23–28 km which agree (<10%) with those to the seismic E-horizon (bold bars in Fig. 3). The long period divergence of the data between the two modes precludes a precise determination of the thickness and resistivity of the E-conductor with one-dimensional models. A two-dimensional interpretation is required to explain both polarization modes with the same model.

The two-dimensional model (Fig. 4) was constructed using the known conductivity and thickness of the sea water in the Pacific Ocean and in the Strait of Georgia. The parameters of the accretionary wedge beneath the continental margin west of Vancouver Island are consistent with the two-dimensional geomagnetic depth-sounding model of DeLaurier *et al.*[16]. Their model, as well as the seismic interpretation of Spence *et al.*[10], suggest that the oceanic lithosphere/asthenosphere boundary is near 25 km depth and dips to 55 km beneath the coast of Vancouver Island. The depth to the E-conductor is determined by the one-dimensional inversion models (Fig. 3) and by the seismic E-reflector[11], except for that beneath the very northeastern part of the island where there is an apparent absence of deep seismic reflections. The E-conductor increases in dip from about 10° beneath the three MT sites to about 35° beneath the Strait of Georgia, consistent with gravity models[9] and the down-dip of the tension axis from earthquake focal mechanisms[17]. A conductive region[18,19] is required in the lower crust beneath mainland British Columbia to model the long-period geomagnetic transfer functions and the MT data, although its depth and resistivity are not well determined by a survey limited to Vancouver Island. The thickness and resistivity of the E-conductor were varied until good agreement (<5%) was attained between the model response[20] and measured data at site 12. Since no attempt was made to include the near-surface structures apparent in the models of Fig. 3, a good fit to only the long period (>10 s) phases at sites 10 and 14 was obtained. At all sites, however, the geomagnetic transfer functions were predicted for periods >0.1 s.

The E-conductor near the top of the descending Juan de Fuca plate is 6 km thick with a 30-Ωm resistivity, and extends up-dip to merge with oceanic layers 1, 2 and 3. We have not investigated the response of a very thin conductor, say 1 km, since this necessitates a fine mesh in the model, resulting in unreasonably large matrices to invert. However, even a thin E-conductor must have a conductance (thickness/resistivity = 200 S) close to that in the model. Although our data do not resolve detail in the oceanic crust west of the coast, the conductance of the E-conductor is compatible with those obtained in oceanic layers 1 and 2 from seafloor controlled-source electrical sounding experiments[21,22] and deep-sea drilling resistivity logs[23]. The seismic E-reflection zone is 3–5 km thick, and Green *et al.*[11] suggest several possible sources for this, including layered sediments, intercalated volcanics and sediments, layered igneous basement rocks or tectonic structures induced by underthrusting.

The two-dimensional model (Fig. 4) simulates the subduction of the Juan de Fuca plate beneath the forearc region. Low resistivities in the lower crust or upper mantle have frequently been reported and are attributed to fluids filling the pore spaces[24] or to partial melting[25]. The heat flow pattern is typical of forearc regions[26]; heat flow decays from moderate values on the west coast of Vancouver Island to a minimum east of the Straight of Georgia, increasing to high values over the Garibaldi volcanic belt (T. Lewis, personal communication). Based on heat flow measurements, the temperature beneath Vancouver Island increases to 400 ± 100 °C at the top of the E-conductor; at greater depths, within the young subducting plate, the downward displacement of isotherms suggests that this estimate is a maximum. A temperature of 500 °C is more than a factor of 2 less than is required to give a resisistivity of 30 Ωm for dry granites or gabbros[24]. Furthermore, it is not sufficient to induce partial melting in wet basalts or granites[27]. Consequently, the materials within the E-conductor beneath our sites must be porous and saturated with saline fluid.

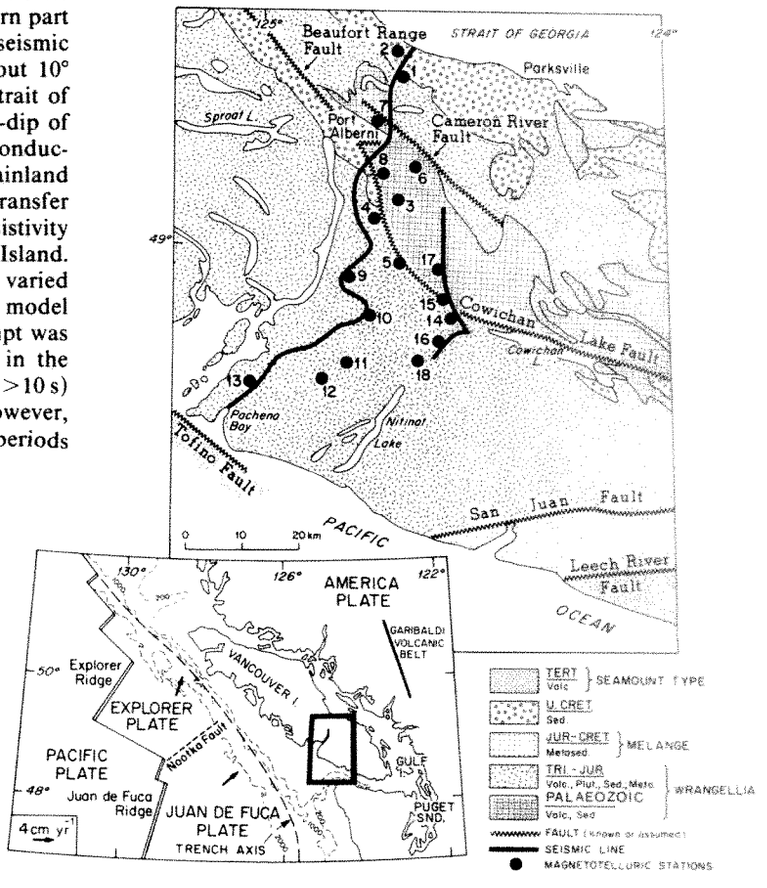

Fig. 1 Simplified geology (adapted from ref. 38) of southwestern Vancouver Island and the locations of the magnetotelluric (MT) sites near seismic reflection lines 1 (west) and 3 (east). The inset shows the location of our survey area with respect to the four plates and the pertinent convergence arrows. Bathymetry is in metres.

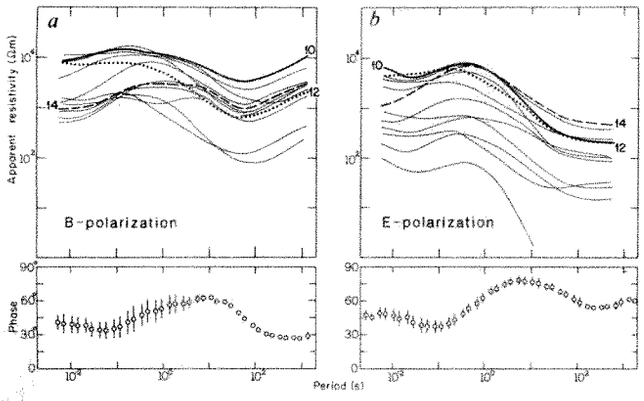

Fig. 2 The apparent resistivity curves for the southern MT sites (including remote reference sites if available). A discussion of the more complex data from the remaining sites will be presented elsewhere. The highlighted curves are for stations 10, 12 and 14 discussed in the text. Lower panels show the averaged phases associated with all the apparent resistivity curves in the corresponding upper panel. Error bars are two standard deviations in length. *a*, B-polarization mode for the electrical field perpendicular to the coast. *b*, E-polarization mode for the electric field parallel to the coast.

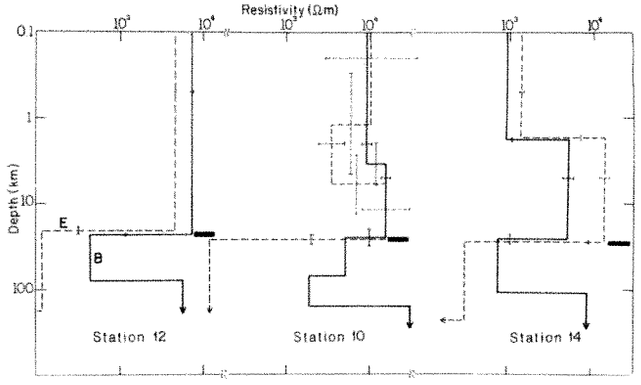

Fig. 3 One-dimensional models obtained by inversion of the apparent resistivity and phase for the E- and B-polarization data from stations 10, 12 and 14. The bold horizontal bars indicate the depths to the top of the seismic reflection zone that originates from the boundary region between the descending Juan de Fuca plate and overriding North American plate. The standard errors are determined from an eigensolution analysis[39].

A simple form of Archie's law expresses the ratio of the fluid resistivity to the bulk resistivity as equal to the square of the porosity[23,28]. If the fluid filling the pore space within the E-conductor has the salinity of sea water (3 wt% NaCl), and its resistivity at 375 °C is 0.04 Ωm (ref. 29), then the bulk resistivity of 30 Ωm leads to a porosity of 3.6%. Salinities higher than that of sea water could be expected since the solubilities of mineral species increase with temperature[30]. Therefore, the porosity can be lower; for example, a 20-wt% NaCl solution at 375 °C has a resistivity of 0.008 Ωm and, with the E-conductor resistivity, the porosity is 1.6%. Pressure effects are negligible, as the load pressure of ~850 MPa (assuming a crust density[9] of 2,920 kg m^{-3}) is more than sufficient to maintain the liquid phase[31] at the expected temperature at the top of the E-conductor. These porosities, an order of magnitude larger than those measured[32] in the laboratory for mafic crystalline rocks, could be supported with fluid pressures equal to lithostatic. This requires impermeable boundaries above or within the E-conductor. If the fluid pressures are hydrostatic, then the rock matrix is supporting the differential pressure. As the pressure and temperature at the top of the E-conductor suggest that metamorphic reactions within the blueschist to greenschist fields[33] are occurring, dehydration[26] may enhance porosity[30] and provide a source for the fluid. The trapping of fluid within the sedimentary and mafic materials of the descending plate is another complementary source.

Our MT depth-sounding data see, beneath Vancouver Island, a highly conducting zone near the top of the subducting Juan de Fuca plate which, at the expected temperatures, suggests that a conductive fluid fills the pore space of the materials within the E-conductor. This result has important geophysical implications for active or exhumed subduction complexes. First, the low level of historic seismic activity compared with the tectonic convergence rate of the Juan de Fuca and American plates[34] suggests aseismic creep on a zone of lubrication, perhaps the result of high pore pressure, although it is possible that strain accumulation occurred over the period of the seismicity data[35]. Second, the variation of the acoustic impedance across fluid-

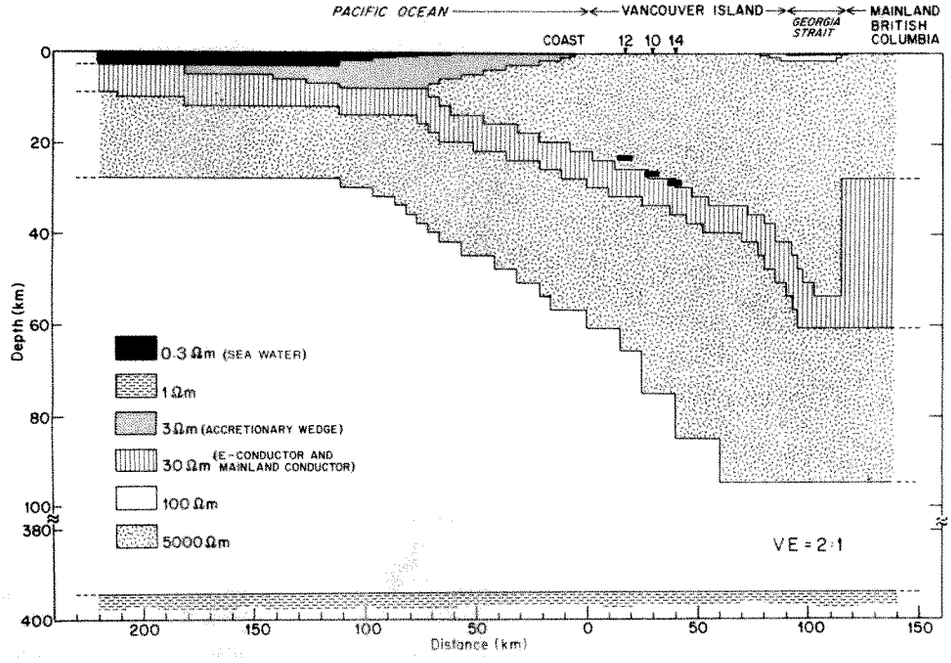

Fig. 4 The two-dimensional electrical resistivity model representing the subduction of the Juan de Fuca plate. The E-conductor (30 Ωm) is near the top of the plate. The bold horizontal bars beneath sites 10, 12 and 14 on Vancouver Island indicate the depths to the seismic E-horizon. The global decrease in resistivity[40] is represented by a 1-Ωm half-space below 390 km.

saturated porous materials[36] could explain the band of multiple, enhanced seismic reflections observed beneath the E-horizon[11]. Third, the conducting zone beneath the western portion of the forearc region suggests a depth of origin for the widespread occurrences of high-pressure/low-temperature metamorphic rocks such as glaucophone schists[37]. All these possibilities seem to necessitate the presence of fluids with pressures near or equal to lithostatic.

We thank Alan Green for reviews and discussions, and R. D. Hyndman, L. K. Law, J. Sweeney and M. J. Berry for reviews and constructive comments. Alan Jones provided analysis programs. This is Lithoprobe paper 14; Geological Survey of Canada contribution no. 11186.

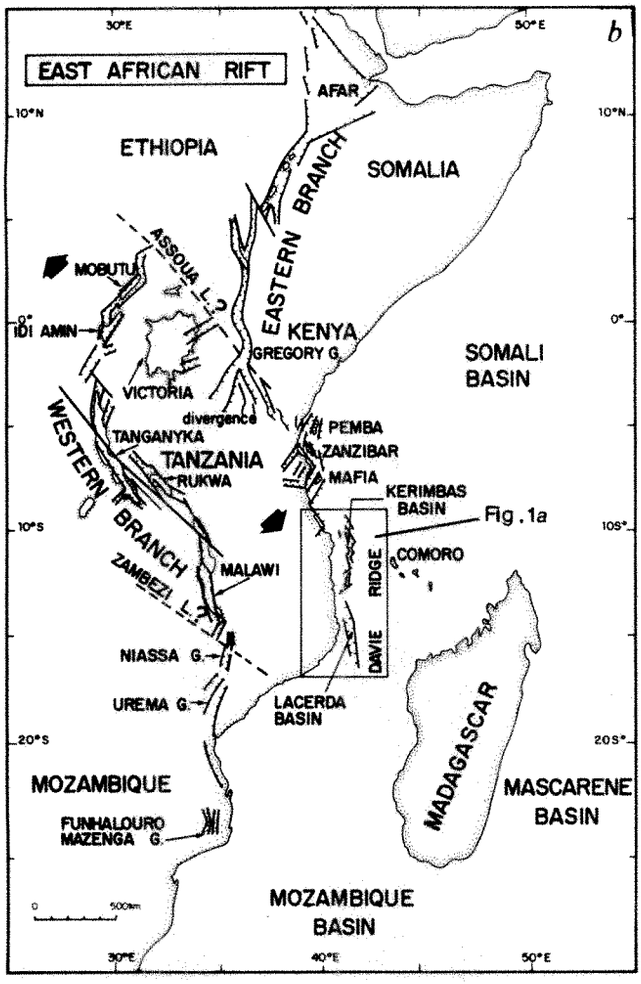
Seaward extension of the East African Rift

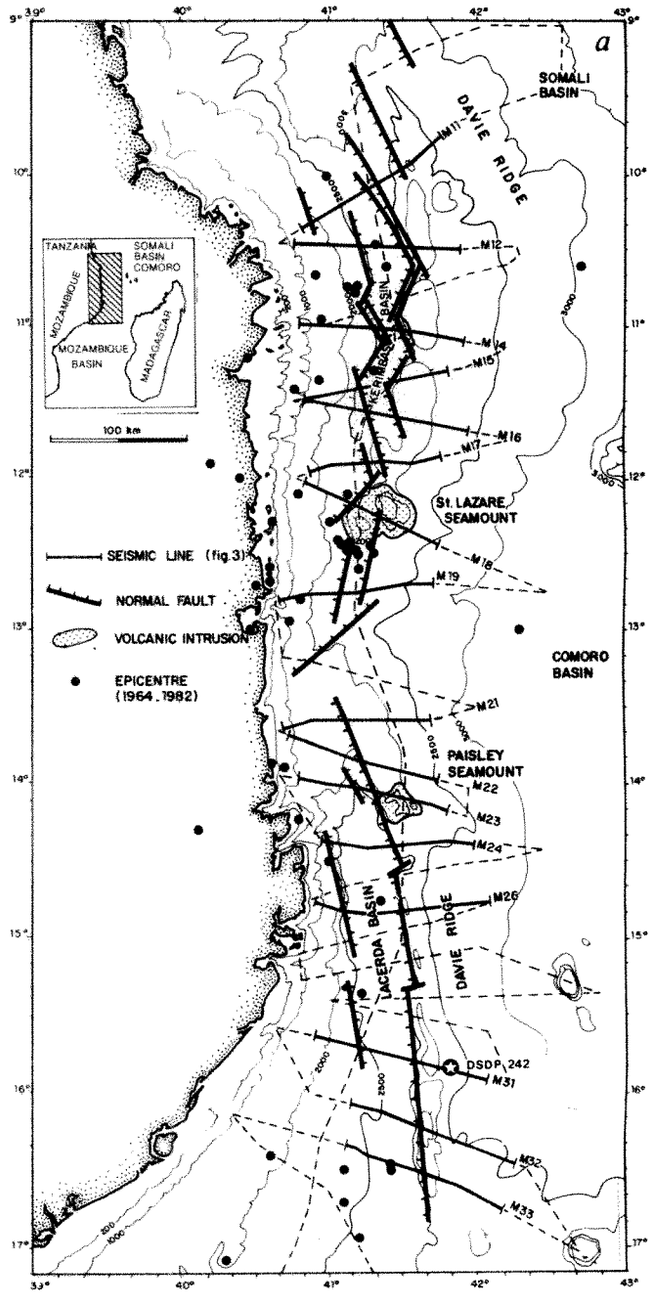
D. Mougenot*, M. Recq†, P. Virlogeux* & C. Lepvrier†

* Laboratoire de Géodynamique Sous-Marine, CEROV, BP.48, 06230 - Villefranche-sur-Mer, France
† Département de Géologie Dynamique et Département de Géotectonique, Université Pierre et Marie Curie, 4, Place Jussieu, 75252 Paris Cedex 05, France

The continental margin of northern Mozambique is edged by a north–south trending alignment of submarine peaks forming the Davie Ridge (Fig. 1*a*). From earlier studies[1–5], the ridge has been interpreted as a remnant transform fault that controlled the late Jurassic/early Cretaceous drift of Madagascar and the opening of the Somali Basin[6–8]. During MD40–MACAMO cruise (June 1984), 7,500 km of water gun seismic reflexion lines have been implemented throughout the region where two flat-bottomed troughs, the north–south trending Kerimbas and Lacerda deep grabens, interrupt the continental slope alongside the ridge. These grabens cut into Tertiary sediments correspond westward, to a Miocene tilting or a recent normal fault; and eastward, to an old discontinuity several times reactivated and located above an abrupt uplift of the Moho. The two grabens are separated from each other by a rigid region of thickened crust, affected by intense seismicity and supporting volcanoes. We report here that the eastern branch of the East African Rift joins the submerged grabens across the Tanzanian continental shelf (Fig. 1*b*).



From 9° S to 17° S, the Mozambique margin is split into three domains (Fig. 1*a*). (1) North of the Saint-Lazare Seamount, the continental slope is interrupted downwards by a 250-km long trough known as the Kerimbas Basin[9]. Its 20–30-km wide flat-bottom dips slightly northward (2,400–2,800 m deep). Its asymmetrical edges are cut into four segments directed either north-northwest or north-northeast. The western boundary runs alongside the foot of the uppermost slope of the margin, which is cut by gullies. To the east, the basin is bounded by the western 1,000 m and more high escarpment of the Davie Ridge, sometimes formed by steps. The top of the wide (120 km) Davie Ridge is 1,700 m below sea level and gently dips towards the Somali Basin. (2) The rugged relief is interrupted southward by two circular features: the Saint-Lazare (12° S) and Paisley (14° S) seamounts, between which the slope gently deepens towards the Comoro Basin. (3) South of the Paisley Seamount, the abrupt uppermost continental slope is cut by several canyons that terminate near the shore. The Davie Ridge is bounded by a flat-bottomed 400-km elongated depression, the 2,700-m deep Lacerda Basin. To the south both edges of the trough become more asymmetrical, as the continental slope widens and the Davie Ridge narrows and rises. Thus, the Davie Ridge culminating at 300 m deep below sea level, is rising as much as 2,300 m above the Lacerda Basin.



The relief pattern on the continental slope off the northern Moçambique is strongly related to neotectonics. Reflection seismic lines reveal that the steep elevation of the Davie Ridge with respect to both basins, appears to be a scarp produced by a normal fault. East of the Kerimbas Basin, several newly formed staggered faults (Fig. 3) cut the thick well stratified sedimentary layers (2.5 s two-way travel time). The fault scarps decrease at either end of the basin (Fig. 3*a*). East of the Lacerda Basin a nearly linear normal fault edges an horst consisting of probably continental basement that forms the diffracting substratum of the ridge. This horst is part of a north–south trending alignment of three parallel ridges underlain by Tertiary cover[9]. This horst has been remobilized as shown by unconformities (Fig. 3*b*) within the Tertiary cover east of the ridge and by upturning at the fault contact in most of Neogene layers infilling the Lacerda basin.

Within the trough, most of the latest depositions are discordant and onlap the fractured, flexured and even folded older formations (Fig. 3). These deformations are related to probable strike-slip subvertical faults. Both normal and strike-slip fractures may have originated by several breaking tectonic phases and by an oblique opening of these troughs. To the west, the basins are edged by a flexure or a normal fault, at the foot of upper slope of the margin. These troughs are thus interpreted as grabens in the central region and as half-grabens at either end.

Volcanic intrusions occur on both sides and at either end of these grabens. A dyke and a sill (Fig. 3) can be observed where the Kerimbas graben is at its narrowest. Here, an alkaline basalt bearing peridotites nodules sandwiched within middle Miocene (N14) to present (N23) haemipelagic sediments has been dredged (DR03). The size and shape of Saint-Lazare and Paisley seamounts, whose intrusive appearance on seismic lines is associated to a sharp magnetic anomaly, denote their igneous origin. Both features are interpreted as volcanoes contemporaneous with the evolution of the grabens.

Fig. 1 *a*, The northern Mozambique continental margin: the continental slope is discontinued downward by troughs (the Kerimbas and Lacerda basins), except between the Paisley and Saint-Lazare seamounts interpreted as volcanic intrusive bodies. These basins are bounded by normal faults running alongside the foot of the upper continental slope and the western scarp of the Davie Ridge. Most of the epicentres are located west of the ridge beneath grabens, south of the Saint-Lazare Seamount and near the shoreline of Mozambique. Bathymetry in metres drawn by Jean René Vanney. Dashed lines, ship tracks. *b*, The East African Rift: graben (G) and transform faults or lineaments (L) after ref. 14. The eastern branch of the East African Rift is not interrupted with the north Tanzanian divergence but extends southeastward across the Tanzanian continental shelf[20] and the continental slope off Mozambique. With such mapping, both branches of the rift are sigmoïd shaped and of the same length. Arrows, direction of extension derived from microtectonic analysis[14,24] and seismicity[11,25].

The age of Tertiary bedding within the continental margin has been inferred from correlations with DSDP 242 drilling[5] and from core samples. The tilting running alongside the upper-slope and the Davie Ridge, the variation in thickness of sedimentary layer at either side of the ridge fault scarp, and the graben itself are likely to have originated at middle Miocene time. The undisturbed horizontal stratification within the trough, and on the other hand the undulation of seismically transparent layers of the continental rise show that the depression was already differentiated at Plio-Quaternary times. The Lacerda graben is originated from an older structure but it is also of middle Miocene age, as shown by flexures and onlaps observed under the continental rise and under the slope (Fig. 2*b*). But the upturning of Miocene strata by faulting denotes a later deformation occurring at Plio-Quaternary time. Faults and flexures located South of the Saint-Lazare Seamount (Fig. 2) are related to this period of activity, however, their throw is small and have a limited influence on the morphology.

Neogene deformations of the northern Mozambique margin can be explained by the tilting of two domains located at either side of a major discontinuity below the western scarp of the Davie Ridge. Samples from a condensed and decarbonated series of late Cretaceous age have been cored on the ridge, indicating an uplift up to 1,500 m since the Maastrichtian[10]. On the continental shelf, emergent marginal reefs and canyon heads also indicate a period of uplift. So the deepening of troughs and the tilting of the upper slope may explain the instability of this zone where canyons and slumps occur (Fig. 3).

From International Seismological Centre data, we plotted epicentres of earthquakes related to this region and occurring between 1964 and 1982 (Fig. 1*a*). Most of the earthquakes are shallow and of magnitude <5. As already quoted for the East

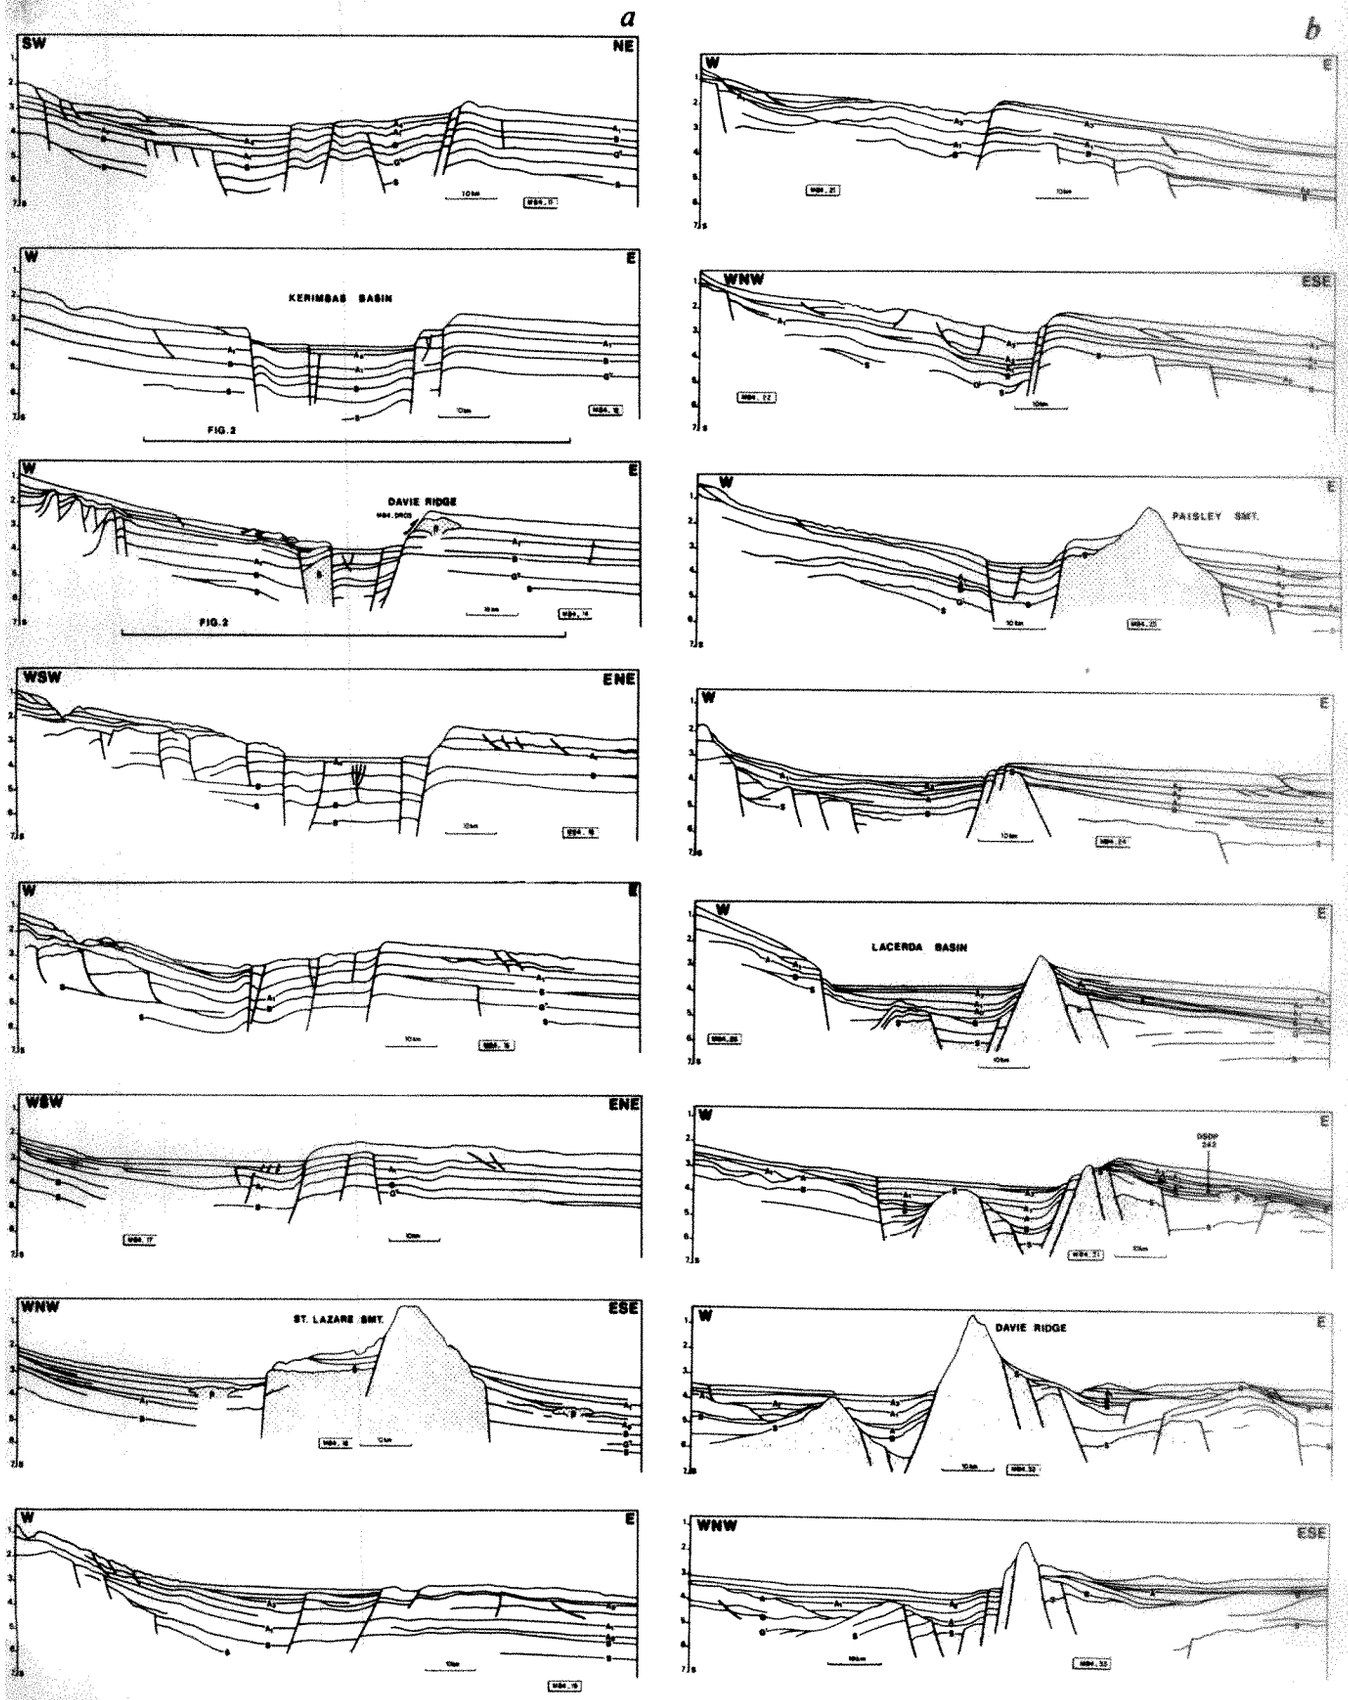


Fig. 2 Two-way travel-time seismic sections (as located on Fig. 1*a*) through the Kerimbas (*a*) and Lacerda (*b*) Basins. The structure formed by symmetrical faults is only shown from the median region of either basin. Only normal faults alongside the Davie Ridge extend towards the ends of the troughs. To the north, the ridge is formed by a thick well bedded sedimentary series; to the south by a horst of diffracting pre-tertiary basement later reactivated. Dotted lines, volcanic intrusive bodies; dashed lines, continental basement; S, acoustic basement; B, Cretaceous/Tertiary boundary; A, Eocene/Oligocene boundary; A_0, Oligocene/Miocene boundary; A_{1-2}, middle Miocene; A_3, late Miocene; A_4, Plio-Quaternary.

Rid) exhibit the asymmetry of the troughs and associated features. β, Volcanic intrusion (dyke and sill); di., diapirism; fl., flexure; fo., fold; on.: onlap; sl. slumping; st. f., strike-slipe fault; un., unconformity; M, bottom multiple. Scale bar, 10 km.

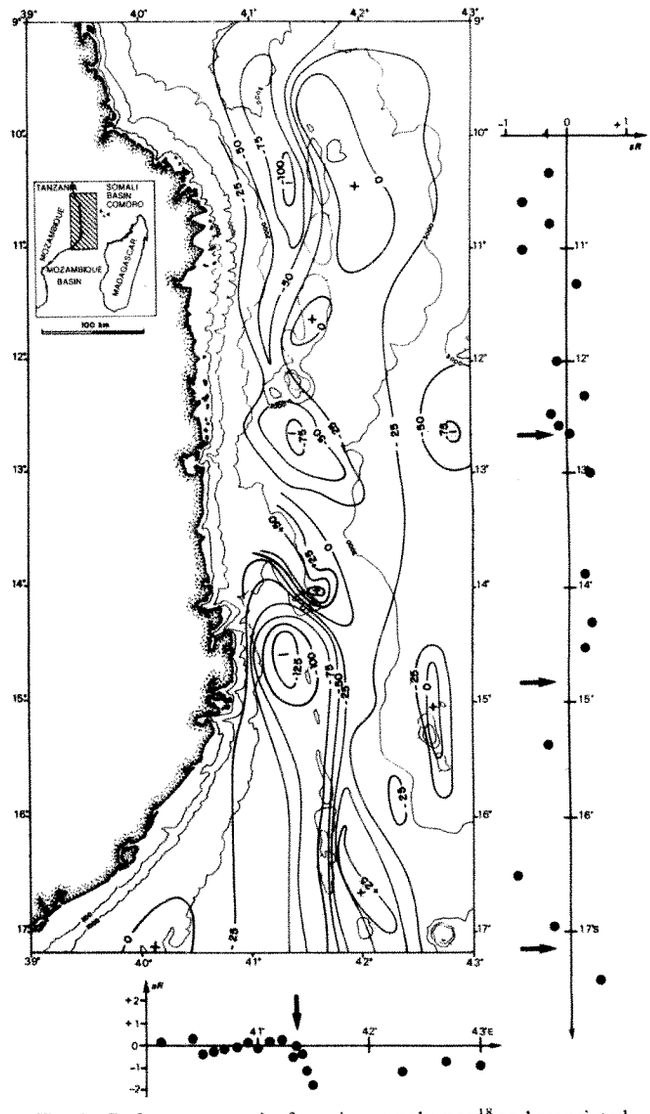

Fig. 4 Bathymetry, gravity free-air anomaly map[18] and associated P-wave residual anomalies[12] alongside the continental margin off northern Mozambique. Across the ridge, the steep gradient between negative and positive gravity anomalies may be correlated with a dramatic advance of P-wave travel-times interpreted on a first step, as a sharp landward thickening of the continental crust, that is roughly superimposed over the westward fault scarp of the ridge. North-west-south-east trending discontinuities are observed between the Paisley and Saint Lazare seamounts, where both earthquake epicentres and volcanic intrusive bodies are clustered. This domain of thickened crust may be one wherein the rift is propagating. *sR* in seconds denote residuals corrected for the structure below the seismological observatories located in Africa and Madagascar.

African Rift[11–14], epicentres are not only located along the grabens, but also extend far away, from the grabens to the shore. Epicentres are clustered south of the Saint-Lazare Seamount where the grabens disappear. Seismicity is poorly active east of the western fault scarp of the Davie Ridge which forms a major discontinuity.

P-wave travel-time anomalies have been computed from residuals (O/C) published in ISC Bulletins (O, observed travel time; C, computed travel time from an Earth model). Having made corrections for the influence of the structure below the seismological observatories located in southern Africa and in Madagascar[15], previous studies[12,13] showed that the variation of residuals with earthquake location suggests at first glance mainly a change in the structure below the epicentre, such as a Moho-deepening of 2 km for 0.15 s residuals. Along the Davie Ridge, residuals are slightly negative (Fig. 4), except between the Saint-Lazare and Paisley seamounts, where grabens are younger or absent. We presume that residuals emphasize the presence of a thickened continental crust below this active zone that may impede the opening of the rift.

From the continent throughout the ridge, a sharp drop of residuals (−1.7 s at 41°30′ E) denotes initially a dramatic eastward shallowing of the Moho from 35 km below Mozambique to 12 km deep below the Comoro Basin. However, the variation of residuals with longitude does not preclude lateral inhomogeneities within the crust and the upper mantle. In the absence of deep refraction lines, some of the results quoted above are not well constrained. This discontinuity is probably inherited from a fossil transform fault[16]. Sandstone and schist samples dredged from the ridge[4] and the lack of significant magnetic anomaly preclude an ocean/continent boundary along the western flank of the ridge and support earlier studies[10,12,17] emphasizing that the Davie Ridge belongs to the African domain with the presence of a sharp intra-continental discontinuity governing the graben pattern and the local seismicity.

The correlation between free-air anomalies[18] and bathymetry is good (Fig. 4). However, short-wavelength anomalies and high gradients may be modelled only by either upright elongated bodies culminating at shallow depth within the crust or by a dramatic change into the crustal structure. Free-air gravity values are negative over Kerimbas and Lacerda grabens, whereas they are positive over the Davie Ridge. Despite a slight eastwards offset, these gravity gradient may be associated with P-wave

travel-time anomalies and support the north–south trending of the crustal discontinuity along the grabens. Although the Kerimbas Basin is newly created, this feature and the Lacerda Basin seem to be generated from an older structure.

Between the Saint-Lazare and Paisley seamounts, north-west–south-east-trending positive and negative gravity anomalies outline transverse structures parallel to the main transform lineaments of the East African Rift[14]. These discontinuities not seen in the shallow fracture pattern, mark the boundaries of the thickened crust zone wherein volcanism activity and most of the earthquakes occur. This area could be a good example of a locked zone[19] to propagating rifts during continental breakup.

Earlier studies[14] quoted that the eastern branch of the East African Rift terminates at the North Tanzanian divergence (Fig. 1*b*). But seismicity[11] suggests the existence of a tensile zone extending the rift, on land in a north-west–south-east direction and seaward from the Tanzanian coastline (7° S) to the northern Mozambique continental slope (17° S). This active zone was not thought to be related to the continuation of troughs observed along the eastern branch of the African Rift[14]. Recently, Neogene basins have been revealed from seismic surveys on the continental shelf off Tanzania[20] and Kenya[21] substantiating the interpretation[22] that Pemba, Zanzibar and Mafia islands (Fig. 1*b*) are remnant horsts, reactivated in Miocene times and edged by subsident Neogene synclines. So, Tanzanian grabens would form a link between the eastern branch of the East African Rift and troughs alongside the northern Mozambique continental margin.

The western branch of the East African Rift extends also southwards as far as Cretaceous southern Mozambique grabens[23], reactivated recently and outlined by a topographic depression. So shaped, both branches of the East African Rift are sigmoïd like and of comparable extent. The distribution of the seismicity[11] and the rift pattern as depicted by this study, support a deformation picture affecting the whole of eastern Africa, rather than well defined boundaries, early stage of an oceanic opening.

MD40-MACAMO cruise would not have reached completion without the logistics and financial support of Terres Australes and Antarctiques Françaises. The seismic sources were provided by IFREMER. We thank the master, officers, the crew of the N/O *Marion Dufresne* and the scientific party, also Carol Williams and Gilbert Boillot for comments and Michel Moullade and Jacques Hernandez for sample study. Additional fundings come from ATP GGO (no. 106) and ATP Transferts (no. 1533) grants. Contribution no. 353 from the Groupe d'Etude de la Marge Continentale (UA718-CNRS).

Eutectoid phase transformation of olivine and spinel into perovskite and rock salt structures

J. P. Poirier*, J. Peyronneau*, M. Madon*, F. Guyot* & A. Revcolevschi†

* Institut de Physique du Globe de Paris, 4, place Jussieu 75252 Paris Cedex 05, France
† Laboratoire de Chimie Appliquée, Université Paris Sud, 91405 Orsay, France

The 700-km seismic discontinuity which defines the top of the Earth's lower mantle is generally attributed to the transformation of the upper mantle (Mg, Fe)$_2$ SiO$_4$ spinel into magnesiowüstite (Mg, Fe)O and (Mg, Fe)SiO$_3$ with perovskite structure[1]. Large-volume high-pressure experiments[2] have provided important thermodynamical information on this transition, but its mechanisms and kinetics are still unknown. Here we report microstructural observations of the products of the transformation of (Mg, Fe)$_2$SiO$_4$ olivine and spinel and Ca$_2$GeO$_4$ olivine, effected in a laser-heated diamond anvil cell (DAC). The observations were made by transmission electron microscopy (TEM), a technique that has already proved useful in investigating the olivine–spinel transition in the DAC[3,4]. We find that, in all cases, the transformed product has a eutectoid-like appearance (as in pearlitic carbon steels), with alternating lamellae of the rock salt and perovskite phases. The thickness and spacing of the lamellae increase with temperature until a granular structure forms. These observations suggest that the transformation starts as a eutectoid transformation, whose physical mechanisms might be as effective in the Earth's mantle as in the DAC.

Fig. 1 Olivine in the DAC, transformed into perovskite and magnesiowüstite in the three vertical strips that have been laser-heated.

The starting material powder was placed in the 300-μm-diameter hole of a hardened nickel gasket, 200 μm thick, and pressurized in the DAC to a maximum pressure (P) of ~400 kbar at the centre of the cell. Pressure was measured by calibrated strain gauges on the steel members of the cell[5], to avoid introducing ruby which could react with the material under investigation. A 60-W YAG laser beam was focused on a 30-μm-diameter spot and scanned across the sample at a speed of 100 μm s^{-1}. Three strips of transformed material, each 50 μm wide, were then produced (Fig. 1), allowing analysis of the effects of various pressure and temperature conditions. (The temperature across a strip ranged from the minimum temperature necessary to effect the transformations at the edges of the strip, up to an estimated temperature of 2,000 °C along the axis.) The two strips at the

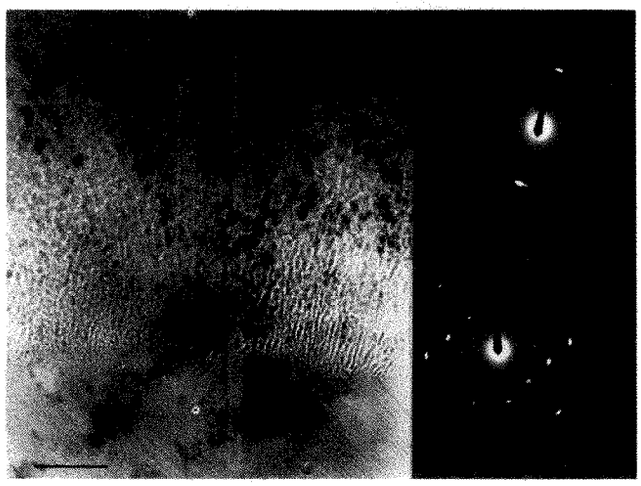

Fig. 2 Contact between sheared olivine–spinel phase (bottom) and eutectoid perovskite–rock salt structure. The dark subvertical lamellae are strongly textured magnesiowüstite (top diffraction pattern at right). Towards the centre of the strip (top) the structure becomes granular. Scale bar, 0.2 μm.

edges of the cell were at pressures too low for the perovskite–rock salt transition, but high enough for the olivine–spinel transition, whereas the centre strip was at the maximum pressure of 400 kbar in the central part of the sample. After heating, the sample was slowly decompressed, ion-beam thinned and examined by TEM at 200 keV.

In the first series of experiments, the starting material was San Carlos olivine (Fo_{88}). Examination of the edge strips confirms previous results[3,4,6,7] on the olivine–spinel transition, showing intercalated olivine and spinel layers at the edge of the strip, giving way to polygonal grains of spinel with stacking faults at higher temperatures towards the strip axis.

At the edge of the central strip, the same sheared olivine–spinel polytype is visible (the superimposed olivine and spinel diffraction patterns show that the (100) plane of olivine and the (111) plane of spinel are parallel); towards the axis of the strip this region is abruptly replaced by another with a very regular lamellar structure (Fig. 2) which becomes coarser and eventually granular at higher temperatures towards the axis. The smallest spacing (and thickness) of the lamellae is ~50–100 Å. The dark lamellae are identified by electron diffraction as magnesiowüstite (Mg, Fe)O; the light lamellae give no diffraction pattern. By continuity, they can be shown to consist of a glass with (Mg, Fe)SiO_3 composition: in the high-temperature region,

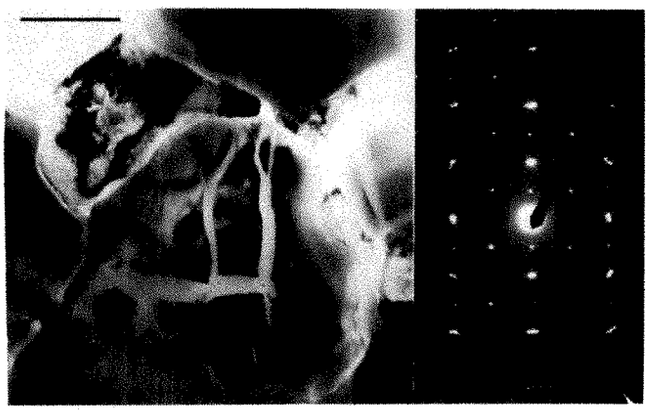

Fig. 3 Rectangular domains of (Mg, Fe)SiO_3 perovskite before amorphization under the electron beam (diffraction pattern at right). In the top left-hand corner a grain of magnesiowüstite with a very high dislocation density is seen. Scale bar, 0.5 μm.

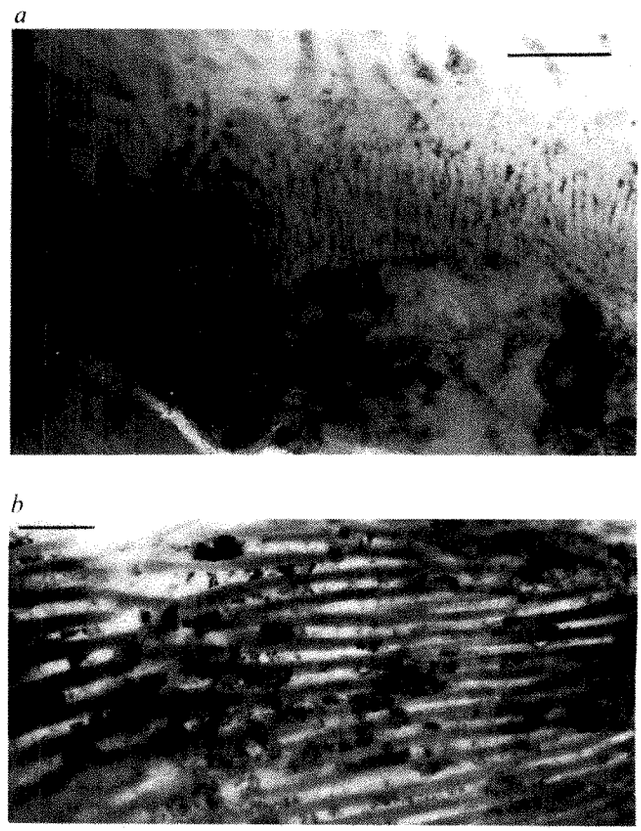

Fig. 4 *a*, Eutectoid structure of the perovskite–rock salt phases formed from *a*, spinel (bottom); *b*, Ca_2GeO_4 olivine. Towards the centre of the strip in *a* (top), the spacing of the lamellae increases. In *b*, dark bands are CaO, light bands are amorphized perovskite. Scale bars: *a*, 0.1 μm; *b*, 0.2 μm.

similar glassy, roughly rectangular grains were produced by amorphization under the electron beam of crystalline (Mg, Fe)SiO_3 perovskite grains (Fig. 3) whose grain boundaries are parallel to (100) planes of the ideal cubic lattice. The grains, without any dislocations, correspond to twinned domains of the $GdFeO_3$-type distorted structure. Magnesiowüstite grains contain a very high density of dislocations, which accounts for the invariably dark contrast of the magnesiowüstite lamellae.

In the second series of experiments the olivine was first transformed to spinel by uniformly scanning the sample, compressed to a maximum pressure of 200 kbar, with the laser beam. The sample was then compressed to 400 kbar and the laser beam drawn across it in strips as previously. TEM examination showed that the starting material then consisted of spinel grains with the usual (110) stacking faults. The transformed material was identical to the previous one and exhibited the same lamellar microstructure (Fig. 4*a*), coarser towards the centre of the strip.

All our observations point to the transformation $(Mg, Fe)_2SiO_4 \rightarrow (Mg, Fe)O + (Mg, Fe)SiO_3$ being of the discontinuous, eutectoid type well known in metallic alloys[8–11]. The lamellar microstructure, typical of the transformed product, is thought to be caused by the growth of nuclei by bulk and grain-boundary diffusion in the direction of grain-boundary migration[10]. From the geometry of our experiments, the reaction seems to start at the centre of the strip, the grain boundaries migrating towards the edges, this direction being favoured by the internal stress arising from the decomposition[9]. The interlamellar spacing decreases as temperature decreases[13]. The mechanism of the formation of nuclei of (Mg, Fe)O or (Mg, Fe)SiO_3 is unclear, but might involve a transient local distortion of the spinel structure into the K_2NiF_4 structure. This structure, denser than spinel, is not stable at any pressure for (Mg, Fe)SiO_4,

but it is stable for Ca_2GeO_4 at pressures greater than 100 kbar (ref. 14); it can be described as an alternate stacking of layers with the perovskite and the rock salt structure. At ~200 kbar, Ca_2GeO_4 transforms into $Ca_3Ge_2O_7 + CaO$ (ref. 15). We performed with Ca_2GeO_4 the same type of experiments as with the silicate olivine, starting with Ca_2GeO_4 powder with olivine structure and compressing it to 300 kbar. TEM examination showed, for the first time, that it eventually decomposes into CaO and $CaGeO_3$ perovskite, also with eutectoid structure (Fig. 4*b*). It is therefore possible that shear and cation shuffling of the spinel structure[16] might produce defects with local K_2NiF_4 structure, thus providing embryos of MgO or $MgSiO_3$ that can grow by diffusion until the grain boundaries start moving and creating the cellular structure.

The DAC and TEM coupled experiments on the perovskite + rock salt decomposition therefore lead to several conclusions: (1) The decomposition in the DAC exhibits all the characteristics of a eutectoid reaction driven by diffusion and grain-boundary reaction, that is, by processes that may be active in the mantle (but leading to different lamellar spacing and thickness). (2) The K_2NiF_4 structure exhibited by Ca_2GeO_4 at moderate pressure decomposes at higher pressure into rock salt and perovskite structures; a transient distortion to the K_2NiF_4 structure may have a role in the post-spinel decomposition of silicates. (3) The high dislocation density of the magnesiowüstite may come from plastic accommodation of the 10% volume decrease on transformation; this could be the first hint that magnesiowüstite could be more deformable than perovskite in the lower mantle.

Visualization of the dynamic instability of individual microtubules by dark-field microscopy

Tetsuya Horio & Hirokazu Hotani

Department of Biophysics, Faculty of Science, Kyoto University, Kyoto 606, Japan

It has previously been shown that two populations of microtubules coexist in a dynamically unstable manner *in vitro*: those in one population elongate while those in the other shorten and finally disappear[1,2]. This conclusion was based on changes in the number and length distribution of microtubules after dilution of the microtubule solution. Here, we demonstrate directly that growing and shortening populations coexist in steady-state conditions, by visualization of the dynamic behaviour of individual microtubules *in vitro* by dark-field microscopy. Real-time video recording reveals that both ends of a microtubule exist in either the growing or the shortening phase and alternate quite frequently between the two phases in a stochastic manner. Moreover, growing and shortening ends can coexist on a single microtubule, one end continuing to grow simultaneously with shortening at the other end. We find no correlation in the phase conversion either among individual microtubules or between the two ends of a single microtubule. The two ends of any given microtubule have remarkably different characteristics; the active end grows faster, alternates in phase more frequently and fluctuates in length to a greater extent than the inactive end. Microtubule-associated proteins (MAPs) suppress the phase conversion and stabilize microtubules in the growing phase.

Microtubules, very dynamic structures that can rapidly assemble and disassemble[3,4], form a cytoskeleton that is stable in the interphase of the cell cycle and that disintegrates rapidly into tubulin subunit in the prophase of mitosis. The subunits then completely reorganize to form the mitotic spindle[5]. In the late telophase stage of mitosis the reverse process takes place, that is, the spindle microtubules disassemble and the cytoskeletal microtubules re-form. To determine the mechanism by which microtubules assemble or disassemble without changing the concentration of tubulin subunits, we observed the dynamic behaviour of individual microtubules by dark-field light microscopy. When a single microtubule is monitored, its two ends grow at different rates (Table 1) as described previously[6,7]. However, each end independently stops growing in a stochastic manner, and then immediately begins to shorten at high speed (Fig. 2). After shortening for 1–30 s, the microtubule suddenly stops this process and starts growing again. Each end can thus exist either in the growing phase or in the shortening phase, and can alternate between the two phases in a stochastic manner.

These phase conversions at the two ends of a single microtubule occur independently, and conversions take place without any correlation among the individual microtubules on each slide in the microscope. As a result, some microtubules shorten whereas others elongate within a field of observation (Fig. 1), and no synchronized phase conversion is observed. This excludes the possibility that a cyclic environmental change in a specimen causes the switching between the two phases of microtubules. All the microtubules shown in Fig. 1 exhibit the phase changes, and >90% of the filaments in any particular observation field undergo phase conversions. The filament labelled b in Fig. 1, for example, attached to the glass surface throughout its length while filament e attached at only one point on the filament. As a result, when the direction of flow changed, filament e pivoted about its attached point whereas filament b

Table 1 Kinetic parameters of the dynamic instability

Values, mean ± s.d.

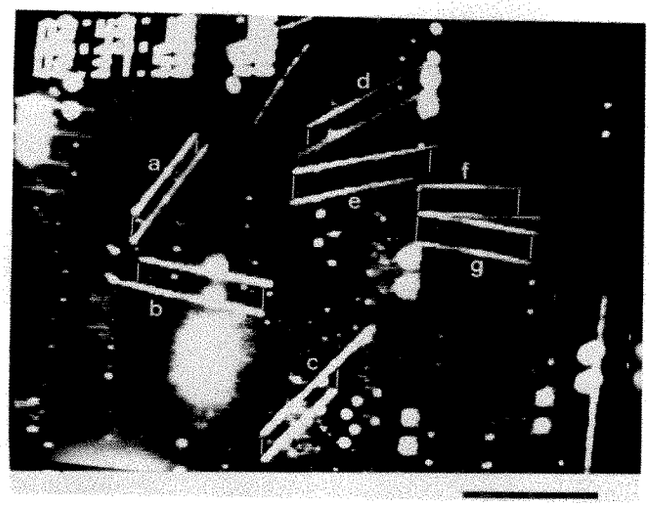

Fig. 1 Instability of microtubules visualized by dark-field microscopy. Several microtubules were attached to a glass surface so that their growing and shortening processes could be monitored continuously. Dynamic images were recorded on videotape. To demonstrate the changes in their lengths, two video images at different times (37 min 53 s and 43 min 18 s) were photographed on the same frame of a film by double exposure. The camera position was moved slightly before the second exposure so that the change in length could be seen. The two ends of a microtubule interconverted a few times between the growing and shortening phases during the time interval between the two exposures. As a result, some ends elongated while others shortened. The white lines show the shift of a corresponding point on a microtubule caused by movement of the camera position. Comparison of the images in pairs shows that the upper end of the microtubule designated as a, has shortened, the upper end of c has elongated, and so on. **Methods.** Tubulin was prepared from calf brains by three cycles of assembly-disassembly as described previously[11]. Further purification of tubulin was performed by phosphocellulose column chromatography[8]. Assembly of a microtubule was initiated by raising the temperature to 37 from 0 °C in the tubulin solution at a concentration of 1.7 mg ml^{-1} in buffer (90 mM PIPES, 1.8 mM EGTA, 0.9 mM $MgSO_4$, 2.7 mM GTP, *p*H 6.9). After incubation for 2 min, 4 μl of the solution was transferred onto a slide glass, mounted with a coverslip (22 × 22 mm) and observed by dark-field light microscopy. Microtubules were illuminated through an Olympus DC dark-field condenser by a Ushio 500-W high-pressure mercury arc lamp and observed with an Olympus Apo ×40 objective lens. The dynamic dark-field images were recorded on videotape using an ultrasensitive Ikegami CTC-9000 SIT video camera as described previously[12]. Scale bar, 10 μm.

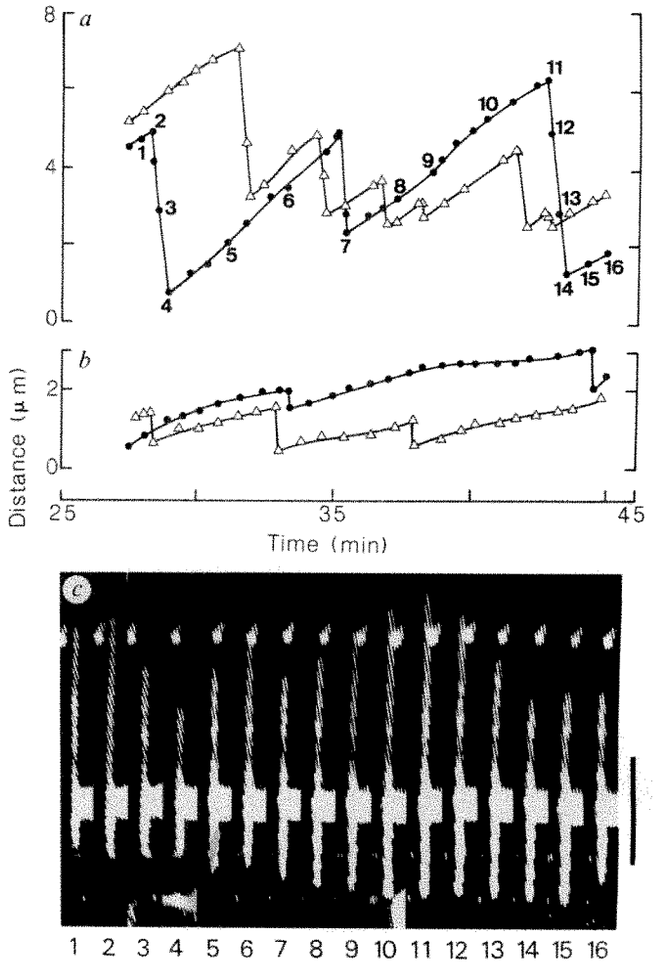

Fig. 2 Interconversions between the growing and shortening phases at ends of a single microtubule. The change in microtubule length at each end was followed by dark-field microscopy and recorded on videotape as described in Fig. 1. The dynamic video images, which were superimposed on the monitor screen of a personal computer (Fujitsu FM 77) with the aid of a superimposer (Fujitsu MB22610), were analysed as a function of time. *a*, *b*, The distance between one of the ends and an arbitrary fixed point on the microtubule was measured so that increase and decrease in the distance correspond respectively to the growth and shortening of the microtubule. The length change at an active (*a*) or inactive (*b*) end of an individual microtubule is shown. The curves were obtained from the microtubules designated as b (●) or e (△) in Fig. 1. *c*, Successive frames were obtained from the video image of the microtubule designated b in Fig. 1. Scale bar, 5 μm. Each numbered datum point in *a* has a one-to-one correspondence with the successive video frames in *c*. The upper and lower ends of the microtubule shown in *c* correspond to the active and inactive ends, respectively.

did not move. Despite the difference in the manner of attachment, the filaments underwent phase conversions in a similar manner (Fig. 2), indicating that the interaction between a microtubule and a glass surface produces only a small, if any, effect on the nature of the phase conversion.

The frequencies of phase interconversion at the two ends of a microtubule are distinct from each other, being 0.63 and 0.23 min^{-1}. We designated the ends which had higher and lower interconversion frequencies as active and inactive ends, respectively. The active end differs from the inactive end not only in interconversion frequency but also in growth and shortening rates. In the growing phase, the active end elongates about three times faster than the inactive end (Table 1); in the shortening phase, it shortens more slowly than the inactive end. In general, at the active end, a microtubule grows quickly, alternating frequently between the two phases and fluctuating greatly in length, while the reverse is true at the inactive end, where growth is slow, phase alternation infrequent and there is a little fluctuation (Table 1).

It is well established that a microtubule has a structural polarity and that the 'plus' end grows about three times faster than the 'minus' end[6,7]. Hence, the active and inactive ends designated in this study must correspond respectively to the plus and minus ends. Despite the independent alternation of phases of the ends which makes the time course of a length change quite unique in each microtubule, similar rates of growth were obtained with active ends and this rate changed very little during the observation period (Fig. 2). This result also holds for the other three kinetic parameters: the shortening rate of the active end, and both the growth and the shortening rates of the inactive end. These homogeneities in rate indicate that each end has a well-defined molecular structure unique to the respective phases and suggests that there is no intermediate phase. The homogeneities also indicate that the concentration of tubulin

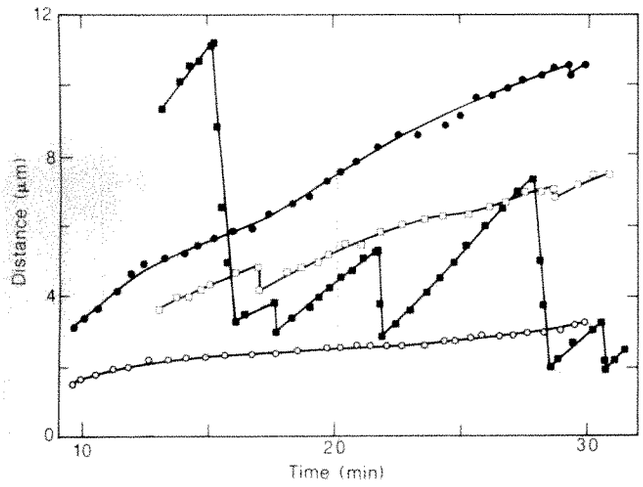

Fig. 3 Effect of MAPs on microtubule instability. Microtubules are formed as described in Fig. 1 except for the presence of MAPs (0.24 mg ml^{-1}). Changes in microtubule length at the active end (●) and the inactive end (○) were measured as described in Fig. 2. In the absence of MAPs, both the active end (■) and the inactive end (□) show the phase conversion in a similar manner to that in Fig. 2. MAPs were purified by phosphocellulose column chromatography as described previously[8].

subunits is constant during the observation period because a change in subunit concentration would cause a change in growth rate. In other words, we observed the phase conversions in an apparent steady-state condition of microtubule assembly and disassembly (see below).

As shown in Table 1, the shortening rate is much higher than the growth rate at both the active and the inactive ends of the microtubules. Hence, once an end switches to the shortening phase, the microtubules often shorten all the way to disappearance. But in practice this is not the case. The active end stays in the growing phase for a period which averages 10 times longer than it stays in the shortening phase (Table 1). As a result, the microtubule length lost in the shortening phase is compensated for by an elongated length in the growing phase. On average, a microtubule loses 2.4 μm during one shortening phase and recovers 1.8 μm during a single growing phase. A similar compensation takes place at the inactive end: 0.7 μm is lost in one shortening phase and 1.2 μm recovered in one growing phase. Therefore, a microtubule does not become so short as to disappear, although its length does fluctuate greatly. This evidence also implies that the net amount of microtubules is almost constant, as it would be in a steady state.

Microtubule filaments are stabilized in interphase cells to maintain the cell shape. How does a microtubule prevent dynamic instability *in vivo*? The purified tubulin used here contained almost no MAPs, whereas in the partially purified tubulin preparation used elsewhere, MAPs make up ~20% of the total protein[8]. Microtubules in the tubulin preparation grow continuously without any shortening phase, and after reaching the steady state they maintain constant length and do not exhibit any dramatic shortening. This suggests that MAPs suppress phase conversion and stabilize microtubules in the growing phase. The results shown in Fig. 3 confirm that MAPs can stabilize both ends of a microtubule as well as their well-known property of nucleation for tubulin polymerization[8]. A detailed description of the effects of MAPs on the stability of microtubules will be published elsewhere.

A GTP cap model has been proposed as the mechanism of phase transition[2,9,13,14]. When tubulin monomers bound to GTP and ligand are incorporated into a microtubule, the GTP is hydrolysed at a constant rate to form a GDP-tubulin lattice. If the polymerization rate is high enough at an adequate concentration of free tubulin, however, the GTP-tubulin lattice will form near the ends of the microtubule because the hydrolysis cannot follow the polymerization[10]. This lattice, or GTP cap, has been proposed as a mechanism to stabilize the growing phase. On the other hand, when the polymerization slows down with a decrease in tubulin concentration, the GTP cap size is predicted to decrease and the GDP lattice to become exposed on the microtubule end. When this happens, rapid depolymerization of the GDP-tubulin takes place which continuously exposes GDP-tubulins at the end until the microtubule disappears or some rare event recaps the microtubule[2].

Our results raise some questions about the GTP cap hypothesis as microtubules can interconvert frequently between the two phases without changing polymerization rate. The active end was frequently in the shortening phase at the tubulin concentration used here. Therefore, if the GTP cap hypothesis is correct, the inactive end may always be in the shortening phase because the polymerization rate at the inactive end is only one-third of that at the active end. To clarify the molecular mechanism of the phase conversion, more detailed studies, especially of the effects of GTP, are necessary.

The cytoskeleton and the mitotic spindle can disintegrate rapidly without decreasing the free tubulin concentration in the cell. These structures can also be formed in a range of tubulin concentrations similar to that at which they disintegrate. These cellular events could be related to our demonstration that growing and shortening microtubules really coexist under steady-state conditions.

We thank Dr Tim Mitchison for helpful comments and Dr M. Yanagida for encouragement. This work was supported by a grant from the Ministry of Education, Science and Culture of Japan.

Evidence that reserve cells are a source of regenerated adult newt muscle *in vitro*

Jo Ann Cameron, Allen R. Hilgers & Timothy J. Hinterberger

Department of Anatomical Sciences and College of Medicine, University of Illinois, 190 Medical Sciences Bldg, 506 S. Mathews, Urbana, Illinois 61801, USA

Skeletal muscle of adult, metamorphosed urodele amphibians regenerates despite the absence of satellite cells[1], the myogenic reserve cells present beneath the external lamina of muscle fibres in larval urodeles and in other vertebrates[2–9]. Adult-stage muscles of several urodeles examined (*Notophthalmus viridescens*[1,10], *Ambystoma maculatum*[10], *Triturus vulgaris*, *Triturus cristatus*[11], *Hynobius tokyoensis*[12] and *Ambystoma mexicanum*[13]) have instead a unique cell type enveloped in its own external lamina. Several studies suggest that these cells are larval satellite cells that have become completely surrounded by a segment of external lamina

during metamorphosis[10–12]. Although Popiela[10] termed these cells 'pericytes', he suggested that they might function as a myogenic reserve population. Cherkasova, who was the first to recognize these cells as distinct from vascular pericytes, termed them post-satellite cells and also proposed that they might be myogenic[11]. Here, we present evidence that post-satellite cells in adult *N. viridescens* give rise to regenerated myotubes *in vitro*. The myotubes could be stained with MF20, a monoclonal antibody to purified skeletal muscle myosin[14], and also with 22/18, a monoclonal antibody that reacts with an antigen present in newt-limb blastema myogenic cells[15]. The presence of myogenic post-satellite cells in adult newt muscle provides an alternative to the hypothesis that myoblasts in regenerating adult urodele limbs arise through dedifferentiation of mature myofibres[15–17].

Recent results from our laboratory demonstrate that adult newt muscle undergoes repair regeneration *in vivo* even though the original myonuclei degenerate[18], and that it is able to form new myotubes from muscle explants *in vitro*, where it is apparent that mature fibres do not give rise to myogenic cells by dedifferentiation[19]. Those studies supported the idea that adult newt muscle can regenerate from a reserve cell population, whose identity remained unknown.

Post-satellite cells in adult *N. viridescens* limb muscle are similar at the fine structural level to those described in other urodeles, with heterochromatic nuclei and varying amounts of rough endoplasmic reticulum, Golgi and pinocytotic vesicles (Fig. 1). Although post-satellite cells can resemble fibroblasts, their distinctive feature is that each is enveloped in an external lamina. In electron micrographs, we observed only post-satellite cells immediately adjacent to myofibres away from nerves or vascular elements. Light microscopy with serial sections showed that cells in this location usually have basophilic cytoplasm that is sometimes wrapped partially around the adjacent myofibre (Fig. 2*b*). To test our ability to identify post-satellite cells by their location and cytology at the light microscopic level, 11 such cells in thick Epon sections from both uninjured and cultured muscle were re-mounted and examined at the fine structural level. All 11 possessed intact external laminae, which in the cultured muscle often appeared loosened (Fig. 2*a*), possibly due to some rounding up of the cells. Therefore, in the subsequent steps of this experiment, post-satellite cells were identified by serial sectioning and light microscopy alone.

We found that post-satellite cells began synthesizing DNA *in vitro* earlier than did any other cell type present in adult newt muscle. Explants of forelimb muscles were prepared according to methods described previously[19] and exposed to ^{3}H-thymidine for 24 h at 2, 4, 6 or 8 days in culture. Incorporation of the label by post-satellite cells and other cell types was determined autoradiographically for each of those days. Up to day 6, ^{3}H-thymidine incorporation was confined to post-satellite cells; no labelled perivascular cells, endothelial cells, perineural cells, Schwann cells or tendon fibroblasts were observed. By day 8, however, an occasional cell of these types was labelled. Of those cells that met our criteria for identification as post-satellite cells by light microscopy, 29.6% (134 of 452 cells in six explants) were labelled with ^{3}H-thymidine on day 6. Only three labelled cells could not be assigned with certainty to a particular histological type because of their appearance and location in the tissue. Thus, restricting the exposure to ^{3}H-thymidine to just the first 6 days in culture appears to provide a means of selectively labelling post-satellite cells, although not all of them incorporate the label during this period (for example, the cells in Figs 1, 2).

Labelled cells identified as post-satellite cells (on the basis of their location and basophilia in serial-section autoradiographs of newt limb muscle exposed to ^{3}H-thymidine continuously for 48 h on days 4 and 5 in culture) were re-mounted for electron microscopy. Some of these cells could be confirmed as post-satellite cells by the presence of intact external laminae (Fig. 3), but many of them lacked intact laminae. As cells lacking intact laminae were not observed in uninjured muscle, we assume that they are post-satellite cells that lost their external laminae before or shortly after synthesizing DNA, although the steps in this process remain to be elucidated.

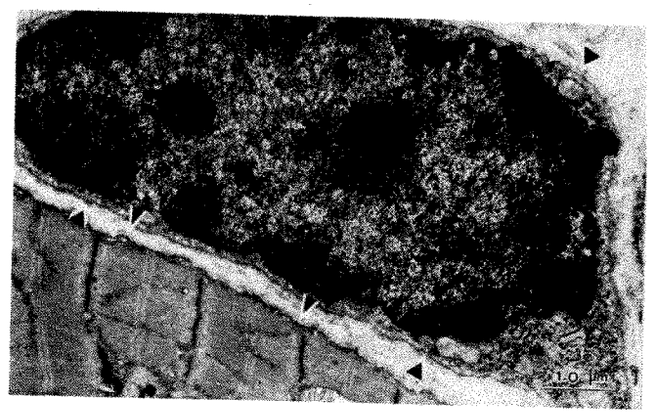

Fig. 1 A post-satellite cell in newt limb muscle after 10 days *in vitro*. Note its external lamina (large arrowheads) and that of the adjacent muscle fibre (small arrowheads). This post-satellite cell did not incorporate tritiated thymidine.
Methods. One μCi of ^{3}H-thymidine was added to cultures on day 5. After 24 h the medium was replaced with medium containing 4×10^{-5} M cold thymidine, and this medium was changed at least three times over the next few hours. The cultures were fixed with 2.5% glutaraldehyde in 0.1 M phosphate buffer at *p*H 7.4, after 6 days *in vitro*. Fixed explants were removed from the plates and either embedded in methacrylate or post-fixed with OsO_4 in 0.1 M phosphate buffer at *p*H 7.4 and embedded in Epon. Serial sections (3 μm) were coated with NTB2 emulsion (Kodak). After exposure for 1 week at 4 °C the autoradiographic preparations were developed, then stained with toluidine blue. Labelled and unlabelled cells in the Epon-embedded muscle tissue were photographed, and selected sections were re-mounted for fine structural analysis.

Fig. 2 *a*, A post-satellite cell in a 10-day explant of newt limb muscle prepared as described in Fig. 1 legend. This cell did not incorporate tritiated thymidine. Note the pinocytotic vesicles along the lower right edge of the post-satellite cell and its loose external lamina (large arrowheads) characteristic of post-satellite cells in injured muscle. Although the two adjacent muscle fibres are degenerating, their external laminae are intact (small arrowheads). *b*, Light micrograph of this cell prior to re-mounting, demonstrating its location with respect to the two adjacent muscle fibres.

Cells labelled with ^{3}H-thymidine *in vitro* as described above were followed until they formed regenerated myotubes in longer-term cultures. When muscle explants labelled with ^{3}H-thymidine for 48 h on days 4 and 5 were maintained for periods of up to 4 weeks, myotubes were observed on the culture plates within 14 days *in vitro*. Following autoradiographic processing, many myotubes were seen to contain ^{3}H-thymidine-labelled nuclei (Fig. 4). Immunocytochemical staining with antibody MF20 (ref. 14) confirmed the myogenic nature of these multinucleated

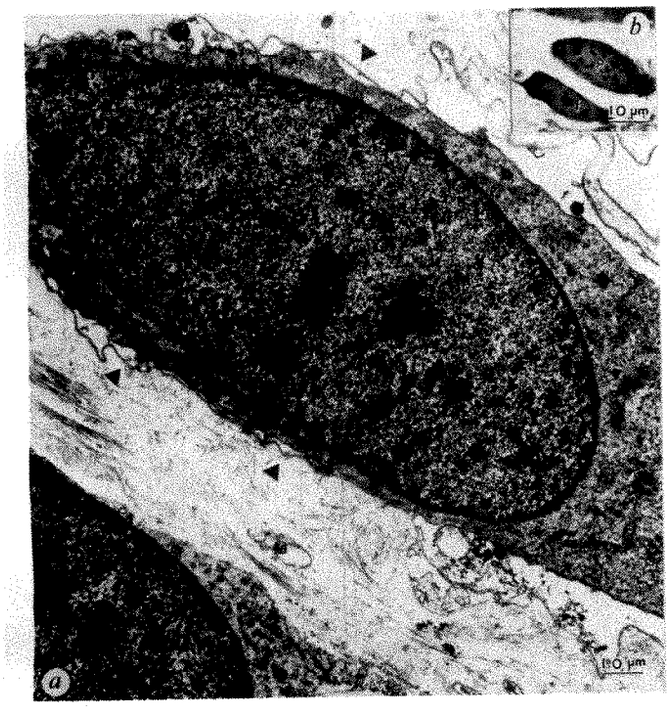

Fig. 3 *a*, A post-satellite cell in a 10-day explant of newt limb muscle labelled with ^{3}H-thymidine on days 4 and 5 and processed as described in Fig. 1 legend. Note the loose external lamina of the post-satellite cell (arrowheads). *b*, Light micrograph of this cell (p) demonstrating its location with respect to an adjacent muscle fibre on one side and a fibroblast (f) on the other. Note the silver grains over the nucleus of the post-satellite cell.

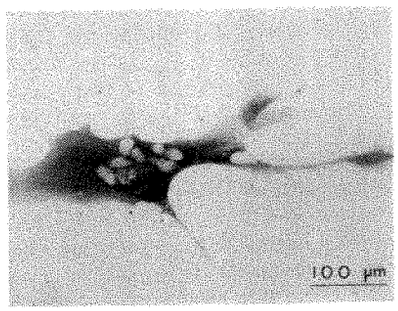

Fig. 4 A myotube in a 14-day culture of newt limb muscle labelled with ^{3}H-thymidine on days 4 and 5 and stained with MF20 on day 14. Note the silver grains over several of the myonuclei; unlabelled myonuclei are also seen.
Methods. Cultures were fixed in 5% neutral formalin and permeabilized with 0.01% Triton X-100 in 0.02 M phosphate-buffered saline (PBS) for 5 min, followed by 95% ethanol for 5 min. Monoclonal antibody MF20, given by Dr Donald Fischman, was raised against purified myosin heavy chain from adult chicken pectoralis muscle[14]. (Immunoautoradiographic analysis of electrophoretically separated adult newt muscle myosin, performed, with slight modifications, according to the protocol of Bader *et al.*[14], demonstrated the specificity of MF20 for a newt muscle peptide of relative molecular mass (M_r) 220,000 (220K) which migrated close to adult chicken myosin (200K) and purified rabbit myosin (220K).) Supernatant containing MF20 was diluted 1:3 in 0.02 M PBS (0.25 M NaCl) *p*H 7.6, and applied to the cultures overnight. After three 5-min rinses in the same buffer, the tissue was reacted with 20 μg ml^{-1} goat anti-mouse IgG (Jackson Immunoresearch Laboratory) for 8 h in the same buffer, followed by three more rinses with buffer. The MF20 was visualized by incubating cultures in a solution of 4 μg ml^{-1} mouse peroxidase/anti-peroxidase (Jackson Immunoresearch Laboratory) in 0.02 M PBS (0.14 M NaCl) plus 1% normal goat serum overnight, followed by three rinses in the same buffer and routine diaminobenzidine treatment. Controls omitting the monoclonal antibody or substituting a known non-reactive primary antibody showed no staining. For autoradiography, culture plates were coated with NTB2 emulsion and processed in the same way as the sectioned material.

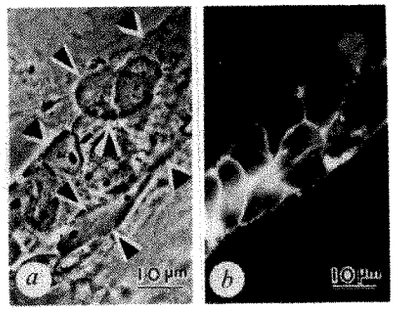

Fig. 5 *a*, A phase-contrast micrograph of a myotube (large arrowheads) in a 21-day culture of newt limb muscle. Two mononucleated cells are also visible (small arrowheads). *b*, The same myotube demonstrating 22/18 immunofluorescence.
Methods. Cultures grown on collagen-coated glass coverslips were fixed in acetone and stained with monoclonal antibody 22/18 (given by Dr Jeremy Brockes) according to the protocol of Kintner and Brockes[15], followed by fluorescein-conjugated rabbit anti-mouse IgG (1:100; Miles). Controls omitting the monoclonal antibody or substituting a known non-reactive primary antibody gave no staining.

cells and in addition allowed some mononucleated cells to be identified as myogenic. Mature fibres within explants were largely degenerated, although they stained weakly with MF20; this is in agreement with our previous conclusion that dedifferentiation of myofibres is not a prerequisite for the regeneration of *N. viridescens* muscle[18,19], and the present study points to post-satellite cells as a source of the myogenic cells *in vitro*.

Recently, Kintner and Brockes[15] examined the possibility of myofibre dedifferentiation being involved in regeneration of *N. viridescens* limbs, by using a monoclonal antibody raised against muscle and a second antibody, named 22/18, raised against blastema tissue. In regenerating limbs 14 days after amputation, cells bearing both the myofibre and blastemal antigens were found only in the region between the blastema and the intact muscles of the stump. Although those authors observed double-labelled cells also in muscle-forming regions of palette-stage blastemas 28 days after limb amputation, they interpreted the appearance of the double-labelled cells in the stump at 14 days as evidence of myofibre dedifferentiation. An alternative explanation for the presence of double-labelled cells in the limb stump at 14 days is that there too it indicates muscle redifferentiation rather than dedifferentiation. Repair myogenesis just proximal to the blastema has been noted at later stages of newt-limb regeneration[17], but we believe it may begin as early as 2 weeks after injury, as it does when newt muscle is injured by mincing *in vivo*[18]. To determine whether 22/18 labelling is associated with muscle regeneration *in vitro*, we prepared cultures as before and exposed them to this antibody after new myotubes had formed. The myotubes and some mononucleated cells stained with 22/18 (Fig. 5); taken together with our other results described above, this demonstrates that 22/18 can label myogenic cells apparently derived from post-satellite cells. If post-satellite cells can give rise to myotubes by 14 days *in vitro*, we hypothesize that they do so in limb stumps *in vivo* and that the multinucleated myofibres labelled with 22/18 observed by

Kintner and Brockes in limb stumps 14 days post-amputation were newly repaired or regenerated.

As we have demonstrated the presence of myogenic reserve cells in adult newt muscle, we believe that electron microscope observations of regenerating newt limbs are open to re-interpretation also. Hay[17] showed that mononucleated cells not present in uninjured muscle appear within myofibre external laminae in adult newt limb stump muscle following amputation. Hay postulated that the mononucleated cells arise from the adjacent fibres, enter the blastema and give rise to myoblasts. But neither the origin of these cells nor their possible role in epimorphic limb regeneration has been established rigorously. Even though in the present study we have described repair myogenesis only *in vitro*, we hypothesize that post-satellite cells are also a source of myogenic cells in the epimorphically regenerating limb; this would be consistent with observations that reserve cells are the source of regeneration myoblasts in other vertebrates and would avoid invoking a unique mechanism for the formation of regeneration myoblasts in newts. It may, however, be impossible to test our hypothesis against that of myofibre dedifferentation until some means becomes available for unambiguously marking either post-satellite cells or the putative viable myofibre fragments.

We thank Bruce Carlson for translating Dr Cherkasova's publications, Donald Fischman and Jeremy Brockes for providing the monoclonal antibodies, Robert Fontaine for conducting the immunoblot tests, and Alex Mauro for encouragement. This work was supported by NSF grant PCM 83-10006.

Stimulation of oligodendroglial proliferation and maturation by interleukin-2

Etty N. Benveniste* & Jean E. Merrill

Department of Neurology, UCLA School of Medicine, Los Angeles, California 90024, USA

There exists considerable evidence that the growth of glial cells can be influenced by T-cell-derived lymphokines and monokines. Astrocytes proliferate in the presence of mitogen- or antigen-stimulated T-cell supernatants[1–3], supernatants from human T-lymphotropic virus (HTLV)-transformed T cells[3], and purified human interleukin-1 (IL-1; ref. 4). Oligodendrocytes proliferate and differentiate when incubated with supernatants from mitogen-activated or HTLV-transformed T cells[3]. In addition, we have recently purified a T-cell-derived lymphokine of relative molecular mass 30,000, termed glial growth promoting factor (GGPF), which specifically stimulates the proliferation of oligodendrocytes[5]. The traditional role of interleukins 1 and 2 is in the initiation, propagation and regulation of the immune response[6]. IL-1, released by a variety of cells including monocytes, stimulates T cells to produce IL-2 (ref. 7); IL-2 in turn induces the expansion of T cells that is critical for immune responsiveness. Recently, IL-2 has been shown to induce B-cell proliferation[8,9] and immunoglobulin secretion[10], indicating that its action is not restricted to T cells. We now report that recombinant human IL-2 influences the growth of glial cells—specifically, the proliferation and differentiation of oligodendrocytes. IL-2 may have a role in the inflammatory neural lesions of multiple sclerosis patients and in the growth of brain glia during injury or disease.

Primary glial cell cultures were established from neonatal rat cerebra by a modification of the McCarthy and DeVellis technique[11]. Meninges were removed prior to culture. After 7–10 days in primary culture, oligodendrocytes were separated by brief mechanical dislodging. (The overnight shaking technique of McCarthy and DeVellis was not used.) Astrocytes (day 10) were obtained by trypsinization. The two cell populations were resuspended in culture media containing 10% fetal bovine serum (FBS)[5]. Oligodendrocytes were seeded in Falcon Microtest II plates at a concentration of 2×10^4 cells per well, while astrocytes were seeded at 2×10^3 cells per well. The IL-2-containing material to be tested was serially diluted, and 0.1-ml aliquots were added to the cells. Assays were performed in triplicate. Cells were cultured for various times at 37 °C, pulsed with ^{3}H-thymidine (TdR, 1 μCi per well), and collected after 17 h with an automated cell harvester (PHD harvester, Cambridge Technology). Cells were monitored for purity by immunofluorescence as described previously[3,5] and by nonspecific esterase staining[12] for contaminating microglia. Oligodendrocyte-enriched cultures were assayed for the presence of the following markers before and after stimulation with IL-2 (see Table 1): galactocerebroside (GalC), a myelin-associated galactosphingolipid that is a surface antigen specific for oligodendrocytes[13]; the A2B5 antigen (which identifies a bipotential glial progenitor cell[14], type II astrocytes[15] and some types of neurones[16]); glial fibrillary acidic protein (GFAP), an astrocyte marker[17]; tetanus toxin receptor (which identifies neurones[18],

Table 1 Composition of oligodendrocyte-enriched cultures

Marker	Pre-stimulation (%)	Post-stimulation (%)
GalC	86	93
A2B5	12	3
GFAP	5	4
Tetanus toxin receptor	0	0
Nonspecific esterase	5	1

Oligodendrocytes were stained on harvesting (day 7–10), and after a 4-day incubation with recombinant IL-2. Surface staining for GalC was performed for 30 min in the cold with rabbit anti-GalC antibody (1:25), followed by fluorescein isothiocyanate (FITC)-conjugated F(ab')$_2$ goat anti-rabbit immunoglobulin (1:20; Cappel) for 30 min; and for A2B5 using mouse monoclonal anti-A2B5 (1:20; Sera Labs) for 30 min, followed by FITC-conjugated goat anti-mouse immunoglobulin (1:20; Tago) for 30 min. Surface tetanus toxin receptors were tested for by staining with tetanus toxin, human antisera to tetanus toxin, and FITC-conjugated rabbit anti-human immunoglobulin (1:25; Accurate). Cytoplasmic staining was performed on fixed cells with rabbit antibody to GFAP (1:20; Dako) for 30 min at room temperature, followed by incubation with FITC-conjugated goat anti-rabbit immunoglobulin (1:20; Cappel). Nonspecific esterase staining was performed as described in ref. 12.

* Present address: Department of Neurology, University of Alabama at Birmingham, University Station, Birmingham, Alabama 35294, USA.

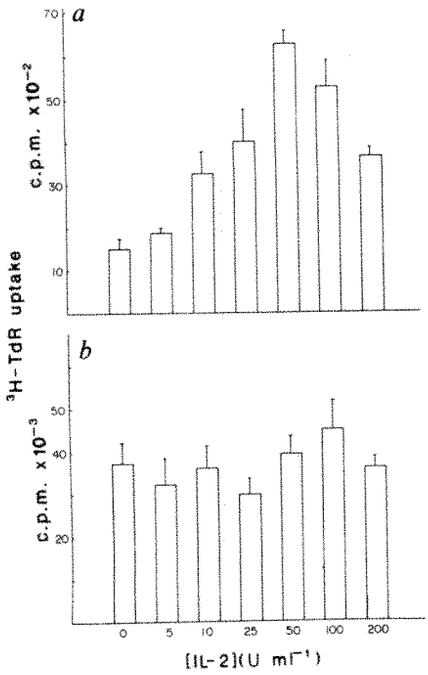

Fig. 1 Effect of recombinant human IL-2 (rIL-2) on oligodendrocyte and astrocyte proliferation. rIL-2 from two sources (Amgen, Thousand Oaks, California and rIL-2 given by Genetics Institute, Boston, Massachusetts) was tested at various concentrations (5–200 U ml^{-1}) on: *a*, oligodendrocytes (2×10^4 cells per well); and *b*, astrocytes (2×10^5 cells per well). The cells were pulsed on day 3 with ^{3}H-TdR, and harvested 17 h later. For oligodendrocytes, three of the experiments were performed with Amgen rIL-2 and three with Genetics Institute rIL-2. The data are expressed as the mean ± s.d. of these six experiments. For the astrocyte experiments, the values represented are the mean ± s.d. of three experiments, all performed with Amgen rIL-2. Control media consisted of 50% Dulbecco's modified essential medium (DMEM), 50% Ham's F-12 medium, 2 mM glutamine, 0.1% gentamycin and 10% FBS. Comparable results for oligodendrocyte proliferation were obtained when the experiments were performed in SFM: DMEM (high glucose formula) supplemented with glucose to a total of 6 g l^{-1}, 0.1 mM non-essential amino-acid mixture, 5 μg ml^{-1} transferrin, 2 mM glutamine and 0.1% gentamycin. Result for experiment using SFM alone = 2,139 ± 222 c.p.m., and for SFM plus 100 U ml^{-1} rIL-2 = 5,494 ± 204 c.p.m.

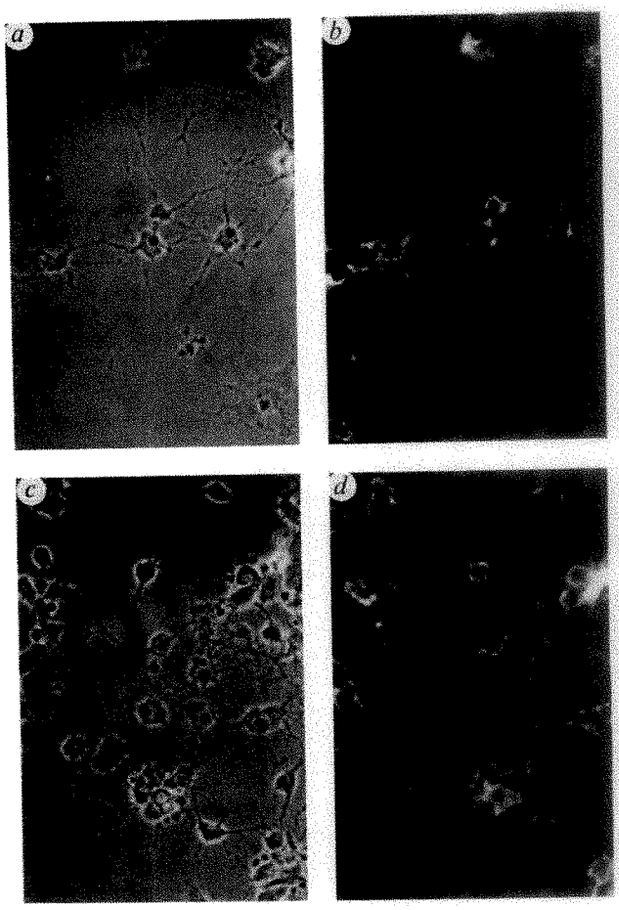

Fig. 2 Photomicrographs of oligodendrocytes after treatment with rIL-2. Phase-contrast microscopy (*a*, *c*) demonstrates the effects of rIL-2 on cultures of rat oligodendrocytes. Cells (2×10^5) were treated for 4 days with either 100 U ml^{-1} of rIL-2 (*c*, *d*) or control media (*a*, *b*). Immunofluorescence staining for GalC demonstrates that rIL-2 stimulated the growth of oligodendrocytes (*d*). Surface staining for GalC was performed for 30 min in the cold with rabbit anti-GalC antibody (1:25), followed by FITC-conjugated F(ab')$_2$ goat anti-rabbit immunoglobulin (1:20; Cappel) for 30 min.

glial progenitor cells[19] and type II astrocytes[15]); and nonspecific esterase, which identifies microglia[12]. Astrocyte populations were more than 95% GFAP-positive before and after stimulation.

We initially tested the ability of partially purified human IL-2 to stimulate enriched populations of both oligodendrocytes and astrocytes. Concentrations of partially purified delectinated IL-2 (Electronucleonics) in the range 0.1–5.0 U ml^{-1} significantly enhanced the proliferation of both cell types, as measured by ^{3}H-TdR incorporation (data not shown). A different pattern emerged when recombinant human IL-2 (rIL-2) was tested. Two different sources of rIL-2 were tested: 99.5% pure recombinant human IL-2 from Amgen and recombinant human IL-2 from Genetics Institute[20]. rIL-2 stimulated the proliferation of oligodendroglial cells (Fig. 1*a*), but not of astroglial cells (Fig. 1*b*). Thus, astrocyte proliferation in response to partially pure IL-2 may result from the presence of other factors or contaminants in the IL-2 preparation. A titration curve demonstrates that oligodendrocytes respond to rIL-2 in a dose-dependent manner: responsiveness begins at 10 U ml^{-1}, with maximal proliferation observed at 50–100 U ml^{-1} (Fig. 1*a*). These rIL-2 concentrations are comparable to those required for human B-cell proliferation[8,9]. Figure 2 shows the oligodendrocyte response to rIL-2: 2×10^5 cells were incubated in 24-well Costar plates with or without rIL-2 for 4 days (previously determined to be the optimal time in culture), after which time the cells were counted and assayed for GalC immunofluorescence. Cell counts were determined by trypsinization of triplicate wells, counting the cells per well, and taking a mean of the three values. The results of three separate experiments indicated that cell numbers were increased in cultures containing rIL-2 (Fig. 2*c*; 5.9×10^5 cells), compared with those without rIL-2 (Fig. 2*a*; 2.5×10^5 cells). Over 90% of the cells in both cultures were positive for GalC (Fig. 2*b*, *d*).

Oligodendrocyte proliferation in response to rIL-2 was confirmed by autoradiography[3,5]. Oligodendrocyte-enriched cultures (89% GalC input cells) were grown for 4 days with or without rIL-2 (100 U ml^{-1}) on sterile coverslips in Costar 24-well plates. The cells were labelled with ^{3}H-TdR (3 μCi per well) for 17 h before collection. After harvesting, the coverslips were washed to remove unincorporated ^{3}H-TdR, and fixed in acetone for 10 s. The slides were then immersed in Ilford K2 nuclear emulsion, exposed for 2 days at 4 °C, and developed. Sister cultures were stained for GalC after stimulation, and were 92%

GalC-positive. In the presence of rIL-2, 60–70% of the cells incorporated ^{3}H-TdR, compared with 10% of cells incubated in control media alone.

At the time of addition of growth factor, oligodendrocyte populations were predominantly GalC-positive. However, there were also 12% A2B5-positive cells, on average (Table 1). The bipotential glial progenitor cell which carries the A2B5 antigen has the ability to differentiate into either an astrocyte or an oligodendrocyte, depending on the culture conditions[14]. To exclude the possibility that our results could be explained by rIL-2 stimulating these progenitor cells instead of exerting a direct effect on GalC-positive cells, the following experiments were performed: oligodendrocyte cultures were treated twice with anti-A2B5 antibody (1:50) plus complement at 37 °C for 30 min to remove progenitor cells[3]. These antibody-treated oligodendrocytes then contained fewer than 4% A2B5$^+$ cells; but they retained the ability to respond to rIL-2 as determined by ^{3}H-TdR incorporation (1,436 ± 449 c.p.m., control media alone; 4,876 ± 222 c.p.m., with rIL-2). This result indicates that rIL-2 directly stimulates the proliferation of GalC$^+$ oligodendrocytes.

Another parameter of oligodendrocyte growth and maturation is the synthesis of myelin basic protein (MBP)[21]. While most oligodendrocytes express the surface antigen GalC[13], the simultaneous expression of GalC and MBP implies a more differentiated state[22]. MBP appears during oligodendrocyte development, and accumulates before the onset of myelination[23]. As determined by double immunofluorescence staining, an increased percentage of GalC$^+$ MBP$^+$ oligodendrocytes (38 ± 5%) was detected in cultures containing rIL-2 for 4 days compared with those in control media alone (11 ± 3%) (Table 2). This finding suggests that rIL-2, in addition to inducing proliferation of oligodendrocytes, enhances and/or accelerates maturation.

Table 2 Immunocytochemical characterization of oligodendrocytes

Total no. of cells counted			% GalC$^+$	% GalC$^+$, MBP$^+$
Expt 1	−IL-2	200	89	14.5
	+IL-2	241	92	32.0
Expt 2	−IL-2	214	89	11.7
	+IL-2	228	91	42.5
Expt 3	−IL-2	170	85	8.0
	+IL-2	168	89	40.5

Double immunofluorescence staining was performed on cultures of oligodendrocytes incubated either in the presence of rIL-2 (100 U ml^{-1}) or in control media alone (−IL-2) for 4 days. Oligodendrocytes (2×10^5) were incubated in Costar 24-well cluster plates on sterile coverslips with or without rIL-2 for 4 days, after which cells were stained for surface (GalC) and cytoplasmic (MBP) markers using indirect immunofluorescence. Surface staining was performed for 30 min in the cold with rabbit anti-GalC (1:25), followed by rhodamine-conjugated F(ab')$_2$ goat anti-rabbit immunoglobulin (1:20; Cappel) for 30 min. The cells were fixed in cold acetone for 10 s, then stained with mouse monoclonal anti-MBP antibody (1:20) for 30 min at room temperature. The cells were then stained with FITC-goat F(ab')$_2$ anti-mouse immunoglobulin (1:20; Accurate). For each experiment, three separate fields (each with a minimum of 150 cells) were counted by phase-contrast microscopy. GalC$^+$ cells were counted using a rhodamine filter, then MBP$^+$ cells were determined with a FITC filter. The values shown are the means of the three fields counted for each individual experiment. Identical experiments performed in serum-free medium (SFM) gave similar results: for SFM alone, 9 ± 1% of cells were GalC$^+$, MBP$^+$; for SFM plus rIL-2, 38 ± 2% of cells were GalC$^+$, MBP$^+$.

Our results demonstrate that rIL-2, a T-cell-derived lymphokine which has previously been shown to influence the growth of T and B cells, is also capable of inducing the proliferation and maturation of rat oligodendrocytes *in vitro*. To our knowledge, this is the first observation of rIL-2 stimulating a non-lymphoid cell, and provides further evidence that the growth of glial cells can be influenced by specific T-cell lymphokines. Our results differ from those of Giulian and Lachman[4], who found that oligodendrocytes did not respond to rIL-2. This discrepancy may be the result of different culture conditions, isolation procedures and age at which the cells were tested. Giulian and Lachman used mixed glial cultures which consisted of both astrocytes and oligodendrocytes. These cells were cultured for 2 days, at which time rIL-2 was added for an additional 3 days. No information was provided as to the number of GalC$^+$ cells or A2B5$^+$ cells present before and after stimulation. In the present study, we used enriched populations of oligodendrocytes obtained after 7–10 days in primary culture. The cells which responded to rIL-2 were predominantly GalC$^+$ oligodendrocytes.

A previous study by Merrill *et al.*[3] indicated that purified human IL-2 stimulated neither astrocytes nor oligodendrocytes. The concentration of IL-2 used in that study was <10 U ml^{-1}, and we now know that oligodendrocyte responsiveness begins at 10 U ml^{-1}, with optimal proliferation at 50–100 U ml^{-1} (Fig. 1*a*). Thus, the concentration of IL-2 used in the previous study was too low to induce oligodendrocyte proliferation.

In the demyelinating disease of multiple sclerosis (MS), there is an astrocytic reaction consisting of hyperplasia and gliosis which results in the formation of brain plaques[24,25]. IL-1 is released in the brain following injury[4], and may mediate inflammation associated with brain injury. In addition, its proliferative effect on astrocytes may promote scar formation in damaged or diseased brain (for example, in MS). The myelin-producing cells, the oligodendrocytes, are to a large extent destroyed during the MS disease process, although a small number do persist and proliferate at the edge of the plaque[26]. The characteristic inflammatory infiltrate in MS consists predominantly of T lymphocytes, with the T-helper/inducer subset being most numerous at the plaque edge, and T-suppressor/cytotoxic cells more abundant within the plaque[27]. Both of these T-cell subsets secrete IL-2 when stimulated[28]. *In situ* lymphoid/mononuclear cells in MS brain secrete immunoregulatory molecules such as IL-2, IL-1 and prostaglandin E_2, which suggests that these cells are activated[29]. In addition, staining with monoclonal antibody to IL-2 is observed in areas of MS brain containing very few lymphoid cells, suggesting that brain cells themselves may provide an endogenous central nervous system source of IL-2 or of an IL-2-like molecule[29]. Astrocytes and glioma cells produce an IL-1-like factor[30,31], which indicates that glial cells are able to secrete immunoregulatory molecules. Oligodendrocytes *in vivo* may encounter IL-2 in the periphery as a result of damage to the blood–brain barrier[32]; alternatively, they may encounter endogenous IL-2 secreted by infiltrating lymphoid cells, or possibly by other brain cells. While we have demonstrated that oligodendrocytes can specifically absorb IL-2 (unpublished observation), it is unknown whether IL-2 acts on oligodendrocytes via the same type of cell-surface receptor as that required for T-cell and B-cell activation. As in the case of IL-1 and insulin, the receptors on different cell types may be distinct. Separate sites on the IL-1 molecule act on fibroblasts and thymocytes[33], while the insulin receptor on rat brain cells is distinct from those on rat liver cells and human lymphocytes[34]. The finding that rIL-2 enhanced MBP expression (Table 2) is particularly intriguing; this may be the result of either accelerated synthesis of MBP or selective proliferation of MBP$^+$ cells. MBP expression in oligodendrocyte cytoplasm precedes myelination[18]. Oligodendrocytes, in the presence of IL-2, may be able to accelerate/enhance their ability to myelinate or remyelinate, which would be beneficial in demyelinating diseases.

We thank Dr Scott Linthicum for the gift of mouse monoclonal anti-MBP antibody, Dr Steve Clark of Genetics Institute for recombinant IL-2, and Richard Burger for preparation of the manuscript. Mechanism of membrane damage mediated by human eosinophil cationic protein

John Ding-E Young*, Christer G. B. Peterson†, Per Venge† & Zanvil A. Cohn*

Recent evidence suggests a role for eosinophil granule proteins in contact-dependent antibody-mediated cytotoxicity[1-3]. Cytolysis may involve a secretory phenomenon whereby granule proteins are released at the site of contact between eosinophil and target cells[1-4]. Several basic proteins have been isolated from eosinophil granules, including the major basic protein[5-7], eosinophil cationic protein[8,9], eosinophil protein-X[10] and eosinophil peroxidase[11]. One of the major granule proteins of human eosinophils is the eosinophil cationic protein (ECP)[3,8,9] which has been shown to damage schistosomula of *Schistosoma mansoni* at concentrations as low as 10^{-7} M (Ref. 12). Here, we describe the formation of functional channels by purified human ECP. The transmembrane pores formed by ECP are relatively voltage-insensitive and non-ion-selective, suggesting a role for channel formation by ECP in target cell damage mediated by eosinophils. Channel formation by granule proteins of immune effector cells[13-20] may represent a general and effective mechanism of target cell killing.

ECP was purified from human eosinophil granules by means of a low-*p*H extraction scheme[8,9]. The purity of the ECP was confirmed by SDS-polyacrylamide gel electrophoresis (Fig. 1*a*) and agarose gel electrophoresis (not shown). Purified ECP showed potent haemolytic activity at submicromolar levels (Fig. 1*b*). Haemolysis by ECP was not dependent on, or enhanced by, the presence of Ca^{2+}, Mg^{2+} or Zn^{2+} but was closely dependent on temperature. Maximal haemolytic activity was observed at 37 °C; below 28 °C haemolysis was decreased several-fold and at 4 °C virtually no haemolysis was observed.

The activity of ECP was also studied using nucleated cells as targets and by monitoring membrane potential changes as a result of incubation with ECP (Fig. 1*c*). All the cells tested (J774 macrophages, CTLL-A11, P388, chicken embryo myotubes) showed rapid and sustained membrane depolarization.

The permeability increase produced by ECP was not restricted to cell membranes. A lipid vesicle-permeability assay, described previously[21,22], was used to study ion fluxes induced by ECP across lipid vesicles (Fig. 1*d*). Vesicles treated with ECP became leaky to monovalent ions (Fig. 1*d*) and also showed some permeability to divalent ions (Ca^{2+}, Mg^{2+}), ^{14}C-sucrose and the fluorescent markers lucifer yellow and carboxyfluorescein.

Voltage-clamped phospholipid planar bilayers[23,24] were used to dissect the permeability properties of ECP. Because of the high impedance of these bilayers, small conductance changes can be measured with better resolution than with other techniques. Planar bilayers formed from egg soybean phospholipids were exposed to nucleus-free homogenates of human eosinophils, derived from three hypereosinophilic patients by means of density gradient centrifugation[25]. Current steps of heterogeneous sizes were immediately observed in the recording, consistent with the incorporation of ion channels into the bilayer (Fig. 2*a*).

Granules from these eosinophils were isolated by centrifugation through a Percoll density gradient[26] and a homogeneous population of granules was obtained, as visualized by electron microscopy (data not shown). Granules were then solubilized in detergent and added to planar bilayers. A significant enhancement of channel activity was observed compared with that obtained with a similar concentration of whole-cell-lysate proteins (Fig. 2*b*). The enhancement of channel activity was even higher when purified ECP was added to lipid bilayers at the same protein concentration (Fig. 2*c*), indicating that ECP is probably responsible for most of the pore-forming activity produced by eosinophil granules. Purified eosinophil protein-X (EP-X) and eosinophil peroxidase produced no channel activity under similar experimental conditions (data not shown).

ECP channels are resistant to closing by high transmembrane potentials. Up to 100 mV, the conductance associated with ECP channels showed little or no relaxation to lower steady-state values in response to voltage pulses (Fig. 3*a*). This is confirmed by a continuous current-voltage (I-V) plot, generated by passing a voltage ramp from −120 to +120 mV (Fig. 3*b*,*c*). As shown in Fig. 3*b*, the current trace became noisy, deviating from linearity only at voltages exceeding 60 mV in either polarity. This region of noise or instability probably represents the closing of individual ECP channels which occurs only at high voltages, as demonstrated with bilayers containing low amounts of ECP channels (Fig. 3*c*). In such bilayers, the voltage-ramp-induced closing of individual channels can be seen as a quantal leap in the current trace (Fig. 3*c*). Thus, human ECP forms stable transmembrane pores which are relatively resistant to the effects of the electrical field, resembling the channels formed by polymerized C9 (unpublished observations) and by the pore-forming protein isolated from granules of cytotoxic T lymphocytes and natural killer (NK)-like cells[16,19,20].

Single-channel fluctuations were observed only at high transmembrane potentials (Fig. 4). In 0.1 M NaCl ECP channels show unit conductances of 120 ± 7 pS ($n = 432$ events; range 95-150 pS). At least two intermediate conductance states were identified, usually observed when channels flickered between open and closed states at high voltages. ECP channels showed

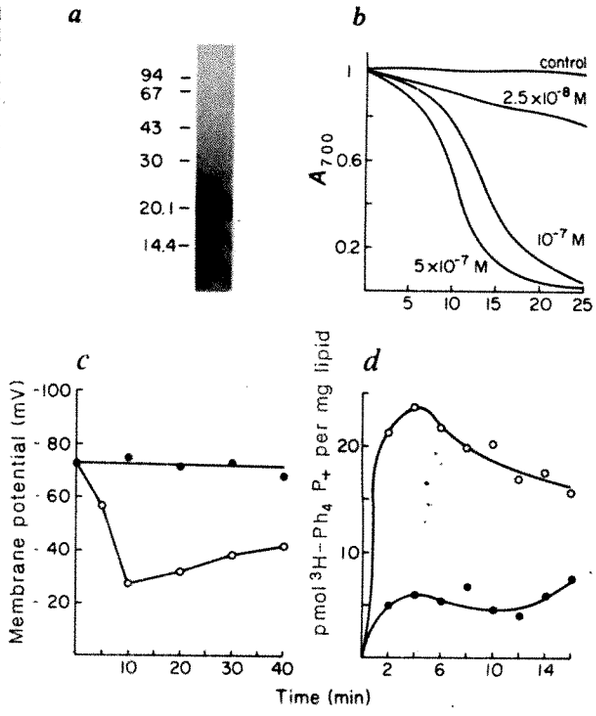

Fig. 1 *a*, SDS-polyacrylamide gel electrophoresis profile of ECP. 10 μg ECP was applied under reducing conditions to a 12.6% polyacrylamide gel slab. The three closely spaced bands migrating with relative molecular mass (M_r) 18,000–21,000 showed cross-reactivity on immunoblotting, using monospecific polyclonal and monoclonal antibodies directed against ECP. The purity of ECP was also ascertained by double immunodiffusion, agarose gel electrophoresis and by radioimmunoassays using a library of polyclonal and monoclonal antibodies directed against several granule proteins from eosinophils and neutrophils. *b*, Kinetics of haemolysis produced by human ECP at 37 °C. Sheep red blood cells (SRBC) were washed and resuspended to 10^6 ml^{-1} in phosphate-buffered saline (PBS) containing 1% Vitrogen (Gibco) with 1 mM $CaCl_2$. ECP in PBS was added in small aliquots (1:100–1:1,000 dilution) to the final concentrations indicated and haemolysis assayed continuously by absorbance reading at 700 nm. Haemolysis curves represent absorbance recordings traced over with continuous lines. *c*, Effect of ECP on cell membrane potential of J774 macrophage-like cells plated on coverslips, as assayed by the uptake of ^{3}H-tetraphenylphosphonium ion (^{3}H-Ph$_4$P$^+$)[16,18,34]. ECP in PBS was added to cells at 37 °C to 10^{-6} M for the indicated periods (○), at which time the medium was aspirated and the coverslips rapidly washed by immersing them four times in separate beakers containing ice-cold PBS and 1 mg ml^{-1} bovine serum albumin (BSA). Cells were lysed in 0.5 ml of 0.05% Triton X-100 and 0.25-ml aliquots assayed for radioactivity. Values for ^{3}H-Ph$_4$P$^+$ trapped in the cells were against background and converted into $\Delta\Psi$ values as previously described[22]. ●), Control: PBS was added to cells. Data points represent average of four experiments. *d*, Ion fluxes in lipid vesicles. The uptake of ^{3}H-Ph$_4$P$^+$ into lipid vesicles was quantitated by filtration[22]. The reaction was initiated by diluting 0.1 ml of lipid vesicles into 0.9 ml of 0.25 M sucrose, 1 ml $CaCl_2$, 10 mM HEPES, *p*H 7.0, containing 50 μM ^{3}H-Ph$_4$P$^+$ and 10^{-6} M ECP (○) or control PBS (●). At intervals, aliquots of the reaction mixture were filtered and washed, and the radioactivity remaining on the filter determined[22]. Data points represent the average of experiments performed in triplicate. All experiments were done at 37 °C.

Methods. ECP used in this study was derived from either normal human blood buffy coat cells or from patients with hypereosinophilia. Leukocytes (~10^{12} cells) were homogenized in 0.34 M sucrose and centrifuged at 800*g* for 15 min to sediment nuclei and large cell debris. The supernatant was then centrifuged at 10,000*g* for 15 min. The enriched granule fraction was extracted with 10 vol. of 0.2 M ammonium acetate buffer, *p*H 4, and centrifuged at 20,000*g* for 30 min. The supernatant was eluted though Sephadex G-75 with 0.2 M ammonium acetate, *p*H 4, and ECP-containing fractions concentrated by ultrafiltration on a Diaflow PM-10 membrane. ECP was further purified by ion-exchange chromatography on Bio-Rex 70 (200–400 mesh; Biorad), equilibrated with 0.09 M ammonium acetate, *p*H 8.4, and 8.7% glycerol and eluted on a 0.09–0.9 M gradient of ammonium acetate, *p*H 8.4–9.3, and 8.7% glycerol. Cells plated overnight on coverslips were washed three times with low-K$^+$ buffer (118 mM KCl, 1.3 mM $CaCl_2$, 0.8 mM $MgSO_4$, 5.5 mM glucose, 20 mM HEPES, 9 mM Na_2CO_3, *p*H 7.4) and incubated with 20 μM ^{3}H-Ph$_4$P$^+$ for 30 min at 37 °C. Lipid vesicles were formed from a mixture of phosphatidylethanolamine/phosphatidylcholine/cholesterol at a wt ratio of 3:2:1 and 25 mM β-D-octylglucoside in 0.05 M Na-isethionate, 0.165 M sucrose, 1 mM $CaCl_2$ and 10 mM HEPES, *p*H 7.0 (buffer A). The mixture was sonicated to clarity and vesicles were formed by a one-step 1:100 dilution with buffer A[21]. Vesicles were sedimented by centrifugation at 100,000*g* for 90 min and resuspended to 10 mg ml^{-1}.

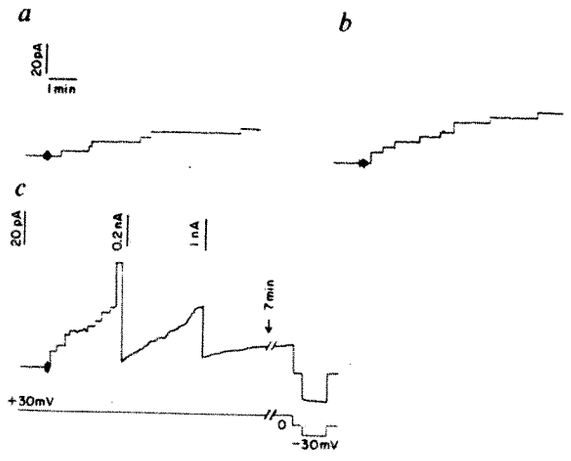

Fig. 2 Effect of eosinophil-derived material and ECP on planar bilayers. Bilayers[22,24] were formed in 0.1 M NaCl, 1 mM $CaCl_2$, 3 mM NaN_3, 10 mM HEPES, *p*H 7.0 (buffer C), and clamped at +30 mV throughout the experiments unless otherwise indicated (the positive side was named the *cis* side). Baseline conductances did not exceed 10 pS. Reagents were introduced into the aqueous phase of the *cis* side, followed by stirring for 15–20 s (which explains the noise in the recording). *a*, Eosinophils were enriched from the blood of a patient with eosinophilia (42% eosinophil count) by density gradient centrifugation[25], resulting in a 94% enrichment, and an aliquot (5 μg protein, 10-μl vol.) containing 0.1% Triton X-100 was introduced into the *cis* side of a bilayer bathed in 4 ml of buffer C. Note the upward deflection of current in steps. Two other patients with eosinophilia were used as sources of cells, yielding comparable results. Time resolution 1 ms; temperature 22 °C. *b*, Granules were obtained from eosinophil lysates by centrifugation, and 5 μg of granule protein in a 10-μl volume containing 0.1% Triton X-100 was added through the aqueous phase of a bilayer (noise). Same scale as in *a*. *c*, 5 μg of ECP, purified from granules as described in Fig. 1 legend and dialysed against buffer C, was added to a bilayer. At the points indicated, the current gain was reduced to accommodate the progressive rise of current. The lower trace shows the applied voltage; the parallel bars represent a lapse of 7 min. Note the many-fold enrichment of channel activity compared with *a* and *b*. The voltage polarity was switched to −30 mV to demonstrate that the amplitude of the current remained unchanged, suggesting that channel activity was not dependent on voltage polarity. ECP incorporated into bilayers in the absence of any detergent. The channel activity from granules could also be incorporated without detergent provided that granules were first ruptured by sonication, freeze-thawing or high-salt extraction.

Methods. Eosinophils, enriched as described previously[25], were washed in relaxation buffer (130 mM KCl, 4 mM NaCl, 1 mM disodium ATP, 2 mM $MgCl_2$, 10 mM HEPES, *p*H 6.8) and resuspended to 5×10^7 ml^{-1}. Cells were cavitated under N_2 (500 p.s.i., 25 min) and collected dropwise in the presence of EGTA, to a final EGTA concentration of 1 mM. After removal of nuclei and unbroken cells (800*g*, 15 min), the cell extract was sonicated for 1 min on ice and dialysed against buffer C. Triton X-100 (0.5%) was added to this cell lysate and the whole mixture was vortexed vigorously. Cell cavitate in relaxation buffer was centrifuged through a pre-formed continuous Percoll gradient[26] (densities 1.02–1.14 g ml^{-1}) at 20,000*g* for 35 min in a Sorvall SS-34 rotor. Granule enrichment was ascertained by β-glucuronidase assay and by ultrastructural examination (not shown). After removal of Percoll[26], granules were sedimented at 13,000*g* for 15 min and resuspended in buffer C to 1 mg protein ml^{-1}.

slow kinetics even at high voltages, with the open channel lifetime persisting for up to several minutes (Fig. 4*c*).

The ion selectivity of ECP channels was determined from the reversal potential necessary to nullify current flow from a 10-fold higher electrolyte concentration (*cis* or positive compartment made more concentrated). The results of such experiments showed permselectivity ratios of 1.00:0.93:0.58:0.21 for $K^+/Na^+/Cl^-/Ca^{2+}$. Similarly, Mg^{2+}, Ba^{2+}, Zn^{2+}, $EGTA^-$, $HEPES^-$, $Tris^-$ and glucosamine (Stokes diameter of 8 Å) also permeated through these channels. Lipid vesicles exposed to ECP for 16 h at 37 °C were examined by negative-contrast electron microscopy. The vesicle interior was stained with uranyl formate, in contrast to control vesicles which excluded the stain (data not shown). These data indicate that the channels formed by ECP are non-ion-selective and of large functional diameter. The relative molecular mass cutoff associated with these pores is being investigated.

No specific lipid requirement for formation of channels by

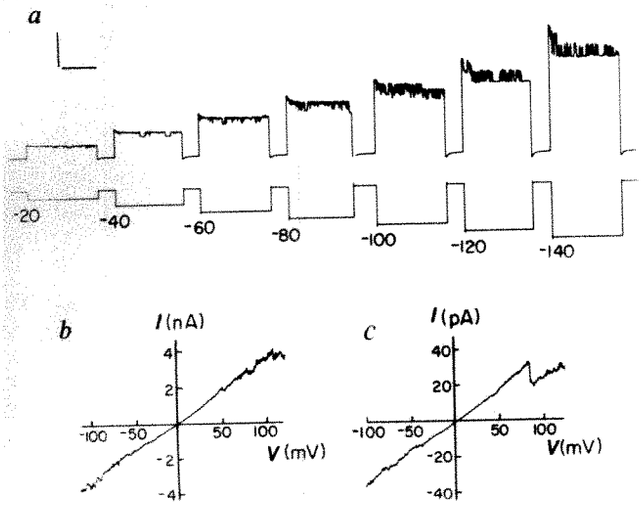

Fig. 3 Effect of electrical field on ECP channels. *a*, A membrane formed in buffer C was treated with 1 μg of ECP for 30 min prior to application of voltage pulses, in 20-mV increments. Upper and lower traces correspond to current (*I*) and voltage (*V*), respectively. Between two pulses, the membrane was allowed to remain at 0 mV for 10 s. Note that the initial capacitative current relaxed to lower steady-state values only at voltages exceeding 80 mV. Increased noise in the recording was associated with current relaxation, corresponding possibly to channel flickering activity at high voltages. Scale bars: 50 pA (vertical) and 20 s (horizontal). *b*, Membrane treated with 1 μg ECP as in *a* and subjected to a continuous voltage ramp running from −120 to +120 mV in 900 ms. The current record became noisy at high voltage but note the relatively small deviation from linearity even at high voltages. *c*, Membrane containing fewer channels after exposure to 0.1 μg ECP and subjected to a voltage ramp as in *b*. The downward deflection of current represents closing of one single ECP channel. This result demonstrates that the increase of noise in a many-channel bilayer induced by high voltages (*a*) can be explained by the voltage-dependent behaviour of each individual channel unit.

ECP was observed. Changing the lipid composition of the bilayer from a mixture of phospholipids to pure phosphatidylethanolamine, phosphatidylcholine or cholesterol membranes did not change the overall characteristics of the channel. At 37 °C, the rate of channel incorporation into planar bilayers was markedly enhanced (data not shown), an observation which is consistent with the temperature dependence of haemolysis.

Pore formation by ECP may represent the mechanism by which this protein damages target cell membranes. The lack of channel-forming activity associated with other granule proteins such as EP-X or peroxidase suggests that pore formation is a function specifically associated with ECP. Preliminary experiments with MBP do not indicate any functional channel formation associated with this protein. MBP has been shown to damage parasites[27,28] and cells[29] but at concentrations exceeding 10^{-5} M. At these concentrations, it is possible that surface charge interaction with negatively charged membranes may result in the increased permeability of target membranes[30,31] without concomitant formation of transmembrane channels.

Pore formation has been associated with a number of different cytolytic proteins in the immune effector system. The prototype of the channel former is the terminal membrane attack complex of complement which appears to be formed mainly by a single protein species, polymerized C9 (ref. 32 and J.D.-E Y., in preparation). A pore-forming protein has also been isolated from granules of cytotoxic T lymphocytes and NK-like cells[16–20], and from the protozoan parasite *Entamoeba histolytica*[21,33] and implicated in cell killing. Pore formation may therefore represent a general and well conserved immunological mechanism by which effector proteins inflict target membrane damage.

A novel cell surface molecule on early B-lineage cells

Max D. Cooper*, David Mulvaney*, Antonio Coutinho† & Pierre-André Cazenave†

B cells and their antibody-secreting progeny represent one of several differentiation pathways that haematopoietic stem cells (HSC) may enter[1,2]. Cells representing intermediate stages between HSC and B cells have been identified in mammalian haematopoietic tissues[3,4] and studied intensively over the past decade. This population of early B-lineage cells, termed pre-B, is characterized by cellular proliferation and an orderly cascade of immunoglobulin gene rearrangements[5-7], a combination of events leading to the generation of clonally diverse B cells which then migrate to peripheral lymphoid tissues. It remains to be determined what elements determine the polyclonal growth of pre-B cells, how immunoglobulin gene rearrangements are regulated, and what happens to pre-B cells undergoing 'non-productive' immunoglobulin gene rearrangements. These issues could be resolved more easily if early B-lineage cells could be identified precisely and isolated. Here, we describe a cell surface glycoprotein that is selectively expressed by pre-B and newly formed B cells in murine haematopoietic tissues. The molecule, a homodimer formed by disulphide-linked chains of relative molecular mass (M_r) 140,000, is identified by a mouse monoclonal alloantibody called BP-1.

Previous attempts to identify cell surface molecules on pre-B cells have involved immunizing rats with mouse pre-B-cell lines, and fusion of the rat spleen cells to form antibody-producing hybridomas. Monoclonal antibodies which identify cell surface molecules on murine pre-B cells have been produced in this manner, but they do not identify differentiation antigens exclusive to early B-lineage cells[8-12]. We have used an alloimmunization strategy to produce such monoclonal antibodies (named BP antibodies to indicate collaboration between our laboratories in Birmingham and Paris) against pre-B and associated cell types.

Mus spretus, a wild mouse captured in Spain (Mus 3 biochemical group[13]), was selected for immunization, and the Abelson murine leukaemia virus-transformed cell line 18.81 was used as the immunogen; this pre-B-cell line is of BALB/c (Mus 1) origin[14]. Following immunization of *Mus spretus* with 18.81 cells, spleen cells were fused with SP2/0 myeloma cells[15]. One resultant hybridoma (G10) produced an IgG2a antibody (BP-1) which reacted with 18.81 cells (Fig. 1*A*) but not BALB/c thymocytes. Immunofluorescence microscopy revealed that crosslinkage of the 18.81 cell surface antigen by the BP-1 antibody (plus a second fluorescein-labelled goat antibody to mouse γ2a heavy chain) induces the formation of fluorescent caps, suggesting that BP-1 reacts with a surface molecule having a transmembrane connection to intracellular contractile elements.

When normal lymphoid tissues from perinatal mice of Mus 1 strains were examined by indirect immunofluorescence, BP-1$^+$ cells were found in the haematopoietic liver and spleen, but not in the thymus. In adult mice, approximately 10% of nucleated cells in bone marrow expressed BP-1 antigen on their surface, but not in the cytoplasm. When bone marrow cells were fixed following surface immunofluorescence staining with BP-1 (fluorescein label)[16] and then stained with anti-μ-chain antibodies (rhodamine label), all cytoplasmic μ^+ cells were BP-1$^+$. The intensity of surface staining of BP-1$^+$ cells from normal haematopoietic tissues was much lower than that of pre-B cells of the 18.81 line (Fig. 1).

Most IgM$^+$ B cells in haematopoietic tissues expressed the BP-1-reactive determinant. In adult bone marrow an average of 61% (s.e. = ±4.6%) of the B cells expressed the BP-1 antigen, as did ~80% of B cells in the neonatal liver. In contrast, BP-1$^+$ cells were not found in non-haematopoietic lymphoid tissues: thymus, spleen, lymph nodes, intestinal Peyer's patches and peritoneal cells from adult mice. None of the cells expressing the Thy-1 (ref. 17), Mac-1 (ref. 18) or BP-2 (an alloantigen on granulocytes; our unpublished observations) antigen markers of T cells and myeloid cells were BP-1$^+$, nor were cells of erythroid, megakaryocytic, endothelial, epithelial or connective tissue lineages.

Table 1 Reactivity of antibodies BP-1 and 14.8 with transformed B-lineage cells

Cell line	Maturational stage	Immunofluorescence intensity* BP-1	14.8
18.81	Pre-B	17.1	20.1
70Z	Pre-B/B	4.0	36.9
38C-13	Immature B	2.9	26.1
4.5	Mature B	1.2	35.5
BCL-1	Mature B	1.0	31.6
WEHI 279	Mature B	1.0	3.2
Ag8.563	Plasmacytoma	1.1	3.3
43.5	Plasmacytoma/pre-B hybridoma	1.0	1.4
56.3	Plasmacytoma/pre-B hybridoma	1.0	1.5

* The ratio of the staining intensities of BP-1 and 14.8 (ref. 5) to the background fluorescence. Methods used for immunofluorescence analyses are described in Fig. 1 legend.

* Unusual immunofluorescence reactivity pattern characterized by the absence of the discrete micro-immunofluorescence patches noted (by fluorescence microscopy) on bone marrow cells from the other Mus 1 strains.

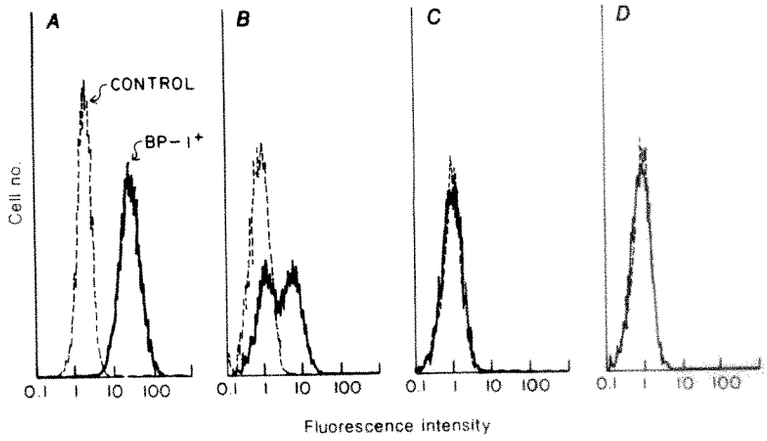

Fig. 1 Immunofluorescence analysis of the reactivity of various cells with the BP-1 monoclonal antibody. The results obtained with cells from different sources (*A*, 18.81 cells; *B*, bone marrow; *C*, spleen; *D*, lymph node) are presented as fluorescence histograms with the relative number of cells plotted on a linear scale and the relative fluorescence intensity on a logarithmic scale, both in arbitrary units. Solid lines indicate the staining intensity of the cell-bound BP-1 antibody (IgG2a) detected by fluorescein isothiocyanate-labelled antibodies to mouse IgG2a. Broken lines indicate staining of the cells with the second antibody alone.

Methods. Viable cells, teased from their tissue sources, were suspended in phosphate-buffered saline (PBS, *p*H 7.4) containing 3% bovine serum albumin and 0.2% sodium azide, filtered through a loose glass wool column, washed by centrifugation and incubated (20 min at 4 °C) with supernatant of hybridoma clone G10-All containing the BP-1 antibody. After extensive washing the cells were incubated with affinity-purified, fluorescein-conjugated goat antibodies to mouse γ2a heavy chains (0.025 mg ml^{-1}; fluorescein/protein molar ratio = 3.9; Southern Biotechnology Associates). The relative fluorescence intensities of individual cells were measured by automated flow cytometry using the FACS IV instrument (Becton Dickinson Immunocytometry Systems) equipped with a 2-W argon laser. Forward-angle light scatter was used to exclude erythrocytes, dead cells and debris from the analysis. In addition, the bone marrow sample was pre-sorted to remove myeloid cells reactive with the BP-2 monoclonal antibody.

BP-1$^+$ and BP-1$^-$ populations of bone marrow cells were separated by fluorescence-activated cell sorting (FACS). Because myeloid cells display considerable autofluorescence and the staining intensity of BP-1$^+$ cells is relatively low, cells of granulocytic lineage were first removed, on the basis of their immunofluorescence staining with the BP-2 monoclonal alloantibody. Residual bone marrow cells were predominantly lymphoid in appearance, and about half expressed μ-chains. Analysis of this population by automated flow cytometry revealed a roughly equal division of BP-1-positive and -negative cells (Fig. 1*B*). When these two subpopulations were separated, ~90% of the BP-1$^+$ population were found to express μ-chains while <10% of the BP-1$^-$ population were positive for μ-chains. Pre-B cells and most of their B-cell progeny in normal haematopoietic tissues can thus be isolated on the basis of their selective expression of the BP-1 antigen.

Various T-cell lines (BW5147, EL4, B6, KGV, PP16, PP17), macrophage lines (A3, P388D) and a mastocytoma cell line (P815) did not react with the BP-1 antibody. Neoplastic representatives of mature B and plasmacytoid cells also did not react with the BP-1 antibody, while transformed cells of pre-B and immature B phenotypes expressed the BP-1 antigen, the relative amounts of which decreased as a function of maturational stage (Table 1). For example, the BP-1 immunofluorescence staining intensity of the 38C-13 B-cell line, which expresses IgM only[19], was approximately three times the background fluorescence level, whereas the IgM$^+$/IgD$^+$ BCL-1 line[20] has no demonstrable BP-1 reactivity. As is the case for normal B-lineage cells, neoplastic B cells exhibited discordant expression of the BP-1 and 14.8 (B220) antigens.

Control of BP-1 expression was examined by immunofluorescence analysis of hybridomas formed by fusion of the non-immunoglobulin producer Ag8.653 plasmacytoma cells with normal pre-B cells from fetal liver. While these hybridomas display the pre-B-cell characteristics of intracytoplasmic heavy-chain expression and non-rearranged light-chain genes[21-23], there was no apparent expression of the BP-1 antigen. Three additional hybridomas formed by fusion of Ag8.563 with the 18.81 pre-B-cell line[24] also failed to express the BP-1 antigen while continuing to express the 14.8 determinant. This suggests a *trans* gene control of down-regulation of BP-1 expression with progression of B-cell differentiation.

Wild mice belonging to the genus *Mus* have been assigned to five biochemical groups based on protein electrophoretic polymorphisms[13]. Our examination of bone marrow samples revealed BP-1-reactive cells in Mus 1 strains, but not in mice representative of other biochemical groups (Table 2). Common laboratory strains of inbred mice (BALB/c, CBA/N, CBA/HeJ, Swiss, DBA/2) also had BP-1$^+$ cells in their bone marrow.

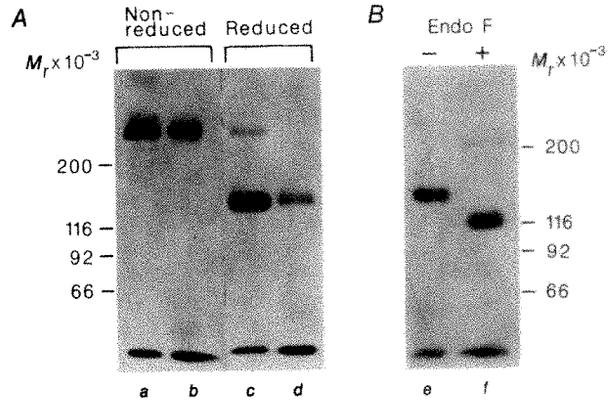

Fig. 2 SDS-polyacrylamide gel electrophoresis (PAGE) of ^{125}I-labelled membrane proteins of 18.81 and bone marrow cells. *A*, The BP-1-reactive molecules in lanes *a* and *c* were derived from 18.81 cells, and those in lanes *b* and *d* from normal bone marrow cells. No bands were seen in control lanes, which consisted of material dissociated from wells coated with irrelevant antibody. *B*, BP-1-reactive molecules examined under reducing conditions and following cleavage of complex sugars by overnight treatment with endoglycosidase F at 37 °C (ref. 29).

Methods. Cells (5.5–7.5 × 10^7) were surface-labelled with 2 mCi of Na^{125}I (Amersham) using the lactoperoxidase-catalysed method[25], washed and lysed in Nonidet P-40 (1% in 0.05 M Tris *p*H 7.5) containing 0.15 M NaCl, 0.02% NaN_3, 50 mM iodoacetamide, 1 mM phenylmethylsulphonyl fluoride, 20 mM ε-amino-*n*-caproic acid and 0.01% soybean trypsin inhibitor at 4 °C for 30 min. The cell lysate was centrifuged at 10,000*g* for 15 min and the supernatant precleared by overnight incubation at 4 °C in a plastic well precoated first with goat antibodies to mouse immunoglobulin, then with a mouse monoclonal antibody to chicken IgM. Precleared cell lysate supernatants were incubated overnight in plastic wells precoated with goat antibody to mouse immunoglobulin and the BP-1 antibody. The wells were washed and BP-1-reactive molecules dissociated from the plate by incubation with 2% SDS without or with 5% 2-mercaptoethanol (reducing conditions) for 1 h at 37 °C. Aliquots of antigens dissociated from the immunocomplexes were examined by SDS-PAGE using 5% polyacrylamide slab gels[27]. Gels were fixed, dried and autoradiographed on Kodak SB-5 film with an enhancing screen.

When surface proteins on 18.81 cells were radiolabelled[25] with ^{125}I and the BP-1-reactive molecules isolated[26] and analysed by electrophoresis in sizing gels (SDS-polyacrylamide, 5–12%)[27],

a band of M_r ~250,000 (250K) was identified under non-reducing conditions. A single band of M_r ~140K was generated under reducing conditions for disulphide bonds (Fig. 2). Internal labelling of 18.81 cells with ^{23}S-methionine, followed by sizing gel analysis of BP-1-reactive material, also revealed a molecule comprising disulphide-linked subunits of ~140K. The 140K band could be detected when the BP-1 antibody was used to identify reactive molecules after electrophoresis of an 18.81 cell lysate (reducing conditions) and transfer of the separated proteins to a nitrocellulose membrane[28], indicating relative stability of the antigenic determinant on individual subunits. When BP-1-reactive molecules on 18.81 cells were isolated, reduced and treated with endoglycosidase F (Endo F) to remove *N*-linked oligosaccharides[29], the M_r of the subunits was reduced to ~115K (Fig. 2*B*).

BP-1-reactive molecules of identical size and composition were also found in normal bone marrow (Fig. 2*A*) and in 18.81, 70 Z and 38C-13 cell lines (data not shown). Immunochemical analysis failed to reveal BP-1-reactive molecules on cells from spleen, brain and kidney or on cell lines representative of later stages in B-cell differentiation.

The restricted expression of the BP-1 alloantigen suggests that it could serve as a cell adhesion molecule for early B-lineage cells, or it could be a receptor for a unique induction signal. Noteworthy in the latter regard is the relatively high expression of BP-1-reactive molecules by transformed as opposed to normal pre-B cells. Whatever the functional role of this surface molecule, the BP-1 antibody provides an incisive probe with which to explore early events in the differentiation of normal and neoplastic B-cell clones. The alloimmunization strategy used to produce this antibody could be useful for identifying a variety of highly conserved molecules involved in cellular differentiation.

We thank Larry Gartland and Lanier Agar for help with the FACS analyses; Chen-lo Chen, Eliane Barbier and Hiromi Kubagawa for help with immunochemical studies; Peter Burrows, John Kearney, Paul Kincade, Ingrid Haas and Carol Gulis for helpful discussions and cell lines; Southern Biotechnology Associates for fluoresceinated antibodies; and Ann Brookshire and Maxine Aycock for help in preparing the manuscript. This work was supported by USPHS grants CA 16673 and CA 13148, and by INSERM and Mission Scientifique.

Chloroquine and ammonium chloride prevent terminal glycosylation of immunoglobulins in plasma cells without affecting secretion

Bernard Thorens & Pierre Vassalli

Department of Pathology, University of Geneva, Centre médical universitaire, CH-1211 Geneva 4, Switzerland

The generation of an acidic *p*H in intracellular organelles is required for several membrane and protein recycling processes. For instance, the internalization of ligands by receptor-mediated endocytosis is followed by the development of an acidic *p*H inside endosomes; this allows dissociation of the ligand, which is then transported to the lysosomes, from the receptor, which is recycled to the cell surface[1-4]. There is evidence that part of this recycling process involves the distal region of the Golgi complex, where terminal glycosylation occurs: when the plasma membrane transferrin receptor is desialylated by neuraminidase treatment, it acquires new sialic acid molecules after endocytosis and before cell-surface re-expression[5]. Golgi membranes have been shown to contain a proton pump[6] and the distal Golgi cisternae appear to have an acidic content[7]. Here, we have studied the effects of chloroquine and ammonium chloride, which raise the *p*H of acidic intracellular compartments[8], on the processing and secretion of immunoglobulins by plasma cells. Sialic acid transfer to terminal galactose residues, a reaction known to occur in the distal Golgi shortly before secretion[9], is completely and rapidly inhibited in the presence of these drugs, without significant modification of the secretion rate. This effect is accompanied by a dilatation of the Golgi cisternae and is not rapidly reversible.

Biosynthetically labelled immunoglobulin μ-chains are secreted in the form of pentameric IgM by mouse plasma cells; when fully reduced and alkylated, they have a retarded mobility on SDS-polyacrylamide gel electrophoresis (PAGE) compared

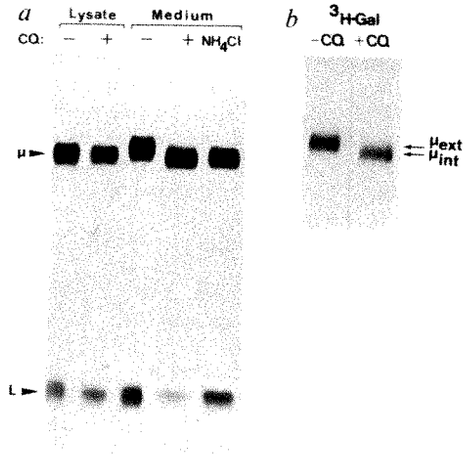

Fig. 1 *a*, Plasma cells, elicited in spleen cell cultures by *Escherichia coli* lipopolysaccharide[18], were labelled biosynthetically with 100 μCi ml^{-1} ^{35}S-methionine for 1 h, the lysates and media were prepared and immunoglobulins were immunoprecipitated and analysed by SDS-PAGE[19] (17.5% polyacrylamide). Chloroquine (CQ) was at 100 μM and ammonium chloride (NH_4Cl) at 10 mM. μ, μ-chains; L, light chains. *b*, Plasma cells were labelled biosynthetically for 1 h with 100 μCi ml^{-1} ^{3}H-galactose in Dulbecco's modified Eagle's medium containing 0.1 mg ml^{-1} glucose and 10% dialysed fetal calf serum, in the presence or absence of 100 μM chloroquine. Secreted μ-chains were on the same gel, analysed as in *a*. μ_{ext}, Mobility of secreted normal μ-chains; μ_{int}, mobility of intracellular incompletely glycosylated μ-chain precursors.

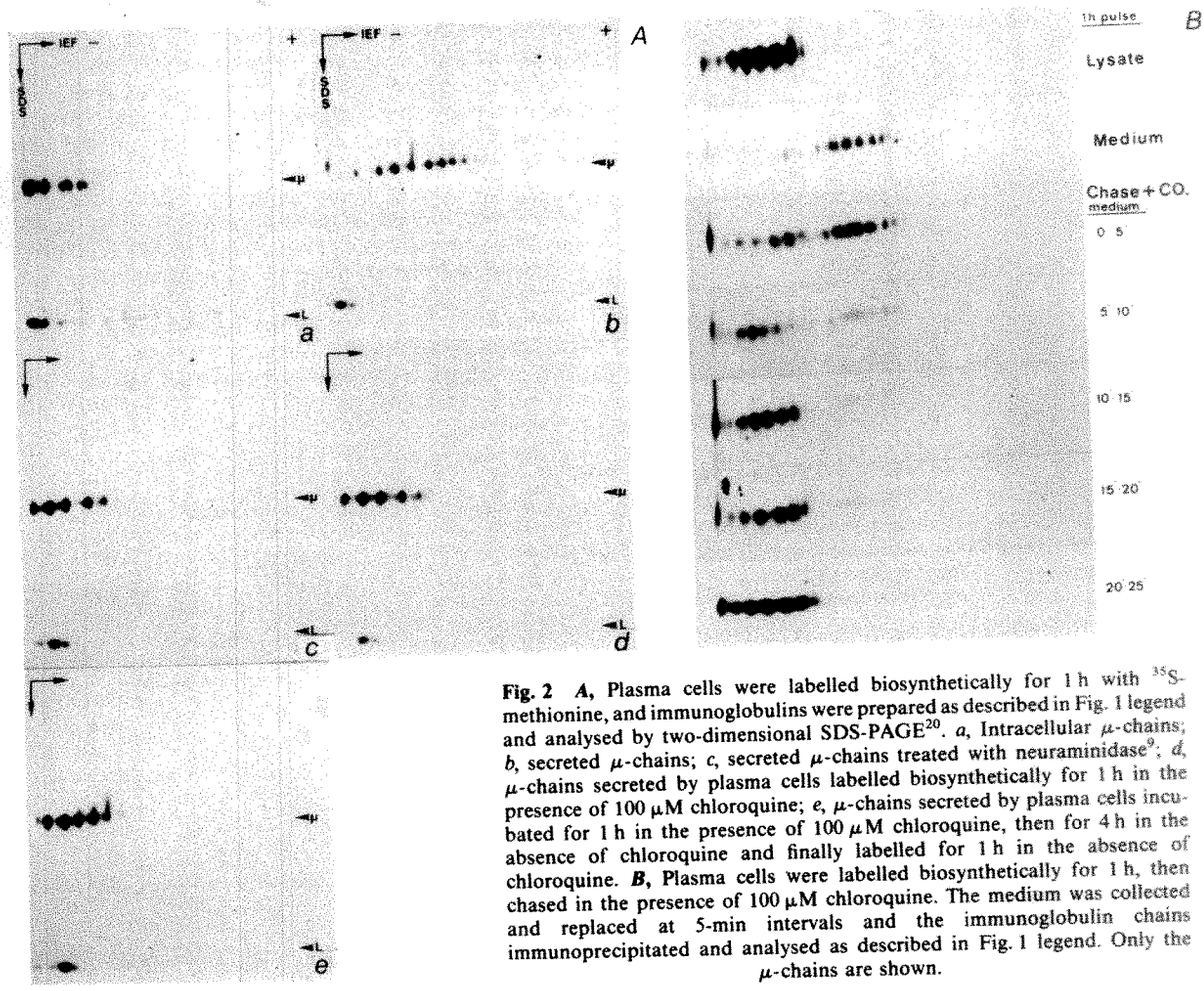

Fig. 2 ***A***, Plasma cells were labelled biosynthetically for 1 h with ^{35}S-methionine, and immunoglobulins were prepared as described in Fig. 1 legend and analysed by two-dimensional SDS-PAGE[20]. *a*, Intracellular μ-chains; *b*, secreted μ-chains; *c*, secreted μ-chains treated with neuraminidase[9]; *d*, μ-chains secreted by plasma cells labelled biosynthetically for 1 h in the presence of 100 μM chloroquine; *e*, μ-chains secreted by plasma cells incubated for 1 h in the presence of 100 μM chloroquine, then for 4 h in the absence of chloroquine and finally labelled for 1 h in the absence of chloroquine. ***B***, Plasma cells were labelled biosynthetically for 1 h, then chased in the presence of 100 μM chloroquine. The medium was collected and replaced at 5-min intervals and the immunoglobulin chains immunoprecipitated and analysed as described in Fig. 1 legend. Only the μ-chains are shown.

with intracellular μ-chains, due to the complete glycosylation of their oligosaccharide side chains (ref. 9 and Fig. 1). When plasma cells were labelled in the presence of chloroquine or ammonium chloride, the secreted μ-chains had the same mobility as their intracellular precursors (Fig. 1*a*), indicating that the glycosylation process was impeded. To determine the nature of the missing sugar residues, plasma cells were labelled biosynthetically in the presence of ^{3}H-galactose, the penultimate sugar residue in complex-type *N*-linked oligosaccharides. Figure 1*b* shows that the presence of chloroquine did not prevent the addition of ^{3}H-galactose to μ-chains and that the galactose-labelled chains secreted by the chloroquine-treated cells also had a higher mobility. The degree of sialylation of μ-chains was then assessed by two-dimensional SDS-PAGE (Fig. 2*A*). Heavy μ-chains secreted by plasma cells have more acidic *p*Is (Fig. 2*Ab*) than do intracellular μ-chains (Fig. 2*Aa*) (the vast majority of which have not undergone terminal glycosylation, topologically and chronologically a very late event in the intracellular pathway[9]). This difference in *p*I was totally suppressed after treatment of secreted immunoglobulins with neuraminidase (Fig. 2*Ac*). Secreted μ-chains synthesized in the presence of chloroquine (Fig. 2*Ad*) or ammonium chloride (not shown) had the same mobility as unsialylated μ-chains.

Pulse-chase experiments showed that the abolition of immunoglobulin sialylation by these drugs is induced very rapidly, but is not rapidly reversible and has no effect on the kinetics of immunoglobulin secretion. Plasma cells were first labelled biosynthetically for 60 min to allow homogeneous labelling of the immunoglobulins present along the secretory pathway, then placed in a chase medium containing chloroquine; the medium was collected and replaced at 5-min intervals. Two-dimensional SDS-PAGE showed that μ-chains lacking sialic acid could be detected within 5 min of chloroquine addition, and that sialylated μ-chains were dramatically reduced after 10 min of chloroquine treatment (Fig. 2*B*). To explore the reversibility of this inhibition, plasma cells were treated for 1 h with chloroquine without labelling, then placed in a medium without chloroquine for 4 h and finally pulse-labelled for 1 h: the secreted μ-chains were still not sialylated (Fig. 2*Ae*), indicating that the effect of the drug is not rapidly reversible. Similar observations were made with ammonium chloride (not shown). That this inhibition of sialylation has no significant effect on the kinetics of immunoglobulin secretion was found by labelling plasma cells for 30 min then chasing for periods of various length, in the absence or presence of chloroquine; analysis of the μ-chains remaining in the cells or secreted in the medium at these various intervals (Fig. 3) showed that the presence of the drug did not significantly modify the secretion rate.

To explore the possibility that the inhibition of sialylation resulted from a greater sensitivity of sialyltransferase than galactosyltransferase to changes in *p*H or to the presence of high concentrations of chloroquine, plasma cell membranes were

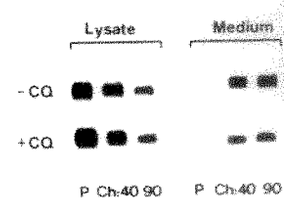

Fig. 3 Plasma cells were labelled biosynthetically with ^{35}S-methionine for 30 min (P), then chased (Ch) for 40 or 90 min, in the presence or absence of 100 μM chloroquine (CQ). The μ-chains present in the lysates of, and secreted by 2×10^{6} cells were immunoprecipitated and analysed by SDS-PAGE.

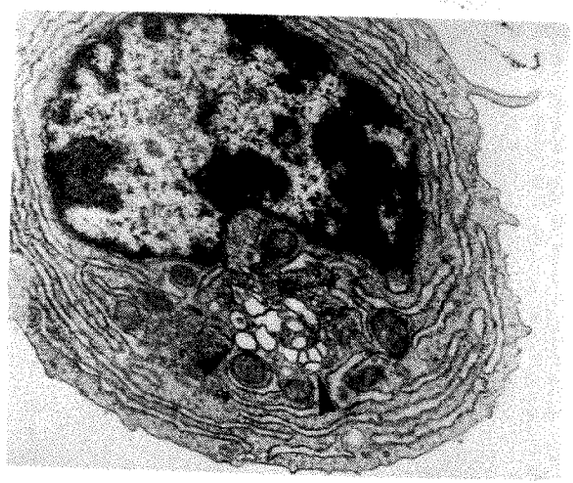

Fig. 4 Electron micrograph of a plasma cell incubated for 1 h in the presence of 10 mM ammonium chloride, showing the dilatation of the Golgi cisternae (arrowheads) (×9,800).

prepared[10] and their sialyl- and galactosyltransferase activities determined[11] at *p*Hs between 5.8 and 7.0, in the presence or absence of 10 mM chloroquine. The activity of neither enzyme was modified within this *p*H range; chloroquine at this high concentration decreased the sialyltransferase activity by 30–40% and the galactosyltransferase activity by 60%. Thus, defective sialylation does not result from a simple differential effect of *p*H or chloroquine on the terminal sugar transferase activities.

Plasma cells incubated for 1 h in the presence of chloroquine or ammonium chloride showed two types of ultrastructural alterations: a dilatation of some of the Golgi cisternae (Fig. 4), which were usually positive for thiamine pyrophosphatase activity (not shown), and the presence of very large, clear vacuoles with a scattered distribution, which were observed only in the presence of 100 μM chloroquine, and which have been described in similar conditions in other cells, such as fibroblasts[12]. Golgi alterations were still present 3 h after removal of the drug, while the large vacuoles observed in 100 μM chloroquine, which are probably swollen lysosomes or endosomes, had disappeared. Thus, only the Golgi dilatation is consistently correlated with the metabolic abnormality.

It is not clear why drugs that raise the *p*H of acidic intracellular compartments, such as ammonium chloride, chloroquine and monensin, induce an irreversible, probably *trans*, dilatation of the Golgi complex. In the case of monensin, a carboxylic membrane ionophore, the perturbations of the Golgi complex are probably both structurally and functionally more complex since, in addition to an extensive vacuolation of the Golgi cisternae, secretion of immunoglobulins by plasma cells is blocked[13]. In the case of ammonium chloride and chloroquine, it is not obvious why the more limited Golgi alteration is accompanied by inhibition of sialic acid addition but not of galactose addition or immunoglobulin secretion, even though it is usually considered that the two transferases share the same cisternal localization[11,14–16]. However, in highly secretory cells such as plasma cells, there is an enormous and very rapid vesicular traffic between the distal Golgi cisternae and the cell surface. Sialyltransferase, being the last enzyme to act in the processing of immunoglobulin carbohydrate side chains, may lie still more distally along the secretory pathway; indeed, it has recently been shown in hepatocytes that sialyltransferase is present not only in the Golgi *trans* cisternae, but also more distally in a complex network continuous with these cisternae[17] and in which no galatosyltransferase has been detected[15]. If a comparable structure exists in plasma cells, it is conceivable that the enzyme should be constantly carried back towards the distal Golgi cisternae, as part of a membrane protein recycling process. This may require the constant generation of a *p*H gradient to allow the persistence of a steady enzyme gradient. Disruption of the *p*H gradient may allow sialyltransferase and perhaps other membrane proteins (for instance, the Golgi proton pump itself) to remain at the cell surface irreversibly, explaining the persistence of the Golgi alterations and of the lack of sialylation seen in the present experiments. Since the *trans* part of the Golgi complex is involved in the intracellular traffic of endocytosed plasma membrane receptors[5], its involvement in the recycling of other membrane-associated proteins may explain the effects of intracellular *p*H-disrupting drugs in highly secretory cells.

We thank Dr J.-D. Vassalli for helpful advice in the preparation of this manuscript.

Structure of DNase I at 2.0 Å resolution suggests a mechanism for binding to and cutting DNA

Dietrich Suck & Christian Oefner

European Molecular Biology Laboratory, Postfach 102209, D-6900 Heidelberg, FRG

Bovine pancreatic deoxyribonuclease I (DNase I), an endonuclease that degrades double-stranded DNA in a nonspecific but sequence-dependent manner[1–4], has been used as a biochemical tool in various reactions, in particular as a probe for the structure of chromatin and for the helical periodicity of DNA on the nucleosome and in solution[5–10]. Limited digestion by DNase I, termed DNase I 'footprinting', is routinely used to detect protected regions in DNA–protein complexes[11]. Recently, we have solved the three-dimensional structure of this glycoprotein (relative molecular mass 30,400) by X-ray structure analysis at 2.5 Å resolution[12] and have subsequently refined it crystallographically at 2.0 Å (ref. 26). Based on the refined structure and the binding of Ca^{2+}–thymidine 3′,5′-diphosphate (Ca-pTp) at the active site[12], we propose a mechanism of action and present a model for the interaction of DNase I with double-stranded DNA that involves the binding of an exposed loop region in the minor groove of B-DNA and electrostatic interactions of phosphates from both strands with arginine and lysine residues on either side of this loop. We explain DNase I cleavage patterns in terms of this model and discuss the consequences of the extended DNase I–DNA contact region for the interpretation of DNase I footprinting results.

In our earlier paper[12] we described the binding of Ca-pTp to DNase I the binding of Ca-pTp to DNase I. The di-*p*-nitrophenylester of pTp is a substrate for DNase I (ref. 13). Similar

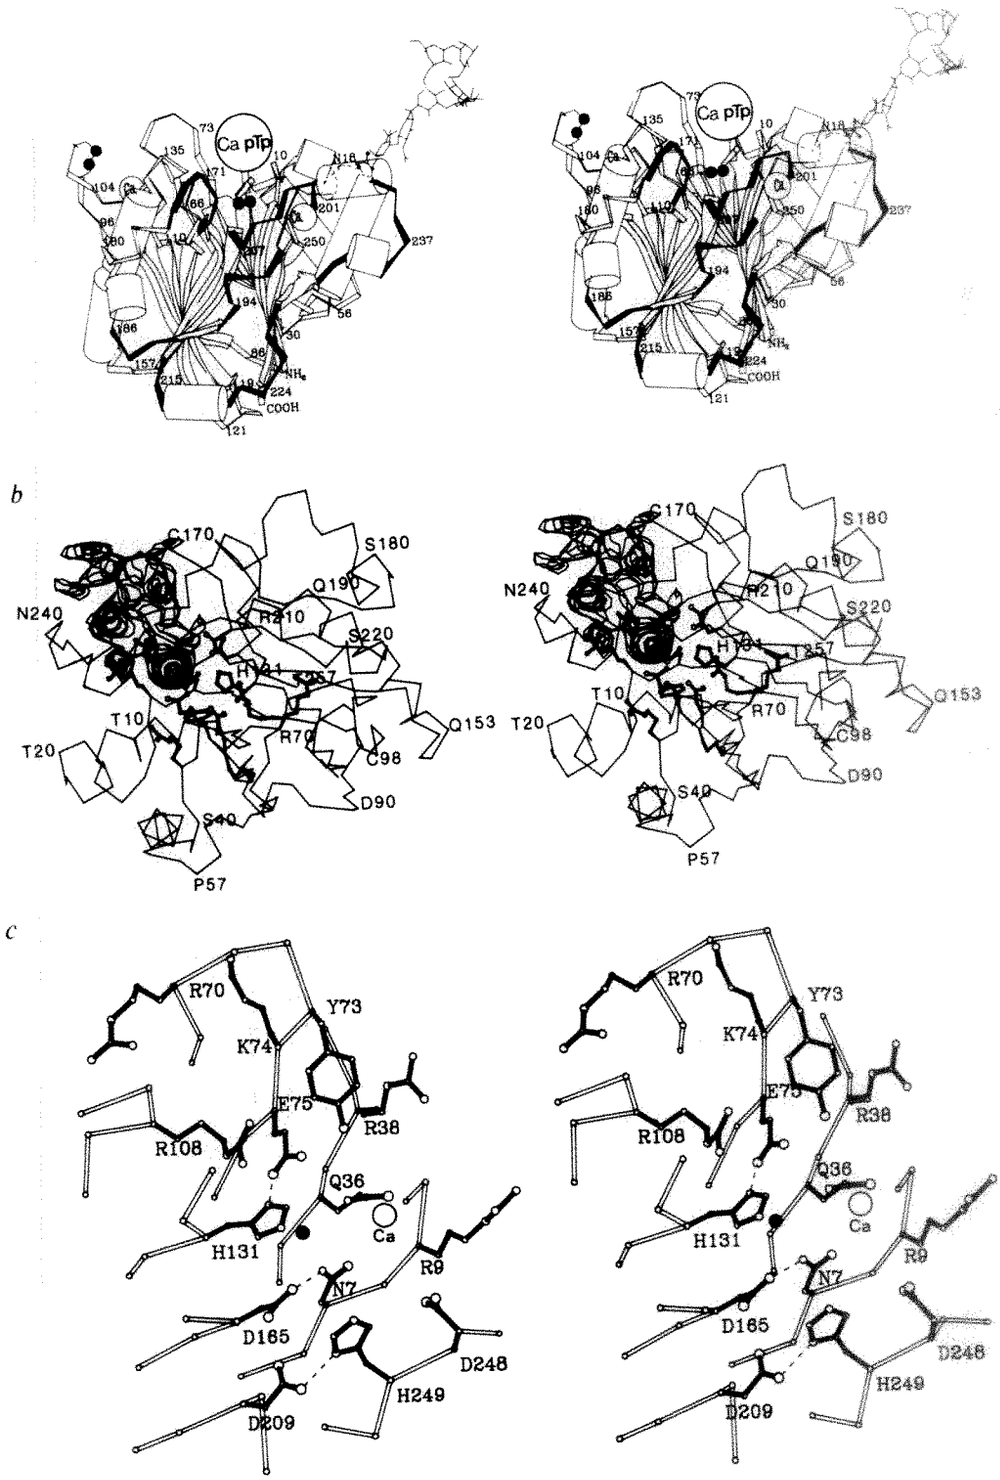

Fig. 1 Three-dimensional structure and active site of DNase I. *a*, Schematic stereo representation of DNase I with the Ca-pTp binding site indicated. DNase I is a sandwich-type structure with two 6-stranded β-sheets (arrows) forming a large hydrophobic core surrounded by helices (cylinders) and loop regions. The carbohydrate unit (drawn in skeletal form) protrudes by ~15 Å from the otherwise compact structure. The disulphide bridges connecting C 170/C 206 and C 98/C 101 are indicated by black dots; the two structurally important Ca^{2+} binding sites, which are distinct from the active-site Ca^{2+}, are marked. *b*, Stereo representation of the C^{α} backbone of DNase I viewed along the *b*-axis with the Ca-pTp difference density superimposed. The position of the Ca^{2+} ion is clearly defined as the point of highest density in the difference map. Some of the side chains at the active site including His 131 are shown as heavy lines. *c*, Stereo view of the active site of DNase I. Indicated are the position of the Ca^{2+} ion as determined from the Ca-pTp complex and the position of water molecule 390 (black dot) which is in hydrogen-bonding contact with N-3 of the essential H 131 and which, according to the proposed mechanism, acts as the attacking nucleophile. The remarkably strong hydrogen bonds between E 75 and H 131 (2.6 Å) and D 209 and H 249 (2.7 Å) are indicated by dashed lines.

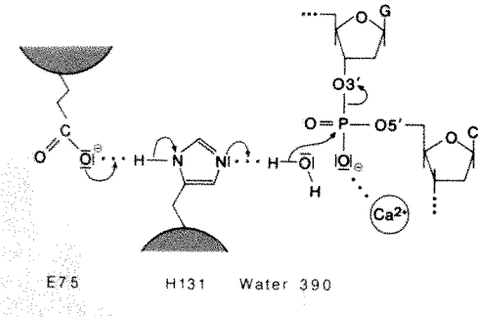

Fig. 2 Proposed mechanism of action. In a general acid–base catalysis, E 75 accepts a proton from H 131, which in turn accepts a proton from a water molecule which then as a nucleophile attacks the phosphorus and cleaves the P–O-3′-bond. The nucleophilic attack of the water hydroxyl is facilitated by the positive charge of the Ca^{2+} ion interacting with the phosphate. This proton acceptor–donor chain Glu-His-water is reminiscent of the catalytic triad Asp-His-Ser found in serine proteases. In agreement with this mechanism, carboxymethylation of H 131 at N-3 as well as protonation by lowering the *p*H inactivates the enzyme.

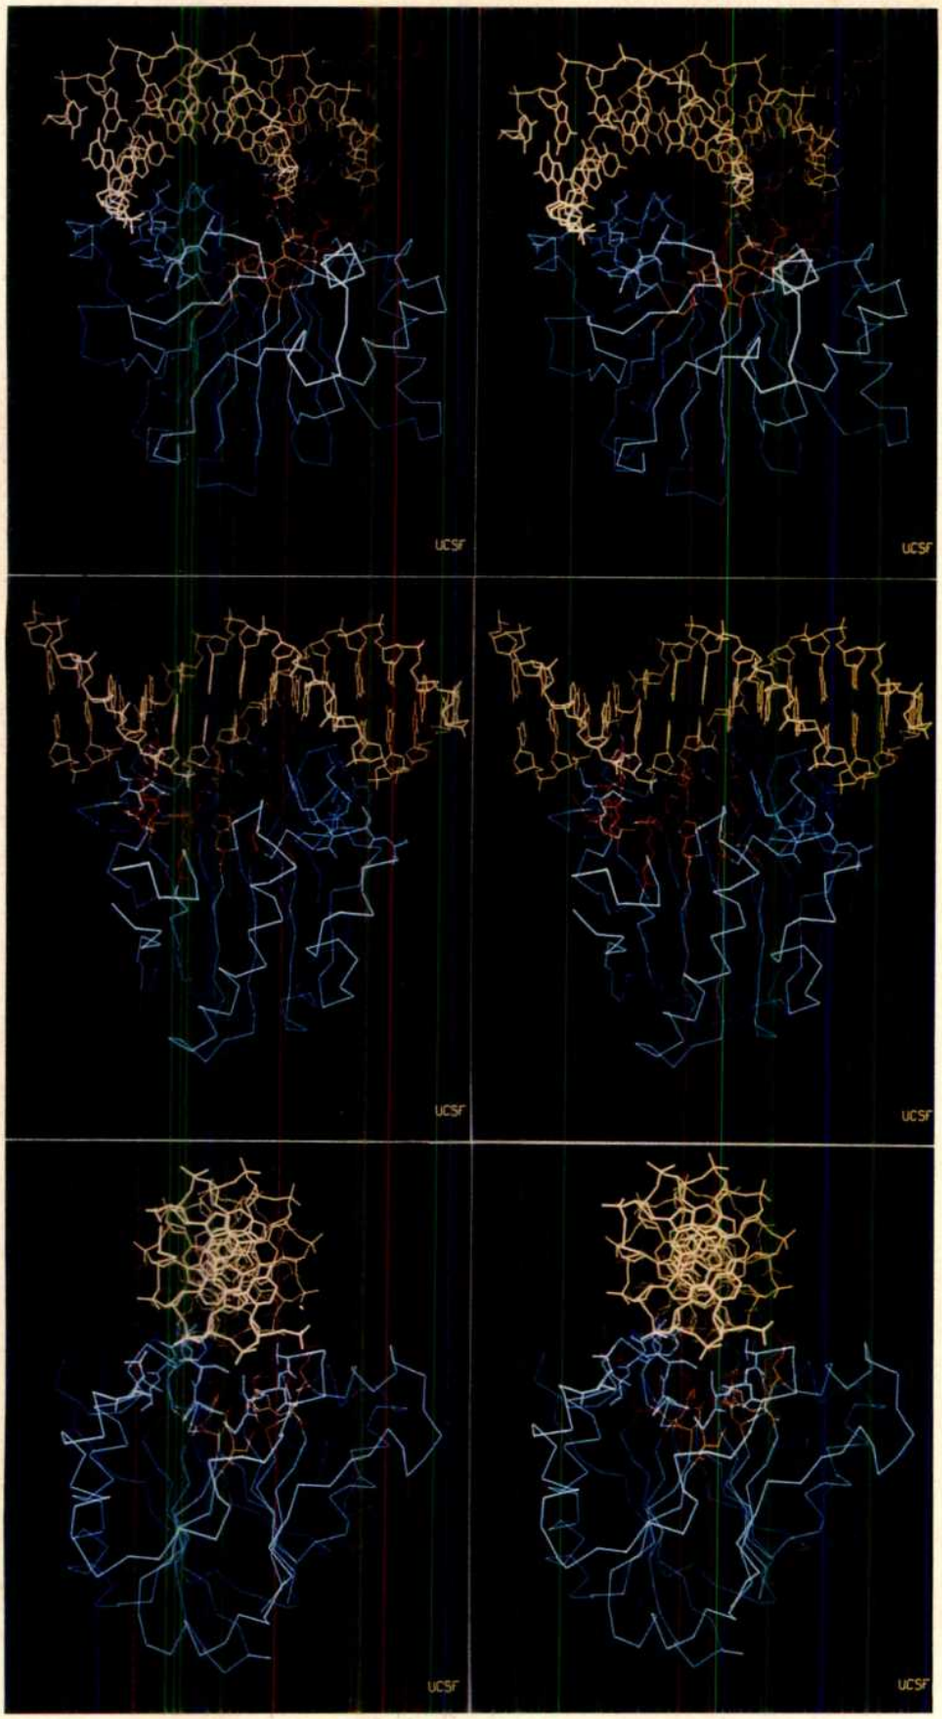

Fig. 3 DNase I–DNA interaction. Three different stereo views are shown, with a piece of B-DNA on top (in yellow) and the DNase I C^{α}-backbone beneath it. The catalytic Ca^{2+} ion, represented by a green dotted sphere, is in contact with the scissile phosphodiester bond (marked in red). Amino-acid side chains directly interacting with the DNA are shown in red and orange, other side chains in the contact region are shown in blue. Y 73, located in the exposed loop R 70-N 71-S 72-Y 73-K 74, is interacting in the minor groove with O-2 of a pyrimidine base. Phosphates from both DNA strands opposing each other in the minor groove make electrostatic interactions with positively charged side chains on either side of the exposed loop (R 9, R 108, R 70 and R 38, K 74). About 5 bp away from the cutting site, additional, mainly van der Waals' type interactions occur in the region of C 170 and T 174. The DNase I contact region extends over approximately one complete turn on one side of the DNA double helix.

to the degradation of DNA, the hydrolysis of this small substrate requires divalent cations and is inhibited by carboxymethylation of the essential residue H 131 (one-letter amino-acid notation). We diffused Ca-pTp into a native crystal and determined its binding site from a 4-Å difference Fourier transform. As expected from the biochemical data, Ca-pTp binds near H 131 at the surface of the protein in a shallow groove between the central β-pleated sheets of DNase I (Fig. 1). (There are two six-stranded β-pleated sheets packed against each other, forming the core of DNase I.) Because of limitations in resolution, the orientation of the nucleotide could not be determined unambiguously but, as we have discussed previously[12], this orientation may not be the same as with DNA. Precisely known from the difference density map, however, is the position of the Ca^{2+} ion bound at the active site in the presence of the nucleotide (see Fig. 1). As described below, we used the position of Ca^{2+} together with the geometry of the active site to derive the model for the DNase I-DNA interaction. The disposition of the Ca^{2+} ion, the amino-acid side chains and the water molecule at the active site is shown in Fig. 1. Note that the assignment of Q 36, which is in contact with the Ca^{2+} ion, has changed compared with our earlier paper[12], because of the insertion of a tripeptide at position 27. (Previously this residue was identified as D 39.) During refinement at 2 Å it became obvious that the chemically determined sequence[14] had to be corrected at several places, the major correction being the insertion of the tripeptide I-V-R at position 27. Remarkably strong hydrogen bonds exist between the carboxylate group of E 75 and the N-1 position of H 131 (2.6 Å) and between D 209 and H 249 (2.7 Å). These salt bridges will shift the pK_a values of the involved histidines to values about one unit higher than expected for a free histidine at the surface of a protein[15]. One of the water molecules found in the active-site region (water 390) is within hydrogen-bonding distance of the N-3 position of H 131. As discussed below, this water molecule is the most probable candidate for the attacking nucleophile in DNA hydrolysis.

Mehdi and Gerlt investigated the stereochemical course of the DNase I reaction by nuclear magnetic resonance techniques using substrates with chiral phosphorus atoms[16]. Their results show that hydrolysis by DNase I is accompanied by an inversion of configuration at the phosphorus, indicating that a single displacement has taken place during the reaction. The most straightforward explanation for such a reaction course is that the enzyme catalyses the direct nucleophilic attack of a water molecule at the phosphorus atom. A second possibility that was discussed by Mehdi and Gerlt is the formation of an acyl-phosphate intermediate with a carboxylate side chain and subsequent hydrolysis of this intermediate by nucleophilic attack of a water at the carboxyl carbon (and not the phosphorus). This reaction route also implies that there is a single displacement at the phosphorus and would therefore lead to inversion of configuration as well. But for stereochemical reasons, this type of mechanism seems unlikely because even with the most accessible candidate, D 248, the necessary close approach between the phosphate group of the DNA substrate and the carboxylate group appears to be impossible. Based on the geometry of the active site and using in particular the positions of the Ca^{2+} ion in the Ca-pTp complex and of the water molecule 390 in contact with H 131, we propose the following mechanism of action for DNase I (Fig. 2): in a general acid-base catalysis the carboxylate anion of E 75 accepts a proton from H 131, which in turn accepts a proton from the water molecule (water 390), which then, as a nucleophile, attacks the phosphorus cleaving the P—O-3′ bond. The Ca^{2+} ion correctly positions the phosphodiester bond with respect to the enzyme and also facilitates the nucleophilic attack of the water hydroxyl through its positive charge. The proton acceptor-donor chain E-H-water of DNase I is reminiscent of the 'catalytic triad' D-H-S found in serine proteases. In agreement with the proposed mechanism, carboxymethylation of H 131 at N-3 (ref. 17) as well as protonation of the histidine by lowering the pH (the pH optimum for DNase I lies between 7.5 and 8.5) inactivates the enzyme. In both cases H 131 can no longer act as a general base and accept a proton from the water molecule.

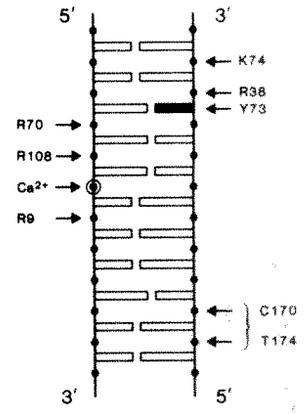

Fig. 4 Schematic drawing of DNase I-DNA interactions. The scissile phosphodiester bond (circle) is anchored by a Ca^{2+} ion to the enzyme. Adjacent phosphates on either side of the cleavage point interact with arginine side chains (R 9, R 70, R 108). Two phosphates of the other strand directly opposite across the minor groove interact with R 38 and K 74. Black rectangle, base interacting with Y 73.

Based on the geometry of the active site and using the crystallographically determined position of Ca^{2+} we have derived a model for the interaction of DNase I with double-stranded DNA in its B-form. Given the constraints imposed by the Ca^{2+} ion, the distribution of the charged residues and the van der Waals' surface of the protein around the active site, the docking was rather straightforward and immediately suggested a starting model similar to the final version shown in Fig. 3. Details of the interaction were elucidated using a colour-graphics display system and the docking program MIDAS (from the University of California at San Francisco). Only the orientations of some exposed side chains of DNase I were altered to optimize the interactions with DNA. The basic features of our model are the rather tight fit of the exposed loop R 70-N 71-S 72-Y 73-K 74 in the minor groove of B-DNA and the electrostatic interactions of phosphates from both DNA strands with positively charged side chains on either side of this loop. The DNA strand being cut is bound at the slightly concave surface between the β-sheets. The scissile phosphodiester bond is anchored to the enzyme through the Ca^{2+} ion, two neighbouring phosphates in the 5′-direction make ionic interactions with R 108 and R 70, the phosphate following in the 3′-direction interacts with R 9 (Fig. 4). Two phosphates of the other DNA strand, directly across the minor groove, are bound to K 74 and R 38. Additionally, mainly van der Waals'-type interactions involving C 170 and T 174 occur 5–6 base pairs (bp) away from the cutting site. The schematic drawing in Fig. 4 shows where the interactions occur on the DNA relative to the point of cleavage. Further ionic interactions, not included in this model, can occur between negatively charged side chains and the phosphate backbone mediated by divalent cations. Possible candidates for this kind of contact are the carboxylate groups of D 248, D 136, E 13 and E 99. The last residue is not visible in the crystal structure because it is located in the flexible loop containing the short disulphide bridge between C 98 and C 101, which, however, is not essential for enzymatic activity[18]. Therefore, it appears that any interactions involving this disordered loop are of only minor importance for DNA binding. It is the combination of these interactions—tight fit of a loop region in the minor groove, ionic interactions of phosphates from both DNA strands and van der Waals' interactions somewhat remote from the cutting site—which provides the precise alignment of the DNA-substrate on

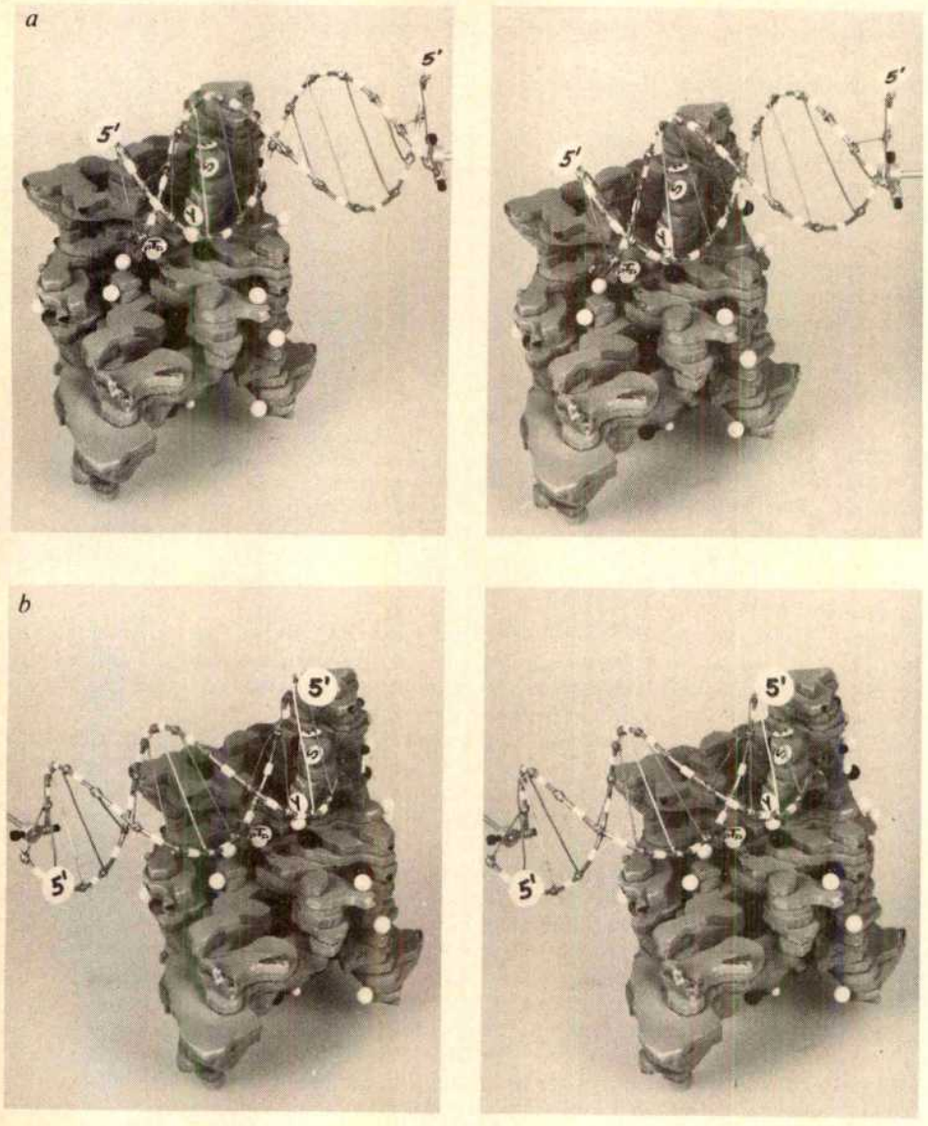

Fig. 5 DNase I cleavage at the 3′ end and near the 5′ end of DNA. Stereo view of the 5-Å balsawood model of DNase I with a piece of B-DNA at the same scale. Charged residues at the surface of DNase I are indicated by black (R, K) and white (D, E) spheres. Active site marked by pTp, residues N 71, S 72 and Y 73 in the exposed loop interacting in the minor groove of DNA are labelled. *a*, Cutting a bond at the 3′ end allows full binding in the minor groove and accurate alignment of the DNA, with R 9, R 108, R 70 interacting with phosphates on the DNA strand to the left of the exposed loop and R 38 and K 74 interacting with phosphates on the other strand. The contacts to R 38 and K 74 to the right of the exposed loop are lost when the cleavage site is 5 bonds away from the 5′ end. This feature of the model nicely explains the observation that oligonucleotides are cut near the 3′ end or the centre but not, or at very low rates, near the 5′ end.

the surface of the enzyme. Y 73, which is located in the exposed loop mentioned above, penetrates into the minor groove of DNA such that its OH-group is in hydrogen-bonding distance from either O-2 of pyrimidines or N-3 of purines. These two atoms are located in equivalent positions relative to the helix axis, so that this interaction in a first approximation will not lead to a purine/pyrimidine discrimination, in agreement with the biochemical results. However, the NH_2 group in position 2 of a G will have a steric effect which could influence the binding (see below).

As shown in Fig. 3, one of the DNA strands follows the direction of the β-sheets and residues at the N- or C-termini of the β-strands or the connecting loop regions participate in the binding or cleavage of DNA. A somewhat similar situation has been found in the *Eco*RI/DNA complex, possibly indicating a general correspondence of β-sheet structure displaying a left-handed twist with a right-handed double helix (J. Rosenberg, personal communication). Whereas the recognition of DNA is different in both cases—major groove interactions in the case of the sequence-specific restriction enzyme, minor groove interaction in the case of the unspecific or better, less-specific DNase I—the catalytic portions of the two enzymes seem to have some resemblance, reflecting the fact that both are endonucleases.

In this context it is interesting to note that DNase I, if present in high concentrations, is able to degrade single-stranded DNA at a rate about four orders of magnitude slower than double strands[1]. The smallest substrate being attacked is a tetranucleotide (NpN↓pNpN) or a trinucleotide carrying a 3′-phosphate group (NpN↓pNp), whereas a trinucleotide (NpNpN) is resistant. In good agreement with our binding model, this shows that phosphate groups on either side of the scissile bond are necessary to align the oligonucleotide on the enzyme for cutting (Fig. 4).

Various biochemical results concerning the enzymatic activity and cleavage patterns observed with DNase I can be explained in terms of our model. Evidence for the involvement of Y 73 in the binding comes from a chemical modification study[19]. The oligopeptide antibiotic netropsin, which is known from X-ray studies to bind in the minor groove at A+T-rich sequences[20], prevents DNase I cleavage at these sites. According to our model, netropsin binding in the minor groove will directly interfere with the binding of the exposed loop R 70 to K 74 of DNase I. Indirect evidence for binding of DNase I across the minor groove stems from a comparison of DNase I cleavage patterns of a hairpin loop structure with a double-stranded piece of DNA of identical sequence[21].

DNase I digestion studies of self-complementary oligonucleotides show that the enzyme cleaves near the 3′ end or the centre of a DNA strand but not, or at very low rates, near the 5′ end[3,21]. The reason for this behaviour is obvious from our model: full binding and accurate orientation of the DNA with respect to the enzyme are only possible with a complete minor groove

allowing for interactions with phosphates from both strands. The situation for binding near the 3′ and the 5′ ends of a DNA strand are illustrated in Fig. 5. In the case of 3′-end cutting, both strands of the DNA interact with the protein, whereas the contacts to R 38 and K 74 are lost when a phosphodiester bond about 4–5 bonds inwards from the 5′ end is cut. One can use this argument to exclude binding across the major groove: exactly the opposite behaviour (cutting all the way to the 5′ end and no cutting near the 3′ end) would be expected from this kind of model.

Figure 3 shows that the fit of the exposed loop R 70 to K 74 in the minor groove is rather tight and therefore the width of the helix grooves will be a critical factor for the binding. X-ray studies on short double-stranded DNA pieces indicate that the groove width can indeed vary with the sequence[22,23]. The sequence-dependent variation of the DNase I cleavage pattern and cutting frequencies can therefore be nicely explained in terms of this model by a variation of the minor groove width that directly affects the binding. Among other factors, variation of helix groove width has been discussed by Drew and Travers as a possible explanation for the DNase I cleavage pattern they observed for a 160-bp DNA fragment[4]. They found that the locally averaged probabilities of cleavage were usually higher in regions with random base sequence than in those with runs of A-T or G-C. In agreement with these digestion data, our model predicts optimal binding for a minor groove width of 12–13 Å, a value occurring in 'normal' (that is, random-sequence) B-DNA. There are, however, considerable variations in cutting frequencies of neighbouring phosphates which cannot be explained by a smoothly varying parameter like the groove width. As mentioned above, Y 73 interacts in the minor groove with N-3 or O-2 of the purine or pyrimidine base on the opposite strand, 3 bp away from the cutting site (Figs 3, 4). If there is a G-C (or C-G) pair at this position, steric hindrance between the NH_2 group in the 2-position of the guanine base and the tyrosine hydroxyl group will force the tryosine into a different orientation compared with the A-T (or T-A) case. Similarly, local changes in the helix twist angle, the base-pair propellor-twist and the roll and tilt angles will have an effect on this interaction. Therefore, it seems probable that the tyrosine interaction in the minor groove has a modulating effect on the cutting frequencies of DNase I.

Another feature of our model is the rather extended binding surface. One side of the DNA double helix is in contact with the DNase I over ~10 bp, that is, over almost a complete turn (see Figs 3, 4). For optimal binding and therefore rapid cutting of DNase I, a piece of DNA of at least this length is required. The well-known fact that the rate of cutting is a function of the length of the DNA fragment[1,3] can be explained by this feature of the model. The fact that DNase I, unlike a chemical probe, has an extended DNA binding surface has important consequences for the interpretation of DNase I footprinting studies: at least 4 bp to the 5′ side and 6 bp to the 3′ side of the cutting site are covered by DNase I on one side of the DNA double helix. In other words, DNase I cutting at a given site implies that the protein whose interaction with DNA is being probed by the footprinting experiment is interacting neither in the minor groove following in the 5′ direction nor in the major groove following in the 3′ direction. Our model nicely explains the difference observed in the size of footprints generated by DNase I and the synthetic DNA cleaving reagent methidiumpropyl-EDTA·Fe(II) (ref. 24). Knowledge of the mode of DNase I–DNA interaction will solve the problem of overestimating the size of DNA binding sites by DNase I footprinting experiments and will therefore significantly increase the accuracy of the method. Another implication of our model is that DNA segments displaying an A- or Z-type conformation will either be resistant to DNase I digestion or will be attacked only after conversion into a B-type conformation. In fact, brominated poly (dG-dC), which was shown by spectroscopic methods to exist as Z-DNA under the conditions used, was degraded to only 10% by DNase I (ref. 25). Finally, our model can be used to predict the accessibility of phosphodiester bonds by DNase I (angle of attack) in the nucleosome.

We thank Graham Frost and Harald Lahm for technical assistance, Dr Wolfgang Kabsch (MPI für medizinische Forschung, Heidelberg) for discussions and the use of his data-reduction and scaling software, Dr Heinz Bosshard and Chris Carlson (EMBL) for advice with the PS2 graphics display system and Drs Arthur Lesk (MRC, Cambridge) and Johann Deisenhofer (MPI für Biochemie, Martinsried) for molecular plotting programs.

Note added in proof: An X-ray structure analysis of a complex between DNase I and a self-complementary octanucleotide proceeding in our laboratory confirms the proposed binding of the exposed loop R 70 to K 74 in the minor groove of DNA.

L1 family of repetitive DNA sequences in primates may be derived from a sequence encoding a reverse transcriptase-related protein

Primate and rodent genomes contain a family of highly repetitive, long interspersed sequences, designated the L1 family or LINE-1 (refs 1–4). Characteristic features of the L1 family sequences such as an A-rich stretch at the 3′ end, a truncated 5′ end, the existence of significantly long open reading frames (ORFs)[5–9] and the presence of L1 family transcripts in various types of cells, including pluripotential embryonic cells[10–15], suggest that the L1 family is derived from a sequence encoding a protein(s) and dispersed in the genome through an RNA-mediated process. These features of the L1 family are believed to be due to reverse transcription

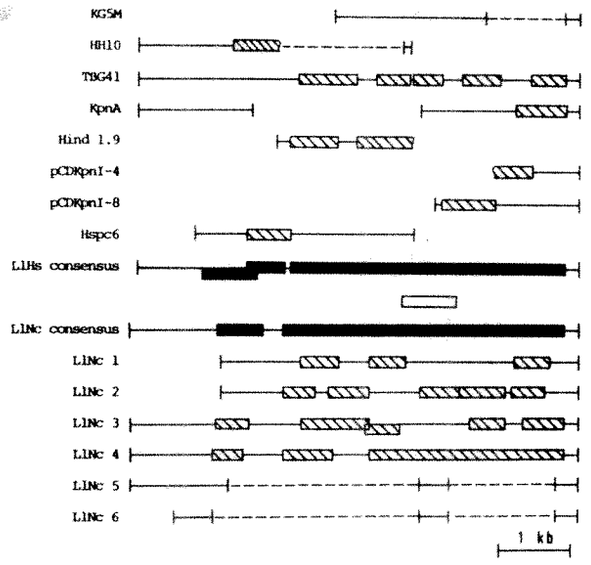

Fig. 1 Schematic representation of the structure of L1 family members and the consensus sequences. The human consensus sequence was deduced from TβG41 (ref. 9), KpnA (ref. 8), Hind1.9 (ref. 5), pCDKpnI-4 and pCDKpnI-8 (ref. 6), HH10 (ref. 25 and K. Yoshioka *et al.*, unpublished), Hspc6 (ref. 26 and K. Yoshioka *et al.*,, unpublished) and KG5M (A. Fujita *et al.*, unpublished). The *N. coucang* consensus sequence was deduced from the sequence data of six members (L1Nc1–L1Nc6) analysed here. Filled bars in the consensus sequences and hatched bars in each member show positions of ORFs over 420 base pairs. An open bar between two consensus sequences indicates the region homologous to reverse transcriptase sequences (see text). Broken lines show the region where the sequence has not been determined.

Methods. *N. coucang* DNA, prepared from liver, was partially digested with *Eco*RI, and 15–20-kilobase (kb) fragments were ligated to *Eco*RI-digested arms of bacteriophage vector Charon 4A. After *in vitro* packaging, the recombinant phages were propagated in *Escherichia coli* LE392. The phage library was screened with ^{32}P-labelled fragments of a human L1 family, TβG41 (refs 9, 27). Positive phage clones were further analysed by the Southern blotting technique[28] and selected DNA fragments subcloned into pUC13 or pUC18 (refs 29, 30). Cloned DNA was subjected to sequence determination by the method of Hattori and Sakaki[31].

beginning at the 3′ end of the L1 transcript and terminating prematurely and to the site duplication caused by the insertion of the complementary DNA (reviewed in refs 3, 4). It is likely that this type of transcript is converted to cDNA and inserted into the chromosome through a process similar to that of the formation of processed pseudogenes[16]. The above model, however, does not necessarily explain why the L1 family should produce the extraordinarily large number of copies (more than 10^4 per haploid genome[17]) seen during evolution. It seems likely that the progenitor of the L1 family itself carries (or carried) a function which promotes the active dispersion of the L1 family sequence. We reasoned that such a function, if present, must be conserved during evolution and may be shown by comparative analysis of L1 family sequences from evolutionarily distant species. We show here that the L1 family sequence contains an ORF possessing significant sequence homology to several RNA-dependent DNA polymerases of viral and transposable element origins. This provides a plausible explanation for the preferential and active dispersion of the L1 family sequence during evolution.

For a comparative analysis, we chose the human and prosimian, which diverged from each other about 70 million years ago. Six 'full-length' or nearly 'full-length' L1 family members were isolated from a genomic DNA library of slow loris (*Nycticebus coucang*) and their complete (L1Nc1–L1Nc4) or partial (L1Nc5, L1Nc6) nucleotide sequences determined. These members showed a homology of 90% or more among each other

Fig. 2 Amino-acid sequences of large ORFs found in human (L1Hs, upper) and prosimian (L1Nc, lower) consensus L1 family sequences. The amino-acid sequences were deduced from the consensus nucleotide sequences and aligned by the program of Wilbur and Lipman[32] in the GENAS system[33] to achieve maximum homology. Colons indicate amino acids identical in both sequences. Only the region homologous between the two sequences is presented. The numbers shown alongside each sequence correspond to those given for the large ORFs. The homology is 65% at the amino-acid sequence level and 71% at the nucleotide sequence level. Underlining indicates amino-acid sequences homologous to reverse transcriptases.

and a very large ORF of 927 amino-acid residues was found in L1Nc4 (Fig. 1). All the large ORFs in other members were found to use the same reading frame as the very large ORF of L1Nc4, and overlapped each other (Fig. 1). From these sequence data, a consensus nucleotide sequence for the prosimian L1 family was deduced and found to be capable of encoding a very large ORF of 1,294 amino acids. Similarly, a consensus sequence of the human L1 family was deduced from family members (the consensus sequences of human and prosimian are available on request). Just as in the case of prosimian, a very large ORF (1,280 amino acids) was identified at a position similar to that of the prosimian ORF (Fig. 1). Figure 2 shows the two ORFs of the consensus sequences. Human and prosimian large ORFs showed a homology of about 65%, and these ORFs, a large ORF in a mouse L1 family member (L1Md4)[7,18] and a partial consensus ORF of rat L1 family[19], were found to be using the same reading frame. Our results provide additional support for the idea that the L1 family is derived from a sequence(s) encoding a protein(s)[7] and, moreover, suggest that the protein is a relatively large polypeptide which is evolutionarily conserved.

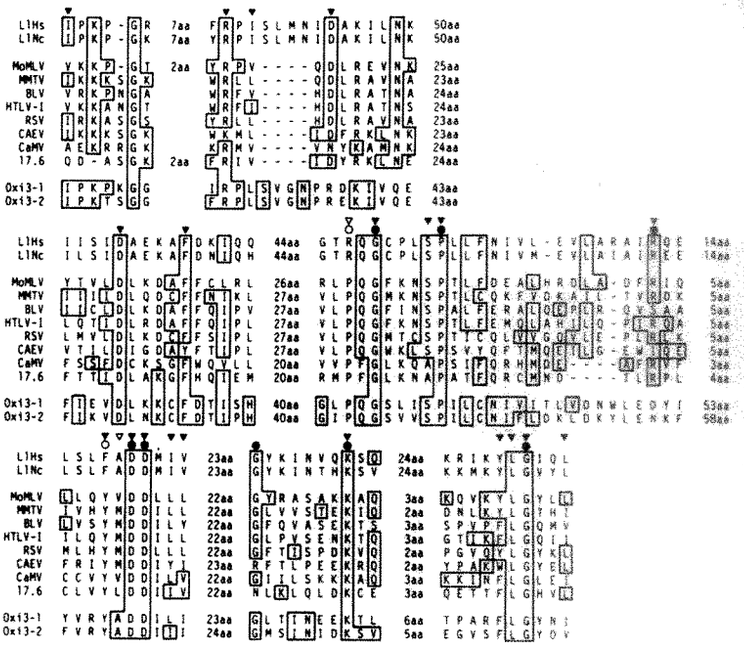

Fig. 3 Homology of amino-acid sequences between L1 consensus ORFs and RNA-dependent DNA polymerases of various origins. The amino-acid sequences were taken from Moloney murine leukaemia virus (MoMLV)[34], murine mammary tumour virus (MMTV)[35], bovine leukaemia virus (BLV)[36], human T-lymphotropic virus type I (HTLV-I)[37], Rous sarcoma virus (RSV)[38], caprine arthritis-encephalitis virus (CAEV)[35], cauliflower mosaic virus (CaMV)[22,39], 17.6 (ref. 40) and the mitochondrial class II introns Oxi 3-1 and Oxi 3-2 (ref. 41). Seven homologous sequence blocks shown by underlining in Fig. 2 are presented here. Amino acids that are common to at least five polymerase sequences and either of the L1 consensus ORFs, and amino acids in polymerase sequences identical to those of either of the L1 consensus ORFs are boxed. Ten invariant amino-acid residues[21] are indicated by circles; the residues conserved in L1 ORFs are shown by filled circles. The 27 identical and chemically similar amino-acid residues reported by Toh *et al.*[22] are indicated by triangles; among these, the residues conserved in L1 ORFs are shown by filled triangles (5 out of 27 amino-acid residues are not included in the region shown here). Using the mutation matrix of Schwartz and Dayhoff[42], the significance of each homologous sequence block was estimated using a computer algorithm[43]. The statistical test showed that the homologies of most of the sequence blocks between L1 ORFs and yeast intron-encoded ORFs are significant with a probability of $\leq 1.3 \times 10^{-3}$ ($>3\sigma$).

To investigate the protein encoded by the progenitor of L1, we searched the Protein Sequence Database of the National Biochemical Research Foundation for amino-acid sequences homologous to ORFs in the human L1 family sequence TβG41; a relatively high homology was found between TβG41 ORF and transferrins[9]. Using the same approach, significant homology was also found between consensus ORFs and some retroviral reverse transcriptases. Alignment of the amino-acid sequences of RNA-dependent DNA polymerases of various origins was then carried out together with those of L1 family ORFs. As shown in Fig. 3, the L1 family ORF is evidently homologous to RNA-dependent DNA polymerases, particularly to that of yeast mitochondrial class II introns (Oxi3-1 and Oxi3-2), which show a high sequence homology to RNA-dependent DNA polymerases[20]. Out of 102 amino-acid residues, 37 were identical between the consensus ORFs and Oxi3-1. Toh *et al.*[21] found 10 invariant amino acids in 5 viral RNA-dependent DNA polymerases, and we found that 8 of these were conserved in human and prosimian consensus ORFs (Fig. 3, filled circles). Toh and his colleagues[22] also noted 27 positions at which identical or chemically similar amino acids occurred in 8 RNA-dependent DNA polymerases. At 20 of the 27 positions, the consensus ORFs were found to possess amino acids common to the polymerases (Fig. 3, filled triangles). A highly conserved sequence, YXDD (one-letter notation), flanked by three hydrophobic residues was described by Toh *et al.*[21,22]. Although L1 consensus ORFs use F (phenylalanine) instead of Y (tyrosine) in the sequence, the RNA-dependent DNA polymerase of the yeast Ty transposable element[23,24] also uses F instead of Y, and the sequence LFADDMI of L1 consensus ORFs is very similar to the sequence LFVDDMI of Ty polymerase. Thus, the L1 consensus ORF shows significant homology to known RNA-dependent DNA polymerases. It is probable that the protein potentially encoded by the L1 family or its progenitor is closely related to reverse transcriptases. If the protein is actually a reverse transcriptase, it is conceivable that the enzyme binds to its own messenger RNA immediately after translation to start cDNA synthesis. This is consistent with a preferential and active dispersion model for L1 family sequences. It will be of interest to test whether a protein carrying the amino-acid sequence of the consensus ORF actually possesses reverse transcriptase activity.

We thank Dr Frederick I. Tsuji for a critical reading of the manuscript, H. Hamada for help in its preparation, K. Yoshioka and A. Fujita in our laboratory for unpublished data and Dr K. Saigo for critical comments. This work was supported by grants from the Ministry of Education, Science and Culture of Japan to Y.S.

Note added in proof: After submission of this paper, we found a report[44] pointing out the homology between the ORF of the mouse L1 family and the reverse transcriptases of retroviruses; the results of that study were consistent with ours.

MATTERS ARISING

Physiological relevance of erythroid-potentiating activity or TIMP

WE note the unusual story unfolding in *Nature* concerning the molecular biology of a glycoprotein that acts as a tissue inhibitor of metalloproteinases (TIMP) and has erythroid-potentiating activity (EPA)[1,2]. While the occurrence of two such disparate activities within one molecule would be interesting, the physiological relevance of these data should evoke some caution.

TIMP is a well described entity capable of blocking the action of vertebrate collagenases as well as numerous other neutral metalloproteinases, that is, gelatinases, proteoglycanases and type-specific collagenases. This inhibitor forms a tight ($K_i < 10^{-9}$) enzyme/inhibitor complex and appears to serve as a general tissue anti-proteinase[3]. TIMP is almost ubiquitous in human tissues. Connective tissue fibroblasts of multiple origins synthesize this product[4,5] as do several cell types of haematopoietic origin including alveolar macrophages, HL-60 and platelets[6–8].

In vivo plasma concentrations of TIMP are on the order of 17 nM with a fairly narrow (~25%) standard deviation[5]. TIMP concentrations in amniotic fluid are even higher, averaging 68–102 nM. It is unlikely that the concentrations of this glycoprotein in tissue and bone marrow are significantly different; and these levels are at least 1,000-fold higher than the maximally stimulating concentrations of EPA (10–20 pM)[9]. Although it may be the case that *in vivo* conditions require significantly higher EPA concentrations than the *in vitro* assays, these data suggest that the marrow is saturated with respect to the activity of this modulator.

Thus, the dual role of TIMP/EPA appears incongruous in several respects. This glycoprotein is almost ubiquitous in human tissues and seems to be a common housekeeping product of numerous cell types, perhaps in keeping with its role as a protective agent of the extracellular matrix. While purified EPA demonstrates maximal activity at biologically anticipated concentrations, these are far exceeded by ambient levels of the glycoprotein. It may well be that the erythroid-potentiating activity of TIMP represents a coincidental property of this molecule. Alternatively, it might be best to re-examine the properties of this glycoprotein using both purified natural products and a purified recombinant-derived protein.

GASSON AND GOLDE REPLY—The description of a single glycoprotein with both protease inhibitor and erythroid-potentiating activity is indeed intriguing. Erythroid-potentiating activity was originally purified using a sensitive bioassay which measures the enhanced growth of normal human erythroid progenitors in semi-solid medium[1]. The purified 28,000-dalton protein was subsequently sequenced, and oligonucleotide probes were generated and used to obtain complementary DNA clones[2]. Both the purified natural and biosynthetic (recombinant) proteins stimulate the growth of primitive and more mature erythroid precursors *in vitro*. In addition, the partially purified EPA and the purified biosynthetic material have direct effects on colony formation by human cell lines[3,4]. The availability of human cell lines as homogeneous target cells has made it possible to pursue the mechanism of action of human erythroid-potentiating activity. Our recent studies using radioiodinated human EPA have demonstrated the presence of specific cell surface receptors on responsive cell lines, but not on other types of primary human cells or cell lines (unpublished observation). It seems that EPA has many of the properties of a haematopoietic growth factor, in that it stimulates primary cells, responsive cell lines, and appears to bind to a specific cell surface receptor which could mediate these biological responses. We doubt whether hormonal potentiation of cellular growth observable at picomolar concentrations on target cells with specific binding sites could be considered "coincidental".

The role of the EPA *in vivo* is, of course, a difficult question to address. Using the cDNA clone as a probe, as well as a sensitive radioimmunoassay to look for the synthesis of EPA messenger RNA and protein, we had arrived at similar conclusions to those reported for TIMP. In other words, EPA appears to be synthesized in many cell types; this is not necessarily unusual for haematopoietic growth factors (for example, colony-stimulating factor, CSF-1 or M-CSF, is produced by most, if not all, tissues examined in the mouse). Our estimate of the circulating EPA concentration in human serum was somewhat lower than 17 nM more in the range of 5–10 nM, although these levels are also high relative to the concentration of EPA required for a maximum growth-promoting effect *in vitro*. As we do not know the site of EPA action *in vivo* nor, as pointed out, do we know the actual concentration required for biological activity *in vivo*, it is hard to interpret these findings in a physiological framework.

Because of the availability of cell culture techniques, it has been possible to purify this erythroid growth factor. Molecular biological approaches have allowed us to produce sufficient material to investigate the effects on responsive target cells at the molecular level *in vitro* and at the organismic level *in vivo*. Ultimately it should be possible to reconcile the enzymatic inhibitory effects and the growth-promoting properties of the molecule. We feel it would be unwise at this point to regard the hormonal properties of this molecule as 'coincidental' or trivial.

CONVENIE..T·INFORMATIVE·TIMELY·PROVOCATIVE

FOUR DYNAMITE REASONS WHY YOU SHOULD SUBSCRIBE TO BIO/TECHNOLOGY NOW . . .

1. You'll save time. Because you don't have time to read every journal in the field, BIO/TECHNOLOGY is written and edited to give you all the information you need in ONE convenient source. BIO/TECHNOLOGY is the only journal to give you news. Features. Original research. Product evaluations. Industrial applications. Job openings. Book and product reviews. And more. If it's important to your work, you'll find it between the covers of BIO/TECHNOLOGY.

2. You'll learn new ways to improve your on-the-job skills and run a more successful operation. Each month BIO/TECHNOLOGY gives you the scoop on invaluable start-up information . . . the latest instrumentation . . . marketing breakthroughs . . . funding sources . . . new technologies . . . patents and licences. . . profiles on how others are avoiding the pitfalls and reaping the rewards. In fact, just one practical tip from BIO/TECHNOLOGY can be worth many times the cost of your subscription.

3. You'll be up-to-date on all major industry developments. With correspondents all over the world, BIO/TECHNOLOGY delivers the inside story on who's doing what, where. You'll get the latest word on changing government regulations and tax law, and how they affect your work.

Plus you'll read original research papers by bench scientists, engineers, and biologists that will help keep you in the forefront of every new discovery worth knowing about.

4. You'll get new ideas you can put to use immediately. BIO/TECHNOLOGY lets you rub elbows with eminent scientists, tour new facilities and learn how new processes work in every field from genetic engineering to molecular biology. Each month, BIO/TECHNOLOGY helps spark ideas for your own research, for new industrial applications and for getting along in the increasingly competitive financial arena.

If you're not already subscribing to BIO/TECHNOLOGY, don't delay the moment any longer - return the coupon below and we will send you twelve issues. You risk nothing. If for any reason BIO/TECHNOLOGY doesn't live up to your highest expectations, just let us know and you'll receive a full refund on all unmailed copies. Remember too, that your subscription may be tax deductible.

TO START RECEIVING YOUR SUBSCRIPTION, FILL OUT THE COUPON BELOW AND RETURN WITH PAYMENT TO:

INTRODUCING

serotec QB·AR

integrated analytical grade reagent conjugates

The QB-AR range meets a variety of assay needs and offers significant practical benefits to the user. The range includes:

Streptavidin conjugates

Streptavidin has significant advantages over Avidin for detection of biotin labelled antibodies – principally that it causes negligible background binding. Biotin should preferably be coupled via a flexible linker arm to minimise reduction of affinity due to steric hindrance.

R-Phycoerythrin* conjugates

R-Phycoerythrin has a strong excitation maximum at the same wavelength as fluorescein; it emits in the orange/red while fluorescein emits in the yellow/green, so two-colour fluorescence is easily accomplished. R-Phycoerythrin is very stable and shows negligible non-specific binding.

Rabbit F(ab')2 anti-rodent antibodies

Rabbit antisera are characterised by high titre and very avid, specific antibodies. Purification of IgG and digestion to F(ab')2 fragments eliminates non-specific binding, and purification of the fragments results in high concentration of antibody seeing multiple determinants on first-stage antibody molecules. This gives a much brighter signal than monoclonal anti-Ig reagents which see only single determinants.

* United States Patent Number 4542104

Growth factors spawn new cell cultures

from W.L. McKeehan

Heparin-affinity chromatography allows the isolation and chemical definition of a family of hormone-like polypeptide growth factors that support several important cell types in defined culture conditions.

IMPROVED nutrient media formulas[1] and the discovery that crude serum can be replaced in large part by defined polypeptides[2] have revolutionized regulatory cell biology and opened up subdisciplines of study using isolated cells in culture that can be called cellular nutrition[3] and cellular endocrinology. The commercial availability of high quality chemically-defined preparations of polypeptide growth factors (Table 1)[4] has played a part in the revolution. Despite this progress, many tissue-specific normal cell types and tumour-derived counterparts have resisted routine culture except in the presence of undefined biological fluids, tissue extracts or the medium from cultured cells.

Cultures of tissue-specific cell types are of keen interest as model systems for studying specific organs and their diseases. Fibroblast cells, which arise from many tissues placed in culture, have remarkably similar properties and are unsuitable for such studies. Likewise, the many tumour-derived cell lines that have been adapted to serum-free medium retain few characteristics of the tissues of origin beyond fixed expression of one or more gene products.

Neural tissue extracts

Crude or partially purified extract of neural tissue makes a beneficial additive to many tissue-specific cell cultures, including cell types such as endothelial cells[5], smooth muscle cells[6], keratinocytes[7,8], melanocytes[9], prostate epithelial cells[10,11], breast epithelial cells[12], tracheobronchial epithelial cells[13], intestinal epithelial cells[14] and hepatocytes (H. Hoshi, M. Kan & W.L. McK., unpublished results). To determine whether these cell types are responding to related or different polypeptides, the active species must be isolated to homogeneity and carefully analysed for chemical structure. But isolating these hormone-like factors in quantities sufficient for chemical analysis, which uses cell growth assays, is no light task since the factors are at low concentrations in most tissues and fluids.

Table 1 Commercially available growth factors

Factor	Target cells
EGF, α-TGF	Epithelial/ mesenchymal
PDGF	Mesenchymal
β-TGF	Epithelial/ mesenchymal
Insulin, IGF-I, IGF-II	Epithelial/ mesenchymal
β-NGF	Neurones
IL-2	T-lymphocytes
IL-3	Haematopoietic

Characteristics of these defined polypeptides were recently reviewed[4]. EGF (epidermal growth factor) and α-TGF (α transforming growth factor) act on the same receptor. PDGF, platelet-derived growth factor. β-TGF (β transforming growth factor) is both an inhibitor and growth factor. Insulin and IGFs (insulin-like growth factors) have separate receptors, but act on both at high concentrations. β-NGF, β nerve growth factor. IL = interleukin.

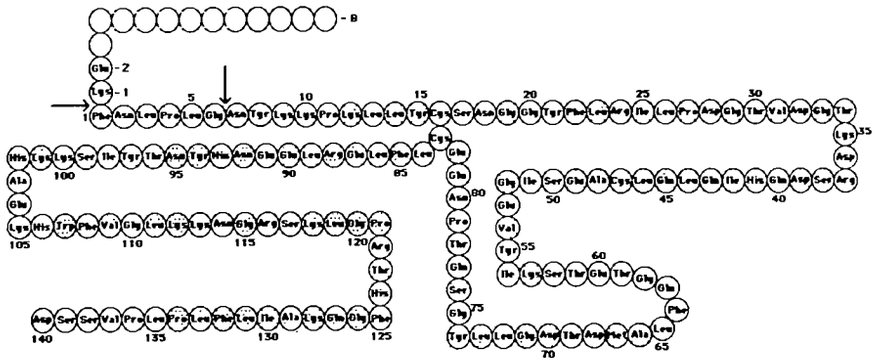

Fig. 1 Primary structure of prostatropin (acidic FGF, acidic ECGF) and homology to basic *p*I heparin-binding growth factor (bFGF). Amino acid residues 1 to 140 are those reported[19] for a truncated form of acidic FGF (M_r = 15,883). Open circles indicate unpublished residues of the 14-amino acid peptide with blocked amino terminus (B)[20,21]. The lysine (residue −1) has been assigned by V8 protease cleavage and the glutamate (residue −2) is inferred from specificity of V8 protease cleavage[20]. Placement of the disulphide bond is tentative, but is present in at least one chromatographic form of prostatropin based on unpublished data from the author's laboratory. Shaded amino acid residues indicate homologies with bFGF[18]. Arrows indicate cleavage points that yield truncated molecular forms of the growth factor.

Purified factors

Heparin-binding growth factors constitute a family of homologous polypeptides in the molecular weight range of 15,000 to 18,000 daltons. The molecular forms fall into two classes based on isoelectric point (*p*I) and amino acid sequence. One class of factor has an apparent *p*I of 8 to 10, and the other, a *p*I of 4.5 to 5.5. The largest sequenced species of the cationic factor contains 146 amino acid residues (M_r = 16,415)[18], and a truncated form, missing amino terminal amino acids 1 to 15, has also been reported.

Three molecular forms of the acidic class of factor have been described in more detail (Fig. 1). One truncated form, consisting of 140 amino acids (M_r = 15,883) and an amino terminal phenylalanine, has been completely sequenced[19]. We have isolated two other forms that are distributed among five chromatographic peaks on reverse phase HPLC. Of these, one form is missing the first six amino terminal amino acids due to cleavage between a glycine-asparagine bond. However, the other, predominant form of the acidic growth factor is longer than the longest truncated form by a 14-amino acid peptide. This predominant form, which can be isolated if proper precautions are taken to limit proteinase activities, has a blocked amino terminus and a molecular weight of 17,400[20,21].

Mitogenic effects

Both the cationic and acidic families of heparin-binding growth factors are potent mitogens for the ubiquitous cultured fibroblasts; hence, their designation as fibroblast growth factors (FGFs)[16,17]. However, these factors have had their largest impact as ECGFs, or endothelial cell growth factors. These factors have angio-

genic activity *in vivo* and are a requirement, in serum or serum-free culture, of cells from a variety of vascular tissues.

Surprisingly, the acidic form of the heparin-binding polypeptides also accounts for the neural extract requirement of normal and tumour rat and human prostate epithelial cell proliferation[10,11,20-22]. All three forms of the acidic factor, called prostatropin in this role, supported half-maximal proliferation rates for normal and tumour prostate epithelial cells at concentrations of 50 and 7 pM, respectively, in chemically-defined medium[20,22]. These findings place at least one epithelial cell type in the target cell spectrum for the heparin-binding family of growth factors.

In summary, this growth factor family enables cell biologists to culture new cell types in defined medium. Until recombinant technologies for factor production are developed, heparin-affinity chromatography can provide purified factors from bovine brain or other tissues in quantities sufficient for commercial distribution. The complete spectrum of target cell types whose maintenance is dependent on these growth factors has not been established. The current spectrum, however, includes both cell types of the human vascular system which are central to understanding heart disease, atherosclerosis and abnormal angiogenesis, and one epithelial cell type important for studying prostate hyperplasia and adenocarcinoma. □

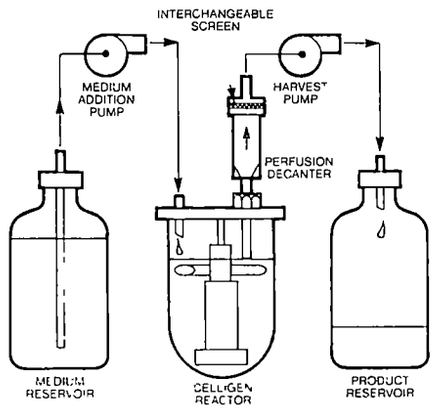
Hi-tech for tissue culture: a growing endeavour

Persuading cells to grow outside of their native surroundings can be a complicated task, demanding elaborate materials and equipment.

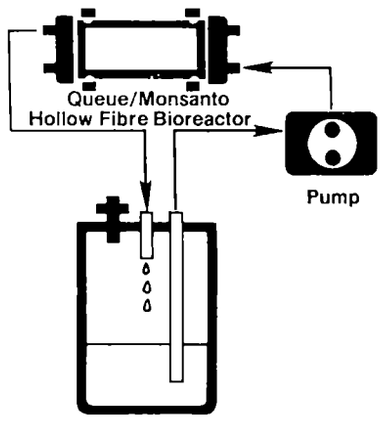


VENTREX makes a **disposable, pre-sterilized airlift fermenter** for one-time use in laboratories that don't routinely perform cell culturing (Reader Service No. 100). Their 650-ml benchtop device, called Cellift, can be used for batch cultures or in continuous feed mode when attached to an infusion instrument. Ventrex also

A fermenter for the infrequent user.

offers a heating jacket as an option to their system. Constructed of polystyrene, Cellift is suitable for bacterial as well as mammalian cell cultures, and it can maintain cultures for up to two months. Positive pressure operation reduces the risk of contamination in the fermentor. Ventrex sells a Cellift starter kit for $225 (US); the Cellift unit alone costs $125 (US).

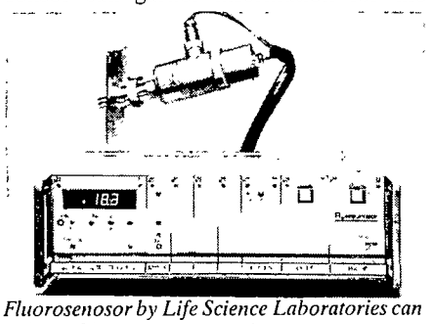
The design of the aeration cavity on New Brunswick Scientific's **bioreactor** enables large quantities of shear-sensitive cells



Cell perfusion is a CelliGen option.

to flourish in sparged medium without damage (Reader Service No. 101). By confining the screened cavity to a remote site on the inside of the hollow impeller, the CelliGen system protects microcarriers and suspended cells from sparging turbulence whilst freely circulating culture medium absorbs the gas. NES says that their bioreactor achieves up to 10 times the K_La efficiency of conventional surface-aeration systems that use a gas overlay. Swept-back, rotating impeller ports keep cells or microcarriers evenly dispersed throughout the CelliGen vessel, and a foam elimination chamber coalesces foam into liquid. NBS put a microprocessor in charge of the four-gas control system, which regulates the volumes of air, N_2, O_2 and CO_2 needed to support the desired dissolved oxygen saturation and *p*H. The microprocessor also regulates temperature to within ± 0.025°C, and stirrer speed to ± 1 r.p.m. over a 15- to 225-r.p.m. range. CelliGen comes in 1.5-, 2.5- and 5-litre sizes starting at $9,450 (US), and is available with four types of impeller systems.

Bellco aims to solve similar cell culture dilemmas with a modified shape for its bioreactor (Reader Service No. 102). Their **conical glass culture reactor** requires less vigorous gas flow, thereby providing gentler circulation for suspended cells and microcarriers. Bellco claims their design also eliminates foaming in high-serum media. The 3.5-litre vessel has a sealed water jacket to reduce contamination, and a microprocessor takes care of harvest/feed cycling to minimize supervision. Bellco's reactor, with its nine-port head, can be expanded via accessory panels. The company also offers an optional dispenser that produces macrocarrier alginate gel beads for cell immobilization. With Bellco's machine, batch or perfusion cycling can be specified through programmable cartridges for the bioreactor's microprocessor.



Modelling the *in vivo* environment, a **hollow fibre perfusion bioreactor** developed by a Queue Systems — Monsanto collaboration lets nutrients flow to culture cells whilst carrying waste away (Reader Service No. 103). A pumping system and a media reservoir complete the basic reactor system, but Queue/ Monsanto recommend a more elaborate control system

The Hybrinet low-shear configuration.

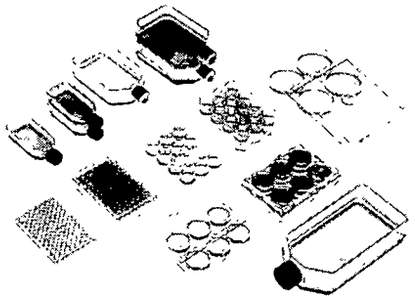
(the Queue Mouse, in particular, was mentioned). Hybrinet is composed of biocompatible materials and does not require pre-sterilization methods or wetting agents that could confer toxicity. The Luer-Loc penetrations accommodate a variety of fittings, probes, valves and filters for specialized applications. Queue/Monsanto say they subject Hybrinet units to non-destructive integrity tests following fabrication. The instrument's specifications are geared towards the maintenance of eukaryotic cells in a low-shear environment: fibres measure 9 inches with a 300 Å pore size, and the flow rate can vary between 10 and 40 m min^{-1}. The hollow fibre module can be purchased alone for $375 (US), or with fittings and a support stand at additional cost.

A **fluorescence probe** from Ingold has just been introduced by Life Science Laboratories in the United Kingdom (Reader Service No. 104). The Fluorosensor can garner information for the

Fluorosenosor by Life Science Laboratories can estimate biomass concentration.

control of oxygen supply and substrate feed and can be sterilized along with bioreactor vessels. Proteins, enzymes, coenzymes, pigments and primary or secondary metabolites can all serve as fluorophores, if subjected to the correct excitation wavelengths. The £10,200 (UK) Flurosensor fits into standard DN25 ports. Once proper excitation wavelengths have been determined for a number of biological compounds, the method's flexibility could open up new control and monitoring options for many biotechnological processes.

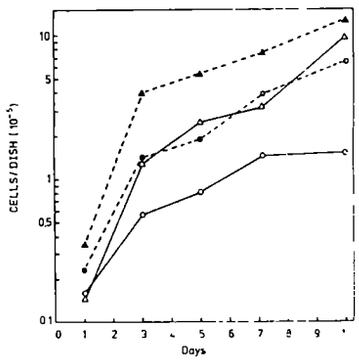
The first chapter of a technical support publication from LH Fermentation Ltd. gives practical advice on fermenter use in **continuous culture fermentation** (Reader Service No. 105). This issue of *Hints & Tips* also expounds upon the applications of continuous culture, as well as problems frequently encountered with this particular technique. LH Fermentation, which recently expanded their airlift fermenter range with a 10-litre version, expects to continue their *Hints & Tips* series chapter by chapter to build a complete laboratory



The first in a fermentation series

manual on fermentation. This first issue comes as part of a larger literature package including LH's newsletter and their 1986 price list.

Labware lookout



Where tissue culture is concerned, **labware coated with extracellular matrix** is often touted as the next best thing to being there. In Vitro International now produces flasks in 25-, 75- and 150-cm^2 sizes coated with bovine ECM, to complement their existing supply of ECM-coated 4-, 6-, 12-, 24- and 96-well plates (Reader Service No. 106). This labware, used like plastic culture labware but stored at 4°C, owes its origin to the efforts of endothelial cells, which excrete ECM into the labware during proliferation. The matrix adheres

IVI expands their ECM-coated labware selection.

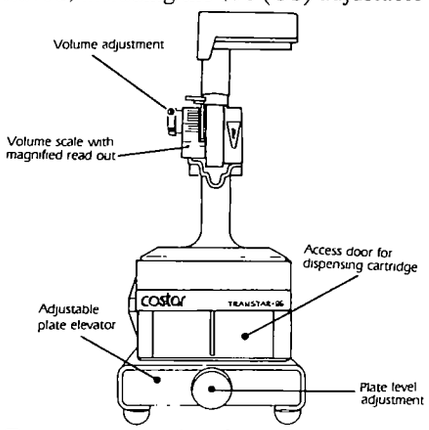
strongly to the plastic, and subsequent removal of the endothelial cells leaves the substratum behind. In Vitro's flasks cost between $20 and $120 (US) in single units or packs of five, and have a shelf-life of four months.

ECM cultured cell lines show reduced requirements for serum supplements and

Cell proliferation on IBT's ECM-coated plates (dotted lines) vs. traditional labware (solid lines).

cellular mitogens while at the same time exhibiting greater attachment, migration, proliferation and in some cases differentiation, than those reared in traditional plastic labware. International Bio-Technologies supplies a wide selection of ECM-coated **tissue culture plastics** and also provides custom-coating services (Reader Service No. 107). One such service is the coating of labware disposables with radiolabelled ECM, tailored to specific customer needs. IBT has compiled technical literature describing the use of their substrate in human amniotic cell and human primary malignant epithelial cell cultures. The main goal is the rapid diagnosis of prenatal disorders and perhaps the *in vitro* study of biologically derived antitumour agents.

Gibco Laboratories, familiar source of cell culture reagents, has taken the plunge into **tissue culture treated labware** (Reader Service No. 108). Gibco has



Gibco goes with surface effects.

flasks, dishes, cluster dishes and roller bottles that have been scored with electron beams to improve cell growth. The company tests its labware for growth support; adherent heteroploid cell lines including CHO-K1, BHK-21 and VERO are used in these plating efficiency and monolayer proliferation assays. Pipettes, microtitration plates, freezing vials and

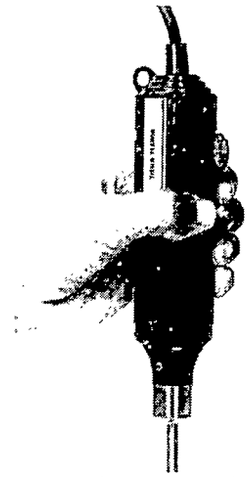
centrifuge tubes are also part of Gibco's labware introduction. A 12-page catalogue gives more information on the new products.

A portable **96-tip dispenser system** from Costar has applications in changing cell culture media, sterile partial removal of media, diagnostic screening assays, and research on and isolation of pathogens (Reader Service No. 109). The 648-gram Transtar will dispense volumes between 25 and 200 µl, under sterile conditions. The entire Transtar unit can be autoclaved, including the $96 (US) adjustable plate elevator that allows plate-to-plate transfers and removal of media without disturbing monolayers. Costar's $496 (US) instrument has a reproducibility of between ±5 per cent at 25 µl volumes and ±2 per cent with 200 µl volumes. It comes with disposable reagent reservoirs having 8 or 12 separated compartments, or with an open reservoir.

Transtar protects microplate and user from contamination.

Chemistry for culture

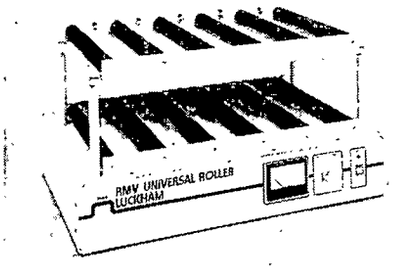
Techniques for **mononuclear cell separation** must welcome a newcomer: Sepratech Corp. has a system based on continuous density gradient centrifugation using their colloidal silica-based medium, Sepracell-MN (Reader Service No. 110). One to six ml of whole blood, added directly to Sepracell tubes, separates with 10 minutes of centrifugation on the gradient established by the rapid sedimentation of Sepracell-MN particles. The resulting MNC fraction segregates above a wide band of Sepracell-MN, whilst the rest of the components are sequestered beneath this band. Sepratech's technique also entails the use of a 'Seprapette' that makes band recovery simple and more complete. The procedure should only be applied to EDTA and heparin anticoagulated blood. Sepratech's $75 (US) package includes 50 sterile tubes, wash media and 50 Seprapettes; Sepratech also gives free samples.



Nearly 500 items for tissue culture are the subject of Sigma's 1986/87 *Cell Culture Reagents Catalogue* (Reader Service No. 111). The brochure's 100 pages cover culture staples such as RPMI-1640 and fetal bovine serum, as well as reagents that only Sigma provides, such as cell culture tested biochemicals.

A culture catalogue with terminology and methodology.

Shear sensitivity



A small volume rotor/stator from Biospec Products can homogenize tissues in less than one minute (Reader Service No. 112). The Tissue-Tearor runs at 28,000 r.p.m. with a 4-inch long probe that draws suspended material into the stator, where the tissue gets repeatedly cycled through six narrow slits. Volumes less than 0.5 ml are fair game for Biospec's device, and samples can be kept cold during the Tissue-Tearor's operation by immersion in an ice bath. The 14-oz instrument can be hand-held or stand-mounted. Speed control allows flexibility: the $388 (US) Tissue-Tearor will mix, emulsify, shred and chop.

Biospec's stainless steel tissue homogenizer.

Roller assemblies for the cultivation of mammalian cells give these fragile cultures gentle treatment (Reader Service No. 113). New Brunswick Scientific has two RollaCell apparatus, RC41 and RC42, that provide precise control of rotation and adhesion for shear-sensitive cells. These units can be expanded from four-place roller assemblies to seven-tiered structures, thereby facilitating mass production. Even larger-scale production models are available, with up to nine tiers and space for 500 mm roller bottles. These systems also incorporate fail-safe devices that signal problems in operation. NBS offers the RC41 and RC42 for £1,231 and £1,425 (UK) respectively.

Luckham Ltd also has a system for continuous **rolling of tissue culture vessels**, with a capacity of up to 25 bottles (Reader Service No. 114). The RMV Universal Roller features a speed meter that fixes rolling speeds up to 60 r.p.m. with a minimum of variation. Luckham's roller will

What happens to NASA now?

This week's report on the shuttle disaster is diagnostic rather than prescriptive. The most urgent need is that NASA should be broken into more manageable pieces.

THE Rogers Commission has at least been swift: it was told to be. While the shuttle catastrophe is still fresh in the mind, there has appeared an intelligent diagnosis of the trouble and a recipe for its avoidance in future. Psychologically, this is what the people of the United States have been yearning for ever since Challenger, with its crew of seven, was destroyed off the coast of Florida in January. The catastrophe was a blow to national self-esteem which has since been made to seem the more cruel by the capture of US citizens as hostages in the Middle East and other assorted insults. Much as it always helps to know the truth, the realism of the Rogers report will persuade people that even if the problems uncovered are serious, they are not insuperable. That is a plus by anybody's reckoning.

The downside is the severity of the criticism directed at the US National Aeronautics and Space Administration (NASA), even if Dr Richard Feynman, a member of the commission, would have preferred a more outspoken report. For several months, it has been clear that the commission would point to errors of two kinds, technical and managerial. The tale of how the different sections of the booster rockets were held together by mechanical joints including rubber seals to prevent the escape of combustion gases has been widely discussed, not least because of the commission's public hearings; these rockets were poorly conceived and their behaviour in exceptional circumstances poorly understood. The managerial errors, for which several senior NASA people have already lost their jobs (the director of the Marshall Space Flight Center in Alabama did well to quit before the Rogers report appeared), have also been apparent for some time. There are many other large organizations in which bad news travels only slowly upwards in the hierarchy, but by the beginning of this year, NASA appears to have been persuaded by the pressure to keep on launching shuttles to devise mechanisms for preserving the innocence among its senior people of the realities of the launching-pad. It is no wonder that the Rogers report is scathing on the subject.

There is every likelihood that the steps recommended by the Rogers Commission will right these faults. The boosters will be redesigned, while there is almost certain for a few months to be a mood in which doubts and criticisms will move freely within the organization and be openly discussed. Given past achievements, there is no reason why NASA should not be able to put these things to rights, so that shuttles will be climbing safely through the atmosphere into Earth orbits a year or so from now. But these are relatively minor and even technical matters, well within NASA's competence. What nobody has considered yet, but what the US administration should take up urgently, is the more teasing question of what NASA is for, and whether its organization is compatible with those goals.

Goals

It tends to be forgotten, but should not be, that NASA as it now is grew out of a federally-supported aeronautical research organization in the United States, and that basic research in the field remains an important part of its function. Much the same is true with rocketry and spacecraft construction. Of necessity, NASA has had to pave the way with these developments. One of its perennial difficulties is that it has been able to shed responsibility for only a small part of its role in technological research and development, mostly the work on satellite design and construction on which the telecommunications companies are engaged. But NASA has also, almost without recognizing it, become an operating agency, continuing to operate satellites that cannot be handed over to commercial interests (which means most of them), launching and recovering spacecraft and so on. That, through the agency of a talented if geographically scattered staff, NASA has also become an essential complement to the academic community, is an uncovenanted benefit.

Defects

NASA's defects, unfortunately, are also many and familiar. Whether it is fair to say, as many newspapers have been doing, that NASA has become arrogant and over-confident is irrelevant. With 15 years of almost unalloyed success in launching well-publicized spacecraft to its credit, it must be tempting to be cocky. But there is plenty of evidence that goes the other way. It is a long time since NASA as an organization behaved as if it were possible to fight the US administration and the Congress for a budget that matched the ambitions with which it had been saddled by public policy. Of necessity always a big spender, NASA has nevertheless become almost a passive spender, willing to cut its coat to suit the cloth the appropriations committees handed out even when this meant abandoning important projects, most often important scientific projects, sometimes projects to which agencies elsewhere (such as the European Space Agency) had been induced to commit funds. Is it possible that NASA's learned behaviour of pleading poormouth and blaming the US Congress for that condition led it also to the view that trouble caused by cutting corners, as in January, could also be blamed on others? The Rogers Commission says the pressure was to run shuttle launches as if by an airline timetable so as to cultivate congressional indulgence. It is a shame that, because this calculation has misled, parts of NASA's operations that are well conceived and imaginatively run may be tainted by the same charge of mismanagement.

The truth is that NASA has acquired too many partially conflicting goals. Space launchers are at best means to a variety of ends, but when the launcher programmes are in trouble, the ends tend to be sacrificed to the means. The solution is to break up the present organization into a few smaller pieces whose objectives would be more coherent. One way of doing this would be to separate technical development (including that of aircraft), the business of running transportation systems and NASA's role as a doer and sponsor of space research (which at present is hurt first when funds are short). Then at least there would be only the budget-people to blame if the parts of the programme swung out of balance. NASA will no doubt protest that the same argument could be used to take high-energy physics away from the Department of Energy, but that is not the case; the department, like its predecessor, the Atomic Energy Commission, has sensibly devised a mechanism by which the high-energy physics community's claims on public funds stand or fall by the good sense of what the High-Energy Physics Advisory

Panel thinks it proper to recommend from time to time.

NASA may also fear that dismemberment into more manageable pieces may complicate its matching of the demand for launching facilities with the supply it has created. That, too, is misplaced. While the vast majority of the projects on which researchers have set their sights could be handled as well by inanimate rockets as by the shuttle, that is not the case for the most valuable of all the projects, the Hubble Space Telescope (which must now languish on the ground for an extra year), while there would be no case against a craft such as the shuttle if it were dependable and cheap. In any case, especially after the latest failure of Ariane two weeks ago, launcher operators are unlikely to have spare capacity for a long time to come.

This is why the best framework in which to solve NASA's problems is quick clean surgery, which will in any case be necessary at some stage in the future, when spacecraft with or without people have ceased to be seven-day wonders. □

Observers in arms

The fate of Britain's oldest observatory will be decided next week. Or will it?

How strong are the nerves of the Science and Engineering Research Council (SERC), the chief sponsor and even manager of Britain's academic research? This is what British astronomers will be asking in the time between now and 18 June, the date fixed for the next meeting of the council and, at SERC's own choice, for a final decision on the future of the Royal Greenwich Observatory (RGO). In the three months since the decision was announced (see *Nature* **320**, 239; 1986) that the observatory would have to move again — forty years have gone since it said goodbye to Greenwich — there has been a fierce rumbling of protest from many of those affected that the decision is mistaken, which message has been blunted and confused by the siren-sounds from those other astronomers with an interest in tempting RGO to some particular place or other. A meeting of astronomers of all kinds in London last Friday seemed to be united in feeling that SERC has somehow mismanaged the whole business. So next week's council meeting becomes a test of SERC's credibility as well as of its good sense.

The reasons why some kind of decision is needed are by now well-known. Because of decisions taken by SERC (then merely SRC) in the 1970s, British astronomers are about to be blessed with a range of what may reasonably be called modern telescopes, and which will also give academic astronomers allocations of telescope time about which they cannot seriously complain. The snag is that the new equipment is a long way from Britain, in the middle either of the Atlantic or of the Pacific. As observers elsewhere know as individuals, geography may be a nuisance but is not an insuperable obstacle to good work. SERC's difficulty is that, having built the new telescopes as part of its terms of reference to foster research at British universities and polytechnics, it discovers on its payroll some 250 people at the two British observatories, RGO and the Royal Observatory Edinburgh. The problem might have been anticipated a decade ago, but was not. Since then, by common consent, the two observatories have done valuable work in supporting the development of instruments for the facilities being built elsewhere and, more recently, have been providing academic users of the new facilities with advice and assistance based on their own experience, frequently much greater. That there will be a continuing need for services of this kind is generally accepted. SERC's problem is three-fold. First, as a consequence of past decisions, it is spending more on astronomy relative to other things than it would if it were starting from scratch (but nothing said about the decision to move RGO suggests immediate savings). Second, without the issue ever having been declared, SERC is seeking (rightly) to effect a shift of responsibility (or opportunity) for observational astronomy from the in-house observatories to the universities, which is why the decision that Greenwich rather than Edinburgh should move was based on SERC's opinion (which RGO disputes) that Greenwich has been the less successful at forming links with universities. Third, at no point during the five years in which the need for reorganization has been apparent, during which time there have been two formal attempts to find an acceptable solution, has there been a serious effort to decide how the now-expanded British effort in astronomy should be managed. There is a sense in which the present council is the victim of its predecessors' neglect which, given collective responsibility, is an explanation but not an excuse. The anger and bitterness that have preceded next week's council meeting have arisen because too little has been said to those whose careers are affected.

What, then, should be done to manage the transition without further exacerbating relations between SERC and important sections of the astronomy community? The first need is for a convincing statement of SERC's strategy for astronomy. To what extent is the long-term aim, that most observers should be academics, desirable, for example? Having made a good if belated beginning on the provision of modern facilities, does SERC intend to follow through when the demands come (as they surely will) for even better equipment? And may it then not act alone, picking up assistance from others as an afterthought (Dutch as well as Spanish astronomers are partners in the La Palma observatory), but by seeking partners from the outset? All three questions should of course be answered yes. But only if they are answered clearly and sympathetically will those at the observatories whose careers will be affected have the stomach to soldier on.

What would such a strategy imply for the immediate future? If the best way of building on past investments in astronomy without jeopardizing science as a whole is to build the next generation of telescopes in collaboration with partners overseas, SERC would recognize more clearly that national support centres are inappropriate. Planning that observers should be distributed among universities, it would conclude that technical support should be similarly spread out. In the long run, neither Edinburgh nor RGO would be needed. The objection to SERC's planned course, amalgamation on the Edinburgh site, is that it would permanently institutionalize the complex. If it were now to say that Edinburgh will in due course follow RGO in being made part of a university, RGO's bitter pill would be easier to swallow. If SERC is not ready to say that, the case for moving RGO diminishes.

SERC should also be more open about its financial plans. It says that present recurrent spending will not increase, but no allowance has yet been made for future capital expenditure. Why not say flatly that SERC needs to save money now on running costs against capital spending in the future? RGO itself will have shrunk to 150 people (of whom 40 will be based in mid-Atlantic) when the present contraction is complete by 1990, but there is a case for going faster and further. The millstone that SERC has made to hang around its successors' necks is the promise that RGO will retain its independence, which will be taken as a promise of constant budgets a decade hence.

There remains the question of how British astronomy should acquire a sense of being led in a recognizable direction. SERC is a benign and well-intentioned organization that has done good works from time to time. Unfortunately, it cannot help but seem part of the civil service: why else have the directors of the two observatories been compelled to say nothing in the past three months about the aspect of their institutions that matters most, their future? Like NASA, which has the more serious problem of the shuttle to accommodate (see previous page), SERC needs a mechanism for helping the community it tries to serve to believe that its true wishes, not some others wished upon it, will be met. If SERC could arrange for that, its difficulties with those at RGO would melt away. If it cannot, its credibility will indeed decline. □

Shuttle catastrophe

Rogers Commission report makes waves all round

Washington

DESIGN flaws, organizational problems and inadequate safety procedures all played a role in the accident on 28 January that destroyed the space shuttle Challenger, according to the presidential commission chaired by William P. Rogers, whose 250-page report was published this week.

The commission concludes that the accident to mission 51L occurred when a gas leak developed at the joint connecting two segments of the right solid rocket booster (SRB). The leak developed within seconds of launch, showing up in photographs as a puff of black smoke. Then it evidently sealed itself, possibly with combustion products from the booster, but after the shuttle successfully passed through severe wind shear, the leak reappeared 58 seconds after lift-off.

Then the slipstream directed the burning gas from the leak onto the external fuel tank, ultimately burning a hole in it. At 72 seconds, the lower strut holding the booster to the fuel tank was severed or pulled away, allowing the booster to pivot, smashing into the external fuel tank and releasing massive amounts of liquid hydrogen. Within milliseconds there was a "massive, almost explosive burning" of the hydrogen spilling from the tank.

The commission concluded that the accident occurred because O-rings supposed to form a seal between two segments of the right solid rocket booster failed to do so. The O-ring seals are designed to be "pressure actuated", only sealing once increased pressure is applied to the joint by the firing of the rocket motor. The commission concluded that the failure was due to "a faulty design".

The commission was also critical of the process that resulted in the decision to launch Challenger. Testimony presented to the commission revealed that the decision to fly was based on "incomplete, and sometimes misleading information". The O-rings had been identified as early as December 1982 as parts whose failure could result in a mission disaster. In July 1985, SRB manager Lawrence Mulloy placed a launch constraint on all shuttle launches, which meant that a waiver had to be signed before each flight could proceed. But neither the constraint nor the waivers were known to the director of the shuttle programme or his senior deputies.

The 24 previous successful launches of the shuttle also contributed to the accident. As commission member Richard Feynman put it, NASA convinced itself that safety standards could be lowered a little bit after each launch "because we got away with it last time".

The commission also investigated the pressures on the shuttle programme caused by NASA's reluctance to relax optimistic schedules. A critical shortage in spare parts forced NASA to turn to cannibalization, borrowing parts from one

orbiter to allow another one to fly. But the accelerated launch schedule meant the shuttle would either be in orbit or preparing for launch, thus not available for supplying spare parts.

The commission's chief recommendation is that the faulty joint and seal of the solid rocket booster should be either eliminated or redesigned. But other recommendations are likely further to increase the cost of bringing the shuttle back into service and to decrease the rate of shuttle launches thereafter.

The booster joints had for several years been suspect. Instead of a complete redesign of the joint, now as seen as necessary, Morton Thiokol Inc. and NASA opted for some retesting and the imposition of "launch constraints", which were then overridden for every launch after 10 July 1985.

The commission is forthright on the need for other safety improvements, landing safety included. Tyres on the landing gear are acknowledged by NASA to be "critical" components, but tyres have shown "excessive" wear during several previous landings. The brakes, which have been damaged on most flights, have "little or no margin".

The commission urges efforts to provide a crew escape system for use during gliding flight. Although early test flights of the shuttle included ejection seats, recent space missions have had no such feature, which would require a major effort, and probably taking up valuable space and weight. "Rocket-assisted extraction" is a possibility.

The commission, impressed that pressure on NASA to maximize launch rates may have contributed to management failures and the accident, says the capabilities of the system stretched "to the limit" to support flight rate in winter 1985–86. In what may be one of the most significant long-term recommendations, the commission urges that the United States should not rely exclusively on the shuttle for launching capacity, a complete reversal of the administration's declared policy.

On management, Rogers says there must be a redefinition of the programme manager's responsibility. Project managers apparently felt more accountable to their particular NASA centre than to the programme as a whole.

Tim Beardsley & Joseph Palca

Other avenues?

Washington

THE Rogers inquiry subdued the natural inclination of Congress to get involved; now that the report is public, both houses of Congress intend to hold hearings on the findings, and on the accident itself.

At least one senator, unable to wait until publication day on Monday, introduced legislation last week following a "recommendation by the Rogers Commission" to revive quality assurance at NASA. Congress has also been impatient with the inability of the White House to decide on buying a new orbiter, and may suggest its own plans for the agency.

The National Research Council (NRC) will also have a future role in the shuttle programme. NRC's standing review committee on NASA's scientific and technological programme will set up a panel to evaluate development and construction of the new solid rocket boosters.

NASA itself is also having to reevaluate its role. The Reagan administration no longer wants NASA to be the sole provider of launch services for commercial satellites, while the Department of Defense has already ordered ten Titan 34D7 rockets capable of launching payloads nearly as large as those carried by the shuttle.

Without the military or industry as steady users, will NASA find itself more interested in the needs of the scientific community? Bruce Murray, professor of planetary science at the California Institute of Technology and former director of the Jet Propulsion Laboratory, says NASA took a procrustean approach, forcing users to fit their projects to the shuttle's capabilities. Murray believes NASA will now have to serve space science and manned exploration of space.

For the time being, with no shuttle and no alternative launch vehicles, space science projects are dead in their tracks. Even if funds for scientific projects are preserved, NASA's chief scientist Frank McDonald says the shuttle's loss will damage the programme. Joseph Palca

Seismic monitoring

Private diplomacy emergent

Washington

A REMARKABLE agreement signed last month would permit a team of US and Soviet seismologists to establish a seismic monitoring station within 200 km of the Soviet nuclear test facility at Semipalatinsk. What makes the agreement all the more unusual, and contentious, is that it was not signed by representatives of the US government.

The agreement came out of a series of meetings between representatives of the Natural Resources and Defense Council (NRDC), a private non-profit organization devoted to protecting the environment, and the Soviet Academy of Sciences. Adrian DeWind, NRDC's board chairman, and E.P. Velikhov, vice-president of the Soviet Academy, signed the agreement in Moscow on 28 May.

Under the agreement, six monitoring stations would be established, three in the Soviet Union near Semipalatinsk and three near the Nevada test site in the United States. All data recorded will be made available to both the US and Soviet governments. NRDC will pay all the travel expenses involved in the project and will take responsibility for obtaining the necessary seismological equipment. DeWind estimates that NRDC will have to raise $500,000 to get the project off the ground. It hopes to establish the first listening post in the Soviet Union by the end of this month, with two more to follow in the fall. The US monitoring posts will be established only when the Soviet posts are in place.

Thomas Cochran, a physicist on NRDC's senior staff, says the idea for the agreement came from discussion last January on the monitoring of US explosions whose occurrence is not made public. Cochran and his colleagues at NRDC felt that monitoring only the Nevada test site might be regarded as "giving away state secrets", so he devised the bilateral plan.

Although the monitoring sites may provide information about the local geology of the Semipalatinsk region useful for evaluating yields of Soviet nuclear tests, that is not the point of the exercise. Rather, says Cochran, it is to show the feasibility of on-site seismic monitoring, proving that verification is not an obstacle to a test-ban treaty. The Soviet Union is currently observing a self-imposed moratorium on tests, but that may expire on 6 August.

Before the plan can go forward, NRDC must obtain export licences for the seismic equipment. A State Department official said last week that no decision had been made on NRDC's request for a licence, but that the agencies responsible for technology transfer issues were considering it. NRDC plans to purchase off-the-shelf equipment for the monitoring stations, according to Charles Archambeau of the University of Colorado who acted as a consultant to NRDC. If the export licences are not granted, Archambeau says the project could still proceed using Soviet-built equipment. But Archambeau says that Soviet equipment is not as sensitive as that from the United States, nor is it digital, making data acquisition and analysis more difficult.

Critics of the agreement believe that it will serve only as a propaganda weapon for the Soviet Union. Misha Tsypkin, Salvatori Fellow in Soviet Studies at the Heritage Foundation, a conservative think-tank, argues that the Soviets are adept at manipulating foreigners to serve Soviet goals. Tsypkin believes that NRDC was "irresponsible and out of order" to proceed with such politically sensitive negotiations off its own bat, without government participation or approval. Archambeau concedes that NRDC's plans may undercut current US government positions on arms control. But according to Cochran, something was needed to "get some movement in the arms control arena".

The agreement comes at a time when the United States has announced it plans to end its observance of the unratified SALT II treaty later this year. The government believes that Soviet unwillingness to abide by the terms of the treaty makes it impossible for the United States to do so. But efforts are under way in Congress to force US compliance with the treaty by eliminating funds for projects that would violate its terms; these are unlikely to succeed, however. Supporters of the Soviet test moratorium are also planning to introduce legislation stopping US nuclear testing, although these efforts also face an uphill struggle.

Accoding to a State Department official, the NRDC agreement "may be encouraging" to the extent that it represents a change in Soviet attitudes on verification of the Threshold Test Ban Treaty, which the United States believes the Soviet Union has been violating. But the State Department believes that negotiations that could have such a great impact on arms control and national security should be conducted only between governments.

Frank Press, president of the National Academy of Sciences, sees the NRDC agreement as an "extraordinary event", but says it is too soon to judge its implications. "Arms control has never been a private sector activity before... When books on arms control are written, this will certainly be included." **Joseph Palca**

Soviet industry

Reformers get the wrong man

IT seems that Mr Mikhail Gorbachev's drive to make Soviet industry more efficient is not without its hitches. Last month, none other than the Central Committee of the Communist Party of the Soviet Union intervened to demand the reinstatement of a person who had earlier been wrongfully demoted from his managerial post at the Irbit Chemical and Pharmaceutical Plant.

The Central Committee's special decree dealing with the state of affairs at the plant is revealing. The plant is supposed to produce high-quality supplies for the Soviet medical services, but is run-down, behind in its modernization programme and provides no scope for the development of new ideas and products. These are precisely the conditions condemned by the plenum of the Central Committee held in April 1985.

The Central Committee now says that, instead of trying to rectify these conditions, the director of the plant, with the support of the local party organization, deprived a certain Vadim Bakharev of his post, in charge of production unit Number 2, on the grounds that "he had ignored the opinion of working teams", shown "crudeness" in dealings with his subordinates and had "consistently failed to fulfil his work obligations". Bakharev accepted his transfer to the lower grade of engineer only because of the threat that he would otherwise be dismissed outright.

Bakharev was demoted on 4 December last year. How and when the higher echelons of the party learned what was going on is not clear, but, on 20 April, the newspaper *Pravda* carried a long account of the affair which claimed that, far from being responsible for the shortcomings at the Irbit plant, Bakharev was a lone hero who had fought neglect and inefficiency, and who had been victimized for his zeal.

According to *Pravda*, Bakharev had in reality combined two previous production units together so as to cut costs by 75 per cent and increased labour productivity by 98 per cent (partly by eliminating 36 jobs) at a saving of 300,000 rubles a year. It was not Bakharev but the plant managers who had "ignored the opinion of the working teams" by demoting such a paragon.

A month later, the Central Committee pronounced. The Ministry of Medical and Microbiological Industry was instructed that Bakharev's demotion had been unjustified, and that he must be reinstated forthwith. The ministry was also told to put matters at the factory right, modernizing and re-equipping the production lines and improving the working and living conditions of the workforce. The party

secretary at the plant has been relieved of his post and other officials disciplined.

The Irbit factory is important in the Soviet Union's plans to build a sophisticated pharmaceutical and specialist chemical industry, and should be at the leading edge of the government's new drive for modernization. The intervention of the Central Committee, and the attention it has been given, may be intended as a warning to plant managers elsewhere that they had better put their affairs in order before the drive for modernization gathers momentum and that a random selection of scapegoats will not suffice.

AIDS research

New foundation begins work

Washington

SUPPORT for research into acquired immune deficiency syndrome (AIDS) has received a shot in the arm from the American Foundation for AIDS Research (AmFAR). The new foundation handed out 20 grants totalling $1.1 million, mostly for basic research on the biology of the virus assocaited with AIDS, with a smaller number for drug development and epidemiology. AmFAR's scientific advisory committee was looking primarily for projects demonstrating "fresh ideas", according to a spokesman for AmFAR.

The 20 projects receiving grants were chosen from 146 applications. The maximum $60,000 grant is not intended to sustain a major research effort, but will instead provide start-up money for new projects.

AmFAR came into existence last September when the AIDS Medical Foundation, based in New York, merged with the National AIDS Research Foundation of Los Angeles. Actress Elizabeth Taylor serves as AmFAR's national chairman, and has been an active force in fundraising. In future, AmFAR hopes to move its financial base away from special fundraising events to long-term commitments from corporations and philanthropic foundations.

Although the $1.1 million offered by AmFAR is only a small fraction of the $233 million AIDS budget of the US Public Health Service, there is always enthusiasm for a new source of funds. "Any branch I can shake for support is marvellous," says Murray Gardner of the University of California at Davis, who received a $60,000 grant from AmFAR to study the structure of the envelope protein of the AIDS virus.

AmFAR can also move more quickly than the federal government. It solicited proposals in January, and made decisions on them just 4 months later. **Joseph Palca**

Rice breeding

Manipulation of cereal succeeds

Tokyo

THE basic techniques for the genetic engineering of rice have been developed in research institutes in Japan. Several laboratories are racing to draw the techniques together so as to be the first to produce a genetically engineered rice plant. The development is important not only because genetic manipulation has so far been mostly confined to dicotyledonous plants but also because rice is the staple food of half the world's population.

The transfer of genetic material into cereal plants has hitherto been held up because they cannot be infected with the *Agrobacterium* species which have provided a simple route to the transfer of genes in dicotyledonous plants. But two new developments have given rise to optimism that genetic manipulation of rice will be possible in the near future.

The regeneration of whole rice plants from protoplasts (single rice cells stripped of their cell wall) is one way. Success has just been reported in print by Professor Yasuyuki Yamada's group at the Kyoto University Research Center for Cell and Tissue Culture (see *Plant Cell Reports* **5**, 85; 1986). Two industrial laboratories, a joint laboratory run by Mitsubishi Chemical and Mitsubishi Corporation and Mitsui Toatsu's research laboratory have also described regeneration techniques at research meetings. Each group has its own method and it is too early to know which will prove most practical.

Yamada can regenerate tissue from protoplasts by the simple trick of adding calf serum, commonly used in the culture of animal cells, to his medium; after all, he says, a "plant protoplast is almost the same as an animal cell".

From one culture cell line, Yamada has been able to produce calli (undifferentiated tissue) from 10 per cent of protoplasts, many of which formed roots and shoots and developed into whole plants when transferred to regeneration medium. Although other strains produced calli, only one regenerated whole plants and there is evidence that the adult plants, now out in pots and the fields, are not entirely normal. Further work may thus be needed to make the regeneration method of general use.

The Mitsubishi group, led by Dr K. Shimamoto, appears to have had much broader success. It has successfully regenerated whole plants from protoplasts of five different genotypes, two of them major commercial cultivars. More than 300 plants have now been regenerated, and of these 120 are now growing in paddy fields. They can later be studied in detail for differences from the parent stock.

The innovations behind the Mitsubishi group's success is that, instead of making protoplasts from rice cell lines maintained for a long time in culture, they have induced calli from rice seeds. The protoplasts so produced are "young" and have strong morphogenic potential. In the past, this approach has not been favoured because cells in fresh culture from seed do not divide — overcoming this obstacle is the secret of Shimamoto's method.

The second group of advances, for the transfer of foreign genes into protoplasts, has also very recently been reported, and depends on the observation that protoplasts prepared from cultured callus cells and treated with polyethylene glycol will take up foreign DNA. Dr Uchimiya's group at the University of Tsukuba has successfully introduced a chimaeric gene containing an antibiotic resistance gene in experiments of this kind. He was not, however, able to regenerate plants from the transformed cells.

With both regeneration and transformation proved possible, the race is now on to "put both techniques in one hand", as Uchimiya says, and to produce the first genetically engineered rice plants. Judging from reports from the five or so laboratories carrying out similar work, the winner should be declared fairly soon.

The question remains of what useful application can come from the research. In theory, the potential is vast, for rice is the major source of carbohydrate for almost half of the world's population. But rice has been intensively improved by breeders for almost a century, while large increases in production can be expected in the poorer countries of Asia simply through extending irrigation. This makes Japanese companies wary about investing heavily in rice research, for even now rice can be grown in Japan only by maintaining an artificial price several times that of the world market.

Early on, genetic engineering may be used to make things easier for the conventional breeder. Male sterile lines, valuable in breeding new strains of rice, are hard to produce by ordinary methods but should be easily made by protoplast fusion. One protoplast carrying the cytoplasmic male sterility factor but with its nucleus inactivated can be fused with the desired strain of rice.

In the longer term there are the possibilities of transferring genes from other cereal crops that seem to perform more efficiently, introducing viral resistance genes and altering genes to improve the quality of the seed protein. Again, there are ten wild species of rice which present an almost untapped reserve of genetic variability. Protoplast fusion will make it accessible. **Alun Anderson**

Germany and Chernobyl

End of the nuclear programme?

Hamburg

THE cloud whose changing direction carried radioactivity from Chernobyl over Western Europe last month has changed the political climate in West Germany. Fallout has become a national issue which will affect the regional (*länder*) elections due in the next few months and even the federal elections next January.

The general confusion in the days following the accident has left its mark. Chancellor Helmut Kohl, in Tokyo for the economic summit, at first reacted calmly, saying that the accident was characteristic of planned economies and could not have happened in West Germany. By the time, six days after the accident, that fallout reached West Germany, Kohl (still in Tokyo) was urging further expansion of nuclear energy in West Germany even as the first warnings against drinking fresh milk were being published.

Conflicting information was given out from several sources. The Minister of the Interior, Friedrich Zimmermann (CSU), was explaining on television that contamination from a reactor 2,000 miles away could not occur while the first radioactive rain began to fall. Officials of the federal and *länder* governments gave out contradictory advice. In Bavaria, the most affected of the *länder*, the right-wing government played down the problem for the first few days, but in Munich, with its SPD (Social Democrat) city government, people were told to avoid contact with soil or grass.

Police clash with demonstrators at Brokdorf last week

The federal government said that people should not drink milk whose radioactivity was more than 500 Bq per litre, but in some *länder* the limit was only half as much, while Hesse fixed it at 20 Bq per litre. In many cities, kindergartens and playing-fields were closed and the marketing of green salad and spinach forbidden. Farmers were forced by the police to destroy vegetables or, as in Nordrhein–Westfalen, to keep cattle off pasture. Geiger counters were sold out after a few days.

Psychoanalysts claim to have identified a novel fear among the people of West Germany, whose dread has been described by the newspaper *Bild* as "Atom-Angst" (nuclear fear).

The political consequences are signalled by the latest opinion polls, to which the political parties have begun to adapt their nuclear policies. The Greens, who have always wanted an end to nuclear construction, now demand that nuclear plants should be abandoned. The Social Democrats (SPD), conscious of the figures, have adopted the slogan "the beginning of the end" and have appointed a committee under Volker Hauff, a former federal minister of research, to suggest by the summer how the nuclear programme should be run down.

Public opinion has changed dramatically. The percentage of those wanting no further nuclear reactors to be built grew in a few days from 46 per cent to 69 per cent and reached a peak of 83 per cent. In Niedersachsen (Lower Saxony), where there is an election on 15 June, the opinion polls put CDU (Christian Democrats) and SPD almost equal with 43 per cent of popular support, compared with 51 per cent for CDU and only 37 per cent for SPD at the 1982 elections. The same poll gives FDP (Free Democrats) less than the 5 per cent required for representation in the regional parliament. The Greens have increased their support to 10 per cent from 6.5 per cent in 1982.

This week's elections in Niedersachsen could have national consequences. If SDP in coalition with the Greens (as in Hesse) is able to oust the present CDU chief minister, the government coalition could lose its majority in the Bundesrat in Bonn.

SDP is looking further ahead, to the federal elections in January 1987. It has already said that it would probably stop the DM7,000 million fast reactor project at Kalkar, but Johannes Rau, the SDP candidate for the chancellorship next year who is at present chief minister of Nordrhein–Westfalen, where Kalkar is situated, has already ensured that the builders of the project will be forced to give it up by demanding new safety measures.

With the Kalkar reactor apparently doomed, attention has turned to the reprocessing plant at Wackersdorf in Bavaria, the technical need for which turns on the manufacture of plutonium for the fast reactor. There have been violent clashes at the plant between police and demonstrators. The Austrian government has also demanded that West Germany should give up the project, but has been told not to interfere. Both Bonn and the CSU Bavarian government seem committed to the DM6,000 million project, although that may change before the autumn's election in Bavaria, whose farmers have been most affected by fallout.

West Germany's present use of nuclear power is impressive. There are 19 nuclear plants producing 16,000 MW of electricity, or 36 per cent of the total. A further seven plants (including 300 MW Kalkar) are due to be commissioned by 1990, equivalent to 50 per cent of generating capacity. In North Germany, around Hamburg, no less than 70 per cent of electricity generation is nuclear.

Meanwhile, the SDP–Green coalition in Hesse has taken up the question of how to implement the Greens' demand that nuclear generation should be halted. A paper by the first regional environment minister (see *Nature* **321**, 299; 1986), Joschka Fischer, accepts that there would be higher electricity prices and more air pollution during a transitional period, and has been called utopian by most politicians. But it won support last week from a surprising source, the director of the huge energy supplier Preussag Electra: a director, Hermann Kramer, said that the calculations are essentially correct.

Elsewhere, the CDU government of Schleswig–Holstein has delayed the start of the construction of the twentieth reactor planned at Brokdorf, near Hamburg, at least until after this week's elections in neighbouring Niedersachsen, while Ernst Albrecht has announced the creation of a new centre of solar energy research.

The federal government is softening its arguments. Chancellor Kohl is no longer asking for more nuclear power stations, while many SDU and FDP politicians suggest a "pause for reflection", while insisting that a halt to the nuclear programme would go too far and would not in any case make West Germany safe from nuclear accidents because there are at present a total of 66 nuclear plants in surrounding countries.

A reminder of that truth came last week, when the Oko-Institut of Darmstadt announced that there had been a small release of radioactivity from its high-temperature reactor at Hamm-Uentrop, previously thought one of the safest. It seems that the leak was swamped by the fallout from Chernobyl, but the Nordrhein–Westfalen government has ordered the reactor closed until the company produces a full report on the safety of the system.

Meanwhile, the Bonn government has conceded one of the first demands of the Greens, and has appointed Walter Wallmann (CDU) as the federal government's Minister for the Environment, Nature Protection and Reactor Safety. The opposition regards the appointment as a clear admission of the mistakes of recent weeks. No issue has so much stirred West Germany as the fallout from Chernobyl.

Jürgen Neffe

US biotechnology

Row over industry regulation

Washington

CONGRESSIONAL frustration with the White House's delay over its regulation of the US biotechnology industry was plain last week at noisy hearings on Capitol Hill into Congress's own proposals on the subject. But Congress's attempt to act alone to regulate biotechnology was decried by administration officials and by industry representatives alike.

Although the administration's plans for coordinating agencies that deal with biotechnology were promised for early this year, they had not appeared by the end of last week. The legislation proposed in the House of Representatives would upstage the administration's plans and make them irrelevant.

The chief proposals in the Biotechnology Science Coordination Act of 1986 are the establishment of a Biotechnology Science Coordinating Committee to scrutinize government actions, and also of a biotechnology science research programme to be paid for jointly by industry and by the government. The bill would also modify statutes governing the Environmental Protection Agency and the US Department of Agriculture (USDA) to ensure that all environmental releases of genetically modified organisms that include DNA from different genera would be subject to special licensing and permit requirements.

The bill (HR 4452) was introduced by Representative Don Fuqua (Democrat, Florida), the outgoing chairman of the House of Representatives' Science and Technology Committee. Because Fuqua will not be present to lobby for the bill, it has little chance of becoming law in the current Congress. But congressional staff think that if a consensus emerges that new legislation is needed, there might be legislation next year.

The administration's proposals rely on existing statutes, and will exempt from special review those modified organisms whose new DNA includes only non-coding regions (see *Nature* **321**, 458; 1986). The proposals have apparently been held up in the White House domestic policy council. David Kingsbury of the National Science Foundation, who directs the day-to-day business of the working group that drafted the guidelines, told an angry Representative Harold Volkmer (Democrat, Missouri) that he was "as frustrated as you are" over the delay.

The chairman, Representative James Scheur (Democrat, New York), even threatened to postpone the hearing until the administration had announced its plans. That draft copies of the administration's proposals have been leaked to industry spokesmen (admitted by the Industrial Biotechnology Association) did nothing to improve the congressman's temper.

One of the chief objections voiced to the bill was that a statutory Biotechnology Science Coordinating Committee would be less flexible than the existing committee of the same name, which consists only of senior officials of the relevant agencies meeting in private. The proposed new committee would have more open meetings, and industry spokesmen fear that it would be unable to deal with confidential business information in secrecy.

The proposed new biotechnology research programme was more popular, although industry spokesmen were worried that their newer members would be unable to afford such a scheme. The programme as outlined in Fuqua's bill would create a database bearing on regulatory decisions that would also point to projects for research. But witnesses were critical of limitations imposed on agencies' discretion to give special consideration to small environmental releases by research institutions, and said the cost of meeting unmitigated safety requirements might well prove prohibitive. **Tim Beardsley**

Chernobyl

Now for the long haul

THE Soviet government's special commission on the causes of the Chernobyl disaster and its aftermath will shortly be finishing its work, according to Academician Valerii Legasov, first deputy director of the Kurchatov Atomic Energy Institute at a Moscow press conference last week. But it has already been established, he said, that there are no grounds for abandoning the commercial use of RBMK reactors.

Not all participants in the press conference were so sanguine. Deputy Premier Yurii Batulin, in particular, called for "more time" to evaluate the disaster "comprehensively". He said that what was at stake was not simply a specific incident but the reliability of the whole nuclear power industry, a comment that tends to support an earlier statement of Academician Eugenii Velikhov that the safety systems of RBMK reactors still in service may have to be modified in the light of the commission's findings.

Time, however, is something the commission does not have if it is to retain its credibility and satisfy the demands of the planners. The optimistic tone of Soviet reports by engineers and servicemen mining under the reactor, dispersing radioactive rainclouds and spreading special decontaminating film have raised public expectations that life in the contaminated area will be back to normal within a few weeks.

By contrast, the experts are becoming more and more cautious. "Why risk your children's health by a premature return?" they urge. So, although the Ukrainian press has reported that the Chernobyl victims will have their names commemorated in new streets in the towns of Chernobyl and Pripyat, it may be some considerable time before the memorial nameplates are unveiled. Instead of an early return home, the evacuated power-workers and construction workers from the Chernobyl power station are to be rehoused in new prefabricated estates on the outskirts of Kiev and Chernigov.

As far as farmland is concerned, Dr Yuri Israel, the head of the state commission for hydrometeorology and environmental control, says only that the "greater part" of the contaminated territory will eventually be "restored to the economy", implying that some areas may not be. A thorough study is now being made, Dr Israel told the press conference, of the potential doses that are involved in "protracted agricultural activity" in the affected areas.

Although (according to Batulin), the long-term economic effect of the close-down at Chernobyl will be "barely perceptible" in the statistical reports, it seems that the shortfall in power generation has been covered only by using all other Ukrainian power stations at full capacity. This is clearly a short-term solution, and it has been officially stated on several occasions that the three remaining Chernobyl reactors will be back in operation in the autumn.

In spite of the use of robots and remote-controlled machinery, there are still considerable health constraints on prolonged work at the site itself. Moreover, the references last week to a new phase of laying up the damaged reactor and the long-term measures to prevent seepage on contaminated ground water suggest that many of the practical details still remain to be worked out.

Meanwhile, new problems continue to occur. A number of wells in Byelorussia have been found to be contaminated (whether through seepage or rainfall is not clear), while forest fires in Poless'ye have begun recirculating the radioactive dust. In spite of earlier assurances that Kiev would remain safe from water-borne pollution, the public have now been warned against bathing in the Dnieper or relaxing on the river-beaches until further notice. **Vera Rich**

French science

Old guard takes high jump

In a week of long knives, the new right-wing government of France has removed three of the old guard in charge of the major scientific institutions. The development is to say the least surprising, coming as it does just a few weeks before the council of ministers has to decide the distribution of a FF40,000 million (£4,000 million) cut in overall government spending.

Last Wednesday, Pierre Papon, director-general of the Centre National de la Recherche Scientifique (CNRS), with its 20,000 staff and budget of FF9,000 million (£900 million), was sacked. Independently, Jean-Jacques Payan, in charge of the universities, and Bernard Descompes, who had introduced innovative new funding structures designed to improve university research, resigned.

The sacking of the CNRS director-general, who was re-appointed by presidential decree for a three-year term only last December, is unprecedented. Papon had been a key figure in the development of the previous administration's policy on science, and his removal may be symbolic of the new government's determination to have its way. Usually (as with Payan and Descompes) the government is content to provoke the resignation of those among its senior officials with whom it is out of sympathy.

Papon seems to have been determined to hold on to protect the considerable achievements of the old regime, and had been planning in September to present a package of policies designed to achieve that to the new science minister, Alain Devaquet. But the new government seemed unable to wait.

Nevertheless, Papon's replacement should not cause too many shudders in the scientific community, at least if he inherits some of his predecessor's power. The new man, Serge Feneuille, is a reputed physicist who for five years has been chief scientist of the cement makers La Farge Coppée, a company which with Feneuille's help had begun to diversify and take an interest in biotechnology.

Despite the pre-election pressure from the right to dismantle the vast and interdisciplinary CNRS, the feeling at the research council, where Feneuille has worked before, is that he will "protect" the institution. With his background, he should also be interested in continuing to forge links between the scientific community, industry and the public in line with the previous administration's policy.

Such doubts as there are arise because of the government's budget-cutting mood and the apparent political weakness of the research minister Alain Devaquet, a man whom most scientists are willing to embrace as an ally against a larger foe, the finance ministry, which has emerged as the main instrument of Prime Minister Chirac's political philosophy. The outlook for research spending in France looks bleak, with a new CNRS director-general reporting to a minister already in a weak political position and with major budget decisions due in July.

Sacked Papon spoke last week of the need to maintain the integrity of CNRS, and especially, the momentum of the interdisciplinary programmes on which he spent much of his effort. "Feudalities are a permanent temptation in France", Papon said.

He is also anxious that the policy of cooperation between universities and industry should be maintained. "The end of the Ministry of Research and Technology was a mistake", says Papon, because of the separation of "responsibilities for science and technology" which is implied. If the ministry is not strong, "it will be the end of the coherence of the whole programme".

Robert Walgate

US policy

Another new White House man

Washington

President Ronald Reagan last week nominated William R. Graham, deputy administrator of the National Aeronautics and Space Administration (NASA), as his science adviser and director of the White

House's Office of Science and Technology Policy (OSTP). The twin posts had been without a permanent occupant for the past 6 months, since George A. Keyworth II resigned in December to form a private consulting company. The acting director of OSTP since the start of the year, John McTague, resigned two weeks ago to take a position in industry.

The six-month delay in finding a replacement for Keyworth has provoked criticism from the scientific community. Several potential candidates have turned down offers, and many observers felt the difficulty in finding a permanent incumbent was indicative of the diminishing influence of OSTP in the White House. Several other senior OSTP officials have resigned in recent months without being replaced, and the office's proposed budget for 1987 is a hefty cut from this year's level.

Graham's nomination has therefore been greeted with subdued relief by scientific leaders, but some express reservations that his military background and advocacy of the militarization of space made him a less than ideal candidate. Robert Park of the American Physical Society said that the appointment was consistent with Reagan's previous appointments of "technocrats" to the post, rather than of distinguished academic scholars.

William Carey, executive officer of the American Association for the Advancement of Science, who had been vocal in his criticism of the hiatus at OSTP, said he was glad someone was now in place who was familiar with high-technology initiatives. But he admitted to being concerned that Graham's background might lead him to offer advice on investment decisions that would be "tilted in one direction". Asked specifically about Graham's known support for the Strategic Defense Initiative, Carey responded "what's new?". Keyworth was also a staunch defender of the programme.

Graham first came to public attention last year when he stepped in to become acting administrator of NASA after the indictment on fraud charges of NASA's former administrator, James Beggs. With the appointment in May of James Fletcher as permanent NASA administrator, Graham needed somewhere to go, as Fletcher had no special desire to keep Graham on as his deputy. Graham's appointment will need confirmation by the Senate, but because his appointment at NASA was also the subject of a confirmation hearing, no serious opposition is expected.

Before going to NASA, Graham was chairman of the general advisory committee of the Arms Control and Disarmament Agency. He started his career as a research physicist at Stanford University, and subsequently worked on survivability of strategic systems for the Air Force and a National Research Council study of submarine warfare. In 1971 he formed a consulting company, R&D Associates, and he has frequently been a consultant for the Department of Defense. But there was some criticism of his performance at NASA during the admittedly turbulent period of his office as acting administrator.

Tim Beardsley

Laboratory accidents

Inquiry into lab's bone cancers

THE Institut Pasteur in Paris has set up an external commission of inquiry to investigate the occurrence of three cases of bone cancer among workers in the same laboratory at the institute. Two of those affected have died in the past few months, and some colleagues suspect that the cluster of cases may be linked with work on oncogenic viruses being carried out in the laboratory. The outcome of the inquiry will be awaited anxiously by those elsewhere whose research involves mammalian oncogenes.

The Pasteur laboratory is called the genetic toxicology laboratory, and is largely concerned with the molecular biology of oncogenic viruses and of oncogenes. One of those who has died, Dr Françoise Kelly (aged 50), had worked in the laboratory for four years. A close friend of Dr Kelly's says that, before her death, she had come to believe that there should be an investigation of the hazards of the research on which she had been engaged.

Most recently, Kelly had been working on a project to effect the transformation of mouse embryo carcinoma (teratoma) cells by the transfer of genes derived from viruses known to be oncogenic in certain circumstances, simian virus 40 (SV40) and adenovirus in particular.

Specifically, Kelly was attempting to endow the mouse cells with a synthetic gene consisting of the "early T" gene of SV40, the DNA coding for a protein produced early in the viral life-cycle, linked with the promoter region of an early gene from adenovirus.

According to a spokesman at the Pasteur Institute, the experimental manipulations were carried under a hood which, while drawing air from the surrounding experimental area, filtered it through active charcoal. The spokesman added that the procedures followed in the genetic toxicology laboratory were "much more careful" than those common in molecular biology laboratories because members of the same staff were also used to dealing with a stream of potential industrial and environmental mutagens and carcinogens.

Little is known about the mutagens and carcinogens handled in the laboratory, apparently because much of the work is confidential to the commercial companies and other interests by whom it has been commissioned. According to an institute report in 1981, it signs secrecy agreements with clients who commission testing. It is, however known that the laboratory has worked on derivatives of the benzo and naphtho-nitrofuranes, known to be powerful mutagens.

The possibility that the cluster of three bone cancers may be linked with the programme of testing for mutagenicity and carcinogenicity is contradicted by the usual length of the latency period for cancers induced by chemicals.

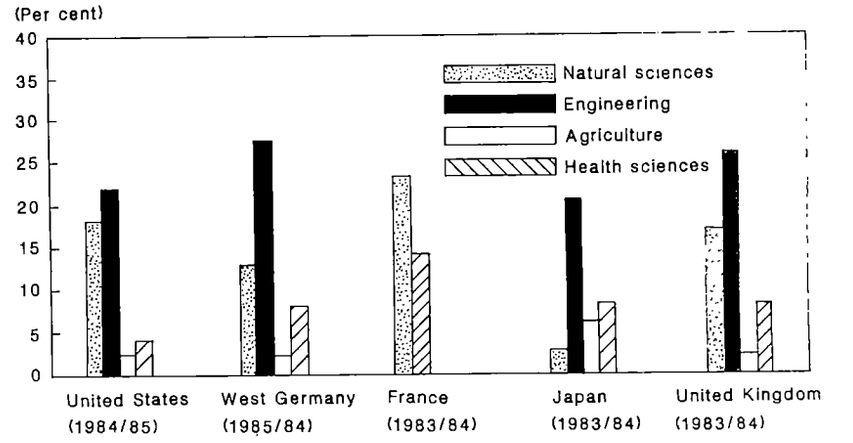
The second researcher to die, aged under 40, had worked in a laboratory across a corridor from Dr Kelly, but only for a period of six months in 1979–80, before the project to transform mouse embryonic cells had been begun. The third bone cancer patient, who is at present ill, is also under 40, and had worked in the same room as Dr Kelly although on a series of genetic manipulations of *E. coli*. There is no sign of damage to the technicians and the two students who had been assisting Dr Kelly with her last project.

These circumstances lend support to the suggestion by the director of the Pasteur Institute, Raymond Dedonder, that the occurrence of the three cancer cases is probably a statistical coincidence. Dedonder put this view at a private meeting with Pasteur staff earlier this year. And while it seems that one of the bone cancers is a primary osteosarcoma, it appears that Dr Kelly's bone cancer was metastatic, and that the character of the primary cancer has not, in her case, been determined.

The case that the cluster may be statistical in origin is further supported by what is known of the movements of those involved. During the past ten years, between 200 and 400 people have worked in the Pasteur laboratories in which the three cases of bone cancer have now been recognized. Senior members of the Pasteur Institute also point to the occurrence of a similar cluster of cancer cases (brain cancers, characterized as glioblastomas) at a laboratory at Orsay over a period of twelve years; surprisingly, this has been shown to be consistent with chance.

Arguments such as these appear to have dampened most fears at the Pasteur itself, but there remains some concern that the external committee of inquiry set up by Dedonder last month may be inclined to cloud the issues. The commission includes Professor Jean Bernard, who is president of the French national ethical committee which considers issues raised by the new biology, and Professor Maurice Tubiana, director of the Parisian cancer hospital at Villejuif, both respected figures in French medicine. But the commission also includes three members chosen by the Pasteur's safety committee, a long-standing thorn in the flesh of the French nuclear industry.

Robert Walgate



Chernobyl fallout: corrigendum

IN the letter "Initial observations of fallout from the reactor incident at Chernobyl" by L. Devell *et al.* (*Nature* **321**, 192–193; 1986), the inventory figures in the first column of Table 2 are low by a factor of 2.92. The correct column should read:

Nuclide	Inventory (10^{17} Bq)
^{137}Cs	1.52
^{131}I	29
^{103}Ru	41
^{141}Ce	53
^{132}Te	41
^{239}Np	543

Foreign students in science and engineering

OF all technical disciplines, engineering has the highest proportion of foreign students in each of the five countries above. The proportion ranges from 28 per cent in West Germany to 21 per cent in Japan. Japan also has the lowest percentage of foreign students in natural sciences (3 per cent), compared with 18 per cent in the United States. For France in the histogram there are no data available for engineering, and agriculture and natural sciences are combined. From International Science and Technology Data Update 1986, National Science Foundation, Washington, DC. □

AIDS virus nomenclature

SIR—Since July 1984 I have been writing on acquired immune deficiency syndrome (AIDS) for the London weekly free newspaper, *Capital Gay*. In the issue of 11 April I referred to a rumour that "human immune deficiency virus", "HIV" or "HIDV", was about to be proposed as the name for the causative agent. I fear that Robert Gallo is therefore mistaken in attributing first publication of this nomenclature to Luc Montagnier.

Your own objection to "HIV", that the "IV" might be confused with the roman "four", could be resolved by adopting the abbreviation "HIDV", for which there is an obvious precedent in "AIDS" for "acquired immune deficiency syndrome". However, combinations such as "HIV infection", "HIV disease", "HIV brain disease", "HIV lung disease" and "HIV lymphadenopathy" read far better than their "HIDV" equivalents.

As for the idea of "HTLV-III/LAV", fossilized forever, forget it. Are we expected to continue with "HTLV-IV/LAV-3" and "LAV-2/HTLV-V"? What next?

While the name of the virus is totally irrelevant to the needs of those directly affected by it, an agreement to use the new name opens the way to an easily-understood terminology for the whole spectrum of conditions linked to this virus, which would be very useful to the agencies concerned with educating the public and health professionals about it.

JULIAN MELDRUM
Capital Gay,
38 Mount Pleasant,
London WC1X 0AP, UK

SIR—At a meeting on 22 and 23 May 1986, the Executive Committee of the International Committee on Taxonomy of Viruses (ICTV) endorsed the name human immunodeficiency virus, recently proposed by a large majority of the members of a study group of ICTV, headed by Harold Varmus (J. Coffin *et al. Nature* **321,** 10; 1986 and *Science* **232,** 697; 1986), as appropriate for retrovirus isolates implicated as causing acquired immune deficiency syndrome (AIDS). The new name describes the host and a major biological property of the virus, recognizes the difference of the virus from isolates of human T-cell lymphotropic virus types I and II and avoids any controversy regarding priority of discovery of the virus and emotive connections of the virus with AIDS and its methods of transmission.

ICTV is working towards a uniform international nomenclature for viruses based on their taxonomy. Much still remains to be learned about the relationships of the human immunodeficiency virus with other retroviruses and therefore designation of an international name would be premature. However, the committee recommends the use of the name human immunodeficiency virus as the vernacular name to replace HTLV-III and LAV.

French science policy

SIR—France may be one of the richest countries in the world, but prosperity does not uniquely determine a country's scientific potential. The recent developments in science policy in France, and in particular the emphasis on applied sciences, is not a particularly creditable achievement for the policy-makers.

Every laboratory now seems to have been diverted towards applied science. In biology, chemistry, physics and mathematics, it is almost as if those responsible for policy have concluded that France has now done enough in basic science, and the time has come to exploit this knowledge for practical purposes. The result is debilitating for the laboratories previously concerned with basic science, now compelled to work in applied science to conform with the present fashion.

There is also a clear difference between the way in which those supported by the Centre National de la Recherche Scientifique (CNRS) establishment are equipped and the provision for ordinary academic scientists, who often work in the same laboratories. While CNRS groups have by no means everywhere attained the targets they have been set, they are nevertheless pampered with generous grants and sophisticated facilities that do not exist in ordinary university laboratories. Why should there be such a segregation?

In the basic science laboratories of the universities, scientists are to be found working on applied projects simply to earn the funds needed for their survival and to remain among the ranks of active scientists. No thought seems to have been given to this problem.

At the same time, research students are busily accumulating theses, a waste of money and time. These students are better served if they are trained in first-class laboratories instead of being fed a huge bulk of theoretical science. Policy-makers would find that if they abolished the present system, they could save time and money that could be used partly to safeguard French basic science.

Chernobyl's message

SIR—An important lesson of the Chernobyl disaster is that "probabilistic risk analysis" is a misapplied science. Its irrelevance to decision-making is now amply demonstrated. A core meltdown, designed to be less than a "one-in-a-million" chance in all reactors adopted by members of the International Atomic Energy Agency, has occurred twice within a decade.

Although such mathematical tools have their use in reactor design, they are still being applied uncritically in technology policy. In this respect they are dangerous, as they divert attention from the essential safety issues. These concern the hazard once realized (however improbably): control, and communication with and protection of the affected public. Doubtless misled by their own reassuring probabilistic predictions, Soviet scientists were caught unprepared in all respects, like their US colleagues at Three Mile Island.

British reactors are, on paper, exceptionally safe compared with Soviet reactors. But can the British public now believe that there is no need for detailed and well-rehearsed contingency plans for nuclear disasters? These should include not merely technical procedures on site, but also tested plans for communication with the public, and evacuation procedures for at-risk populations.

Developing such plans would involve scientists, public authorities and communities, in an extensive, open consultative dialogue. In the absence of such a programme, the nuclear industry's credibility will not be rescued by more reassurances couched in statistical rhetoric.

No chance...

SIR—As positive probabilities refer to events that can happen, negative probabilities presumably refer to events that cannot happen. The greater the probability that the event cannot happen (as distinct from being unlikely to happen), the higher the (negative) numerical value.

Reader Service No.13

CONVENIENT·INFORMATIVE·TIMELY·PROVOCATIVE

FOUR DYNAMITE REASONS WHY YOU SHOULD SUBSCRIBE TO BIO/TECHNOLOGY NOW . . .

1. You'll save time. Because you don't have time to read every journal in the field, BIO/TECHNOLOGY is written and edited to give you all the information you need in ONE convenient source. BIO/TECHNOLOGY is the only journal to give you news. Features. Original research. Product evaluations. Industrial applications. Job openings. Book and product reviews. And more. If it's important to your work, you'll find it between the covers of BIO/TECHNOLOGY.

2. You'll learn new ways to improve your on-the-job skills and run a more successful operation. Each month BIO/TECHNOLOGY gives you the scoop on invaluable start-up information . . . the latest instrumentation . . . marketing breakthroughs . . . funding sources . . . new technologies . . . patents and licences . . . profiles on how others are avoiding the pitfalls and reaping the rewards. In fact, just one practical tip from BIO/TECHNOLOGY can be worth many times the cost of your subscription.

3. You'll be up-to-date on all major industry developments. With correspondents all over the world, BIO/TECHNOLOGY delivers the inside story on who's doing what, where. You'll get the latest word on changing government regulations and tax law, and how they affect your work.

Plus you'll read original research papers by bench scientists, engineers, and biologists that will help keep you in the forefront of every new discovery worth knowing about.

4. You'll get new ideas you can put to use immediately. BIO/TECHNOLOGY lets you rub elbows with eminent scientists, tour new facilities and learn how new processes work in every field from genetic engineering to molecular biology. Each month, BIO/TECHNOLOGY helps spark ideas for your own research, for new industrial applications and for getting along in the increasingly competitive financial arena.

If you're not already subscribing to BIO/TECHNOLOGY, don't delay the moment any longer - return the coupon below and we will send you twelve issues. You risk nothing. If for any reason BIO/TECHNOLOGY doesn't live up to your highest expectations, just let us know and you'll receive a full refund on all unmailed copies. Remember too, that your subscription may be tax deductible.

TO START RECEIVING YOUR SUBSCRIPTION, FILL OUT THE COUPON BELOW AND RETURN WITH PAYMENT TO:

U.S.A.: BIO/TECHNOLOGY
Subscription Order Dept., P.O. Box 1543

Towards understanding snowflakes

The reasons why the microscopic anisotropy of molecules in crystals is reflected in the shapes of the macroscopic structures which they form have been obscure. Now there is some progress.

THE celebrated symmetrical hexagonal dendritic shapes of snowflakes are so familiar that they should long ago have been explained; that might be everybody's reasonable expectation. But the physics of the problem is not nearly as simple as it seems. The essential difficulty is to account for the way in which anisotropy on the scale of molecules is reflected in the shapes of macroscopic crystals.

The problem is not especially difficult with crystals that form a reasonably compact mass. The crystals grown by the multitude in kindergarten classrooms by suspending a crystal seed by a piece of thread in a supersaturated solution form in regular shapes for energetic reasons, because that is how best to minimize the free energy of the system; provided that the access of extra molecules (or ions) is equally easy from all directions, which requires that in practice the crystal seed should not be too close to the side of the jar in which it is suspended, extra elements will be added in such a way as to form sheets parallel to the planes in the basic unit cell. If access is not independent of direction, the result will be a misshapen crystal, but the underlying symmetry will remain at the level of the unit cell.

Dendritic structures such as snowflakes are more difficult because they combine what often seems a startling gross symmetry with a disconcerting disorderliness on the scale of the dendrites. The simple-minded rules of crystal growth seem not to apply. The article by Johann Nittmann and H. Eugene Stanley (this issue, p.663) goes a long way to explain why some recent attempts at a solution have not succeeded fully. More than that, it embodies the essence of an explanation of the growth of dendritic crystals.

Broadly speaking, there have been two complementary approaches to the problem, the first due to J.S. Langer (reviewed by Langer in *Rev. mod. Phys.* **82**, 1; 1980), who has dealt with the growth of dendritic tips by the diffusion of new material through the surrounding medium. The arguments apply as well to crystallization from a solution as to condensation from a vapour phase. The rate at which material is added to a particular point on a growing surface is determined by the local geometry in the sense that protuberances are more likely than re-entry points to acquire material by diffusion. There may be circumstances in which growth is limited by the need that latent heat should be conducted away from the surface. The fact that growth depletes the local environment of the uncondensed phase of material means that growth will also be limited by the rate of diffusion. The usual upshot is a set of differential equations that cannot usually be solved exactly, but can be used to define the conditions under which a dendritic tip will continue to elongate or, alternatively, split.

The frustrations of this approach have stimulated the more recent phase of computer simulation, of which T.A. Witten was the first exponent (see Witten, T.A. & Sander, L.M. *Phys. Rev. Lett.* **47**, 1400; 1981). In the simplest model of diffusion-limited aggregation, as it is called, extra elements of the material of which a crystal is being constructed are supposed to be added to the system at random points of some distant boundary and are allowed to migrate by means of a random walk along the links of some underlying lattice. If the diffusing element should reach a point on the lattice which is an immediate neighbour of the growing aggregate, it may be supposed captured, but there are a host of ways of defining the aggregation rules, most of which appear to have been tried in the past few years.

The virtue of these simulations is that they yield patterns which indeed resemble those of real aggregates. In particular, they show that aggregates whose growth is limited by diffusion are fractal structures; in two dimensions, for example, the number of elements in an aggregate is not proportional to the square of its dimensions but to some lesser power of them, called the fractal dimension. At some cost in computer time, the simulations can be (and have been) carried out in any number of dimensions.

What Nittmann and Stanley have done is to combine these two approaches or, more accurately, to carry out lattice-based simulations of aggregation in a way that can be made to correspond to equations of the kind that Langer (and, now, many others) formulated. They have overcome the persistently annoying feature of simulations, the difficulty of telling the meaning underlying the patterns produced, by producing a series of patterns corresponding to the variation of some physical parameter over a known range. Their aggregation rules are among the simplest there could be, consisting simply of the requirements that new elements are added at random to the periphery of a growing aggregate, but that their assignment to the sites available is biased to reflect what the macroscopic equations suggest will be the rate of growth there.

One result of consequence to emerge arises from the fact that the simulation model can deal only with the addition of discrete elements to the aggregate. There are, as a consequence, departures from the macroscopic prediction of the regular outward extension of a regular envelope of the growing aggregate, which is fairly described by the authors as noise. The essence of this part of the result is that outward extensions of the surface are quickly smoothed out by the later addition of material, but that inward depressions are less readily filled in, but may instead persist as the apices of what are to become fiords in the pattern as the aggregate grows.

The simulations (see p.664) show that the patterns are typically broken up into a number of radially extended tongues of substance separated by lengthening fiords, while the tips of new fiords repeatedly form at the outer surfaces of the extending tongues. Given that the aggregation rules correspond to the penetration of one liquid into another with which it is immiscible, it is pleasing but not surprising that the fractal patterns formed resemble those found in such experiments. The circumstances correspond to those of practical importance in which oil companies pump water down into the oil wells so as to displace crude oil from its reservoirs.

But the most remarkable result of these simulations stems from the apparently successful attempt to allow for the anisotropy of the real world, which depends on the assumption that not all sites on the surface of a growing aggregate are equally suitable energetically. The criteria used in extending the aggregation rules are strictly microscopic; they depend only on the orientation — some sites are more likely to be occupied than their immediate neighbours.

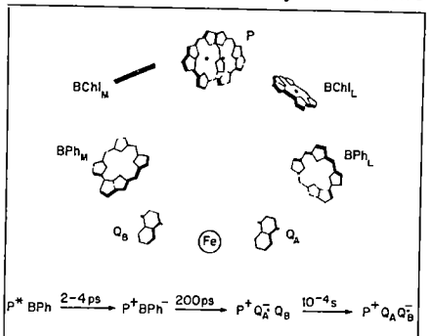
One outcome is the pattern of an aggregate which is virtually indistinguishable from a fairy-tale snowflake, a feathery collection of dendrites which is plainly hexagonally symmetric overall, but whose smaller-scale structure is far from symmetric, which is the case with real snowflakes. That looks a convincing demonstration that the snowflake problem is on the way to solution.

John Maddox

Molecular biophysics

Energy and signal transduction by transmembrane protein complexes

from Alexander N. Glazer



A RECENT conference* brought together molecular biologists, biochemists, X-ray crystallographers and spectroscopists to discuss the structure and function of various transmembrane protein complexes. These molecular machines enable cells as well as intracellular organelles to generate proton and ion gradients, transport metabolites, transduce information from one side of the membrane to the other and to control flagellar motion. But details of the mechanisms whereby these functions are accomplished remain to be discovered.

Approximately two years have passed since the determination of the crystal structure of the reaction-centre complex from the purple bacterium *Rhodopseudomonas viridis*. This achievement provided the first (and to date the only) high-resolution view of an integral membrane–protein complex. The *R. viridis* reaction-centre complex contains four molecules of bacteriochlorophyll-b (BChl), two of bacteriophenophytin-b (BPh), two different quinones (menaquinone, Q_A and ubiquinone, Q_B), a non-haem iron and four haems. All these components are embedded in a complex of four polypeptide subunits. (See Henderson, R. *Nature News and Views* **318**, 598; 1985 for further explanation.)

Electron flow

In principle, it should be possible now to gain a precise understanding of the details of electron flow through the complex, and the first session at the meeting dealt with studies directed towards that end. The formation of the P^+BPh^- state takes place within 4 picoseconds of excitation of the special pair of BChls (see figure). Topological considerations suggest that the electron might flow through the BChl which is between the special pair and the BPh. But P^+BChl^- does not appear to be a resolvable intermediate in the electron-transfer sequence. A P^+BChl^- charge-transfer state facilitates electron tunnelling between P* and BPh (see figure) by mixing electronically with both P* and P^+BPh^- (W.W. Parson, University of Washington).

The protein environment of the prosthetic groups modulates their properties in important ways. For example, electron paramagnetic resonance and electron-nuclear double resonance (ENDOR) data (W. Lubitz, Freie Universität, Berlin) on the *R. viridis* P_{960}^+· radical cation indicate an asymmetrical spin distribution. Moreover, the two BPh groups are spectroscopically distinct — the electron travels selectively down the pathway directed towards the Q_A site. A major feature of the reaction centre is that Q_A accepts one electron whereas Q_B can be doubly reduced. Both semiquinones are bound to the protein through hydrogen bonds. For Q_B^-· these bonds (of length *r*) appear to be symmetrical and fairly long whereas for Q_A^- the ENDOR data clearly indicate two hydrogen bonds of different strengths, about 1.3 and 1.6 Å, respectively. The asymmetrical H bond at the A site might be important in adjusting the redox potentials and locking Q_A as a one-electron gate.

Approximate arrangement of the chromophores in the *R. viridis* reaction centre (modified from Fig. 1 of Woodbury *et al. Biochemistry* **24**, 7516; 1985 and based on Deisenhofer *et al. Nature* **318**, 618; 1985). Abbreviations, P, 'special pair' BChl dimer; L and M, L and M subunits of the reaction centre (see text). The approximate position of the Q_B site is inferred from crystallographic studies of reaction-centre complexes with the competitive inhibitors *O*-phenanthroline and terbutryn.

Attempts to elucidate the biosynthesis, assembly and function of purple bacteria reaction centres and antenna complexes using molecular genetics are also in full swing. Thus far genetic manipulation has been confined to the photosynthetic apparatus of *R. capsulata* (now called *Rhodobacter capsulatus*). Replacement in the L subunit of a special-pair BChl ligand, His 174, by Leu leads to a loss of all three reaction-centre subunits from the membrane. But both the light-harvesting LHI and LHII antenna complexes assemble normally (D.C. Youvan, Cold Spring Harbor Laboratory).

Another surprising result was reported by F. Daldal (Cold Spring Harbor Laboratory). It had been thought that in *R. capsulata* cytochrome c_2 served as an obligate electron carrier between the cytochrome bc_1 complex and the reaction centre. Daldal replaced a portion of the cytochrome c_2 gene encoding the haem-binding domain of the protein with an insert encoding kanamycin resistance. As expected, the mutant cells contain no cytochrome c_2. The unexpected result is that the mutant grows at near wild-type rates under photosynthetic conditions.

Spectroscopic studies of electron transfer in both mutant and wild-type cells prompted by these findings reveal a complex situation (R. Prince, Exxon Corporation). In wild-type cells, the cytochrome c_1 of the bc_1 complex delivers energy directly and rapidly with a half-time of less than 100 μs to about 20 per cent of the reaction centres. A further 20 per cent receive energy rapidly from cytochrome c_2, whereas 30 – 40 per cent receive electrons on a timescale of several milliseconds. The slow transfer is attributed to cytochrome c_2 functioning as a mobile carrier diffusing along the membrane–aqueous interface and shuttling electrons from the cytochrome bc_1 complex to more distant isolated reaction centres.

Cytochrome complex

The ubiquitous cytochrome bc_1 complex was itself much discussed. In photosynthetic organisms, it stands at the crossroads of respiratory and photosynthetic electron flow. Independent of source, the bc_1 complex contains a cytochrome c_1, a cytochrome *b* with two haem centres and an iron–sulphur protein. In the mitochondrial complex described by G. von Jagow (University of Munich), theFe_2S_2 protein of relative molecular mass (M_r) 21,600 (21.6K) is largely polar and is attached to the outside of the mitochondrial cristae membrane by a short anchor at the carboxy terminus. Cytochrome c_1 (M_r = 28K) is also a polar protein with a membrane anchor inserted into the cytosolic surface of the membrane. Cytochrome *b* is a transmembrane protein (M_r = 42.4K) with a haem b_{566} centre (oxidation–reduction midpoint potential E_M = −50 mV) at the cytosolic surface of the membrane and a haem b_{562} centre (E_M = +50 mV) near the centre of the membrane. The iron atoms of the two haem *b* groups are spaced some 20 Å apart. The two haems create a path for electron transfer across the membrane. Six different small subunits, all of unknown function, are associated with the three polypeptides bearing the four redox centres. In contrast, the *Paracoccus denitrificans* bc_1 complex has the simplest composition and one of the highest turnover numbers of any bc_1 complex isolated to date (B. Trumpower, Whitehead Institute). The complex is made up of three polypeptides:

* The Banbury Conference *Microbial Energy Transduction: Genetics, Structure and Function* was held at the Cold Spring Harbor Laboratory on 23–26 February 1986. A summary will be published shortly by the Cold Spring Harbor Laboratory.

cytochrome c_1 (M_r = 62K); cytochrome *b* (M_r = 39K); and the Fe_2S_2 protein (M_r = 20K). The much larger size of the cytochrome c_1 polypeptide suggests that its sequence encompasses some of the components found as individual polypeptides in mitochondrial bc_1.

The notion that bacterial complexes are generally simpler than their mitochrondrial counterparts was supported further by a comparison of *Escherichia coli* cytochrome *d* terminal oxidase (R.B. Gennis, University of Illinois) with the cytochrome oxidase of mitochondria (T.G. Frey, University of Pennsylvania). The former complex is made up of one copy of cytochrome c_1 and two of cytochrome *d*, whereas the mitochrondrial complex contains six to twelve different polypeptides. Structural information on two-dimensional crystals of the mitochondrial complex is available at a resolution of 20 – 30 Å, but the question of whether mitochondrial cytochrome oxidase is a dimer or monomer *in vivo* remains unanswered.

In the examples described above, the distinctive spectroscopic properties of the multiple prosthetic groups provide direct access to information bearing on the consecutive steps in the electrogenic reactions which these complexes perform. Unfortunately, this is not the case with the next group of transmembrane complexes discussed — for example, the H^+-translocating ATP synthases, $(Na^+ + K^+)$ATPase and Ca^{2+}ATPase. Consequently, speculation still occupies centre stage in proposals for the detailed mode(s) of action of these complexes.

Common mechanism

There is increasing evidence that all of the synthases which react with ATP to form a covalent β-aspartyl phosphate (D*) intermediate may share a common mechanism of action. For example, the sequence CSD*KTGTLT (single-letter code) is fully conserved in the H^+ATPase of *Neurospora* and *Saccharomyces cerevisiae*, the $(Na^+ + K^+)$ATPase of sheep kidney and the Ca^{2+}ATPase of rabbit muscle. Moreover, a 15-residue sequence near the carboxy terminus of these enzymes shows variation in only three positions. The sequences of all three enzymes give rise to very similar hydropathy plots (C.W. Slayman, Yale University). In contrast, enzymes of the bacterial phosphotransferase system, enzyme II^{mtl} and enzyme II^{gut}– enzyme III^{gut}, which phosphorylate and transport mannitol and glucitol, respectively, show no significant sequence homology (M. Saier, University of California, San Diego).

R.M. Macnab (Yale University) presented the latest chapter in the continuing saga of studies of the bacterial flagellar motor. Genetic and biochemical studies have focused on five polypeptides which are not integral components of the basal body. Two of these, MotA and MotB, appear to be circumferentially arranged about the basal body and involved in interaction with other components of the motor to transduce proton potential into torque. The rest, Fla AII.2, FlaQ and FlaN, are important for assembly, rotation and switching. Deletion mutants in the corresponding genes do not assemble any detectable flageller structure. Missense mutants, depending on the allele, may be Fla^-, Mot^- or Che^-. The available evidence suggests that these switch proteins form a complex that is peripheral to the membrane and may be associated with the M-ring of the basal body. □

Alexander N. Glazer is in the Department of Microbiology and Immunology at the University of California, Berkeley, California 94720, USA.

Robert Day Allen (1927–1986)

Robert Day Allen, who died at home on 23 March after an intense one-year fight with pancreatic cancer, was one of the modern founders of the field of cell structure and motility, an area that he investigated during his entire career.

After a doctoral dissertation under L.V. Heilbrun on the nature of artificial activation of clam eggs, Allen continued basic studies on the structure of egg cytoplasm and pronuclear movements at the Wenner-Gren Institute, the Kristinebergs Zoological Station in Sweden, followed by a period at the University of Michigan and then at Princeton University. It was during this period that he evolved two major concepts that stayed with him during his entire research career. One concept was that living cells could yield important information about basic biological processes; the other that light optical methods in concert with electronic control and detection devices could yield molecular information in living cells. Allen was clearly one of the pioneers in applying quantitative light microscopy to basic questions in cell and molecular biology.

He next combined the use of biophysical techniques, especially light microscopy, to test the prevailing dogma on the mechanism of amoeboid movement. A combination of studies on living cells and isolated cytoplasm led him to re-examine the tail contraction model. He demonstrated that cytoplasm was not a newtonian fluid and possessed structure as evidenced by its optical polarization properties and ability to transmit applied tension. His observation, in 1955, that isolated cytoplasm from single cells could continue to generate motile forces ultimately led to the preparation of motile cell extracts that continue to yield important biochemical information today.

This early work demonstrated, experimentally, two fundamental concepts that had been discussed previously with much less experimental evidence: first, that cytoplasm can exist as both a medium of weak structural properties (sol) and as a viscoelastic solid (gel); and second, that the elements responsible for the generation of contractile forces exist in the cytoplasm. Allen's research on the structure and motility of cytoplasm led him to propose the frontal contraction model of amoeboid movement, still used as a valuable guide in the design of experiments for testing mechanisms of this type of movement.

In the late 1960s and early 1970s, at the State University of New York at Albany, Allen assembled his first electro-optical microscope. The phase-modulated microspectrophotometer enabled him to measure separately the optical polarization properties of linear birefringence, linear dichroism, optical rotation and circular dichroism in tissue sections, muscle fibres and solutions of proteins.

The last part of Allen's career was probably the most important in that he had a seminal influence on the development and use of video-enhanced contrast microscopy in cell and molecular biology. This method allows large increases in optical contrast which facilitates the detection of structures well below the limit of resolution of traditional optical microscopy. At the Marine Biological Laboratory in Woods Hole, Massachusetts, Allen and his many collaborators investigated fast axonal transport in squid axons and in isolated axoplasm. The fundamental discovery was that particles are transported along single microtubules. Furthermore, individual microtubules can exhibit motility along glass substrates. This exciting discovery has stimulated research in several fields where microtubules have been implicated in motile events.

Robert Allen loved the challenge and thrill of performing basic research and communicating the results. He was particularly interested in seeing the same kind of enthusiasm and drive in students. A major part of his interest in science was in communicating facts and concepts in novel ways. He produced many educational movies and pioneered the use of video disks as a medium for publishing results in the journal *Cell Motility* which he founded. His uncanny intuition in both biological processes and in optical methods was expressed repeatedly in his work on the structure and motility of cytoplasm, organelles and whole cells. The fluid nature of his scientific thought and experimental approach was undoubtedly influenced, in part, by his abilities as a concert cellist. His extraordinary talents will be missed, but his impact will long be felt.

D. Lansing Taylor

Mammalian energetics

Energetic costs of reproduction

from Paul H. Harvey

How expensive is reproduction? The answer depends on how we measure costs. Many evolutionary biologists and behavioural ecologists think in terms of parental investment, which is defined as decrements in a parent's future reproductive success that result from a current reproductive episode[1]. In contrast, ecologists and physiologists tend to focus on energetic costs which can be measured during pregnancy and lactation, either directly as energy allocated to reproduction or indirectly by increases in metabolic turnover or loss of fat reserves. A recent meeting* showed how advances in technology coupled with an ingenious choice of subjects for study provide a useful database which answers some questions but poses many more[2]. One of the most interesting results presented is reported by S.D. Thompson and M.E. Nicoll on page 690 of this issue[3].

Particularly striking contrasts in both reproductive patterns and energy needs are apparent when marsupials are compared with other (eutherian) mammals[4]. Large-bodied mammal species wean large offspring. A head start is given to the young of many eutherians because large species have long gestation length and produce large neonates. This trend is not so evident among the marsupials (gestation length is independent of maternal size, and the increase in neonatal weight with maternal size is much less marked). Furthermore, for their body sizes, marsupials tend to have lower basal metabolic rates than do eutherians, yet they still manage to wean larger offspring. How, then, do marsupials cope with the energy demands of lactation? The simple answer, illustrated by the work of Thompson and Nicoll[3], is that productive females of at least one species of marsupial (and two eutherian mammals with low metabolic rates) increase their resting metabolic rates during gestation and lactation to about the normal eutherian level, whereas the typical eutherian barely increases its higher resting metabolic rate. Which is energetically the more costly mode of reproduction — the short gestation and long lactation of marsupials, or the typical eutherian pattern of long gestation and shorter lactation? We do not yet know.

Size and taxonomic affinity are not the only correlates of basal metabolic rate. For several years, Brian McNab (University of Florida at Gainsville) has been pointing out dietary associations with metabolic rate[5–7]. Among the eutherian mammals, species feeding on invertebrates, fruit, seeds or the leaves of woody plants have low metabolic rates whereas those feeding on vertebrates, nuts and herbs tend to have high rates. McNab postulates cause and effect relationships, arguing that eutherian mammals exhibit the highest metabolic rates that their diet will allow, because high rates permit high reproductive output[6]. Species with low metabolic rates, so his argument runs, live on foods that "limit the rate at which energy is acquired by a mammal". For example, leaves of woody plants and some

Does the mass-specific resting metabolic rate of all marsupials increase during lactation? Bennett's wallaby (*Macropus rufogriseus*) with young, currently being studied at the Zoological Society of London.

invertebrates have low digestibility and often contain chemical deterrants to herbivory or predation. Such arguments may, of course, amount to nothing more than adaptive story telling, and might best be viewed as hypotheses that need testing.

How do the low mass-specific basal metabolic rates of the marsupials fit into McNab's scheme? The alternatives are that marsupials never live on diets which allow high rates of energy acquisition, or that increased metabolic turnover does not result in higher reproductive output among marsupials. Marsupials differ considerably in their diets, and like their eutherian counterparts, frugivorous and folivorous marsupials have low metabolic rates. However, vertebrate- and nut-eating marsupials do not have high metabolic rates. This, McNab claimed at the meeting, is because high basal metabolic rates are not reproductively advantageous for marsupials. His statement is supported by an apparent positive correlation between the maximum rate of population increase and basal metabolic needs in eutherians and the absence of such a correlation in marsupials. McNab's claim needs qualification in the light of Thompson and Nicoll's new work, and does not appear to have a ready explanation.

Metabolic rates like many other physiological and reproductive variables, change with body size. Almost all the work reported at the meeting included routine allometric analyses, which can place many problems into clear perspective. T.H. Kunz, A. Kurta and E.D. Pierson (Boston University) reviewed recent work showing that bats invest heavily in reproduction. Neonates are more than 20 per cent of the mother's body weight in most families, and even reach 38 per cent in the Rhinolophids. Is this unusual for a mammal? It is, but bats are small mammals, and small mammals produce disproportionately large young. When body size is taken into account, bats do produce large neonates but litters are small (generally singletons), so that litter mass is typical for a mammal the size of a bat. Why, then, do bats produce large single young? Bats wean when they are relatively young, perhaps an important feature in such mobile mammals. If the production of large young is an evolutionary tactic to shorten dependence on the parents, a trade-off between prenatal and postnatal development is implied. Yet the opposite pattern is found in primates and birds. Birds with long incubation for their body size also take longer to fledge after hatching[8], whereas those primates with relatively long gestation lengths wean their offspring late[9].

Differences in patterns of reproductive investment found in the primates are also apparent when comparing orders of mammals. For example, primates have longer gestation lengths and slower postnatal development for their body size than do other mammals: gestation is two to four times longer than in other mammals of equivalent weight, whereas milk production per unit time is far lower[10,11]. In this respect, humans turn out to be fairly typical primates, having low daily energetic costs of gestation and lactation. Humans are, however, atypical in one important respect: females have large subcutaneous fat reserves[12] and are thus further protec-

ted from short-term energy crises during pregnancy and lactation.

A.M. Prentice and R.G. Whitehead (Cambridge University) presenting their own and others' work, conclude that the costs of reproduction in humans may be even lower than previously estimated. Important and previously unrecognized factors are a drop in basal metabolic rate over the first trimesters of pregnancy (which can be large enough to mean a net saving over the whole of pregnancy) and, for many women, a further drop in basal metabolic rate during lactation. Perhaps we should not be surprised that, under conditions of acute food shortage, birth weight is decreased by no more than 10 per cent, and that lactation capacity appears to be largely unaffected (except perhaps in women with primary protein deficiency). Prentice and Whitehead, however, were at pains to point out that although "human pregnancy and lactation are remarkably resilient to the effects of energy restriction", babies born in the Gambia with a "biologically trivial deficit in birthweight of about 5 per cent" have significantly increased mortality[2].

Energy is a resource that can have a profound influence on reproductive success. Although the importance of energetic limitations have, on occasion, been over-emphasized by biologists, it can be equally unwise to overlook the energetic costs of biological processes. □

Laser technology

Microfabrication of thin films

from Ian W. Boyd and F. Micheli

THERE is a growing realization that laser-beam processing could provide a powerful and versatile technology for manufacturing thin films and surface structures, and this has remarkable implications for microelectronic, optoelectronic and microwave devices. In recent years this realization has stimulated research interest in laser processing of thin films in almost every major semiconductor industry. The many recent publications and international conferences devoted solely to this topic[1-4] show that lasers can accurately and controllably perform etching, doping, alloying, surface cleaning, crystallization, oxidation and deposition — indeed, all the processes required to fabricate microelectronic circuits. Even more excitingly, because of the tunability, high intensity and focusability of the radiation emitted by lasers, completely new regimes of processing can now be attained.

Technological interests in this area are abundant. For example, as very large-scale integration (VLSI) devices shrink towards sub-micron dimensions, reductions in processing temperature become necessary to improve resolution and to minimize defect densities. Lasers offer both a controllable decrease in high-temperature processing times and many alternative low-temperature methods of film and pattern formation. In optical lithography, ultraviolet radiation from excimer lasers is already replacing conventional light sources, thereby maximizing the resolution of the photoresist definition.

Because of the complex nature of energy redistribution within matter, many different routes to laser-initiated reactivity are possible. Often photothermal contributions can be identified in primarily photochemical reactions. There are usually also subtle but important influences on the reaction arising from surface phenomena. Consequently, the area of laser-surface chemistry presents opportunities to observe many new phenomena, but also presents problems in understanding photon-enhanced chemical reactions.

There are two main modes of operation in laser processing, pyrolysis and photolysis, each defining specific bond-breaking mechanisms. In the former, chemical reactions are stimulated by supplying thermal energy to reduce the reaction barrier. This is conventionally achieved by furnace heating, but a stronly absorbed laser beam can also induce the temperature necessary for deposition, alloying, diffusion, oxidation or evaporation

Photolysis involves direct stimulation of a bond through a precise matching of the energy of the individual photons to particular electronic or vibrational levels in the irradiated species. When a sufficient number of photons have been absorbed, selective dissociation occurs, thereby creating reactive species that promote, say, film growth or material removal In this way many types of gas-solid interactions can be initiated.

Laser etching and removal of oxides, nitrides, metals, silicon and gallium arsenide has led to maskless direct patterning, thereby dispensing with conventional photolithographic methods. The delineated pattern is realized by 'drawing' the focused beam across the film through electronic control of positioning stages The etching reaction occurs around the area of substrate illuminated by the laser beam. An alternative technique involves direct imaging of the mask pattern on to the film using the intense processing beam (Fig. 1).

The complementary process of thin-film growth (or deposition) has also been intensively studied. In fact, direct writing, or laser pantography, has been used at Lawrence Livermore National Laboratory successfully to produce the first functional *ab initio* multi-layered MOS (metal-oxide-silicon) transistors. Figure 2 shows a poly-silicon interconnect pattern obtained by the Livermore group written by a computer-controlled laser beam[6]. Patterned deposition by mask imaging has not been studied nearly so extensively.

The technology is clearly still at the investigative stage. Whether it will be

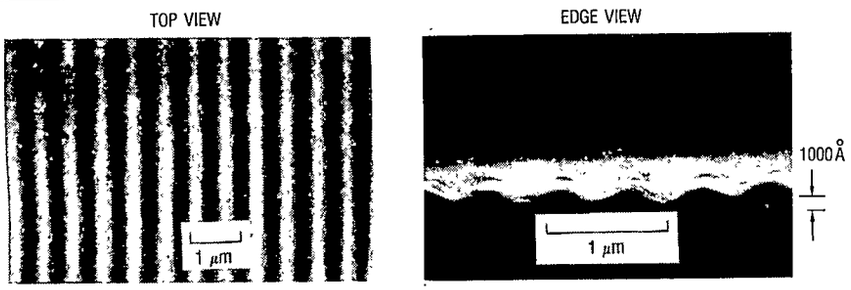

Fig. 1 Pattern-etched molybdenum by projection exposure technique. Conditions: 193-nm laser photolysis of 760-Torr NF_3, fluence 36 mJ cm^{-2}; Ronchi pattern projected with Schwartzchild objective (G.L. Loper and M.D. Tabat, Aerospace Corporation, Los Angeles).

accepted by the microelectronics industry, where present production has been fine-tuned and optimized by a deliberate and complex programme over many years of intensive investigation, depends on several criteria. New methods can only be accepted if they can be fitted succesfully into the production line with minimal disruption. Many laser-processing methods require major redesign of the existing production lines.

Throughput and reliability are also major considerations. We have calculated that it would take almost one month to draw a metallization pattern on a 6-inch wafer using a half-micron diameter laser beam and a rapid deposition rate of one micron per second. For the imaging techniques to be superior in this application, large-area high-power beams would be necessary. Although several years ago the field was somewhat limited by the availability of reliable high-power ultraviolet lasers, there has recently been dramatic progress in excimer laser technology that make this processing mode more realistic.

The essentially 'one-step' maskless processing capability does present a range of modest applications in VLSI that require only discretionary processing, or corrective 'surgery'. Discrete material removal (by etching, ablation or evaporation) filling-in (by deposition), or rerouting (by direct writing) of particular features is possible on a low-volume basis on newly fabricated or prototype masks, thereby dispensing with design correction and costly manufacture.

Similar operations are also feasible on low-volume complex circuitry and on customization of chips using elective interconnection of prefabricated gate arrays or programmable logic arrays. In this way, the development of prototype circuits may be speeded up, through interconnection of predesigned cells on 'generic' chips[8]. Additionally, areas of the circuit that are notoriously difficult to fabricate and that exhibit very low yields can be reproduced many times on the same chip and wired in afterwards using localized metal deposition when one particular cell is found to work satisfactorily.

For the full potential of this emerging technology to be realized, there is a need both for more extensive research into the fundamental aspects and for increased effort in developing more useful precursor compounds and even more powerful and reliable ultraviolet laser systems. □

Immunology

Approaches to tolerance in man

from Leslie Brent

THE title of a recent meeting* suggests that the immunologist's El Dorado — specific unresponsiveness in man — is within our reach. Alas, this proved not yet to be the case. What emerged clearly enough was that it is now possible to manipulate the immune system of experimental animals, from rodents to non-human primates, in various ways so as to achieve functional tolerance of skin, kidney, heart or bone marrow allografts, and that this is almost invariably accompanied by the appearance of suppressor cells.

There are all manner of difficulties in applying these models to man, for some of them are highly complex and others depend on genetic tricks that can be performed only in experimental animals with a short gestation period, such as rodents, but the miniature swine, too, seems to lend itself to this kind of selective breeding (D. Sachs, National Cancer Institute, Bethesda).

A ray of hope was provided by the technique of total lymphoid irradiation (TLI), pioneered for the treatment of Hodgkin's disease, when followed by bone marrow transplantation. This technique involves the irradiation of the patient's immune system with a series of relatively small doses (150–200 rad) over a period of time while shielding certain parts of the body. It is immensely safer than whole-body irradiation and is now being applied not only to bone marrow and kidney transplantation but also to diseases thought to have an autoimmune origin such as rheumatoid arthritis, systemic lupus erythematosus and multiple sclerosis.

Although the elusive suppressor cell provided a link between many of the very heterogeneous contributions to the conference it is fair to say that, in the context of autoimmunity, TLI has so far merely provided a reasonably safe form of non-specific, although long-lasting, immunosuppression, with tolerance to the offending and unknown autoantigens still to be demonstrated. One interesting spin-off was the observation (B. Bresniham, St Vincent's Hospital, Dublin) that TLI given to rheumatoid arthritis patients appears to retard the rate of radiological change in the joints without in the least affecting the level of rheumatoid factor, thus throwing some doubt on the causative role of the immunoglobulin M factor.

The ray of hope alluded to above was provided by TLI in combination with transplantation of bone marrow cells matched for antigens at the major histocompatibility complex (HLA) and depleted of T cells. This was applied in several protocols (with and without chemotherapy and in one group with additonal fractionated doses of whole body irradiation) to patients suffering from aplastic anaemia and to a small group of β-thalassaemic children (M. Slavin, Hadassah University Hospital, Jerusalem). The clinical results are extremely encouraging. It is, however, questionable whether the tolerance of the donor cells to host antigens can be attributed to the irradiation rather than to the absence of mature T lymphocytes in the transplant and the acquisition of tolerance by newly generated T cells, as happens in both animal and human bone marrow recipients when other forms of immunosuppression are used. Likewise, good survival of cadaveric renal allograft can be obtained by TLI given together with an initial regimen of low cyclosporin and prednisolone (J.A. Myburgh, Unversity of Witwatersrand Medical School). But whereas Myburgh has incontrovertible evidence that TLI leads to donor-specific tolerance in baboons, this has yet to be demonstrated in patients.

The question of whether TLI is good and safe enough to supplant immunosuppressive drugs in routine kidney transplantation is finely balanced and, until further information is provided, I suspect that most transplant surgeons will continue to opt for drug-induced immunosuppression which, in the best centres, is now yielding very good results although side-effects continue to be a problem.

The mechanism preventing graft-versus-host disease after TLI and allogeneic bone marrow transplantation in rodents was the subject of lively debate. S. Strober (Stanford University) reminded the meeting that natural suppressor cells generated by this strategy have a null phenotype, that they can be cloned and that they appear to be closely similar to the natural suppressor cells that Strober's group and others have identified in the spleens of neonatal mice. A subset of neonatal suppressor cells can be cultured in interleukin-3 (M. Jadus, University of

**Approaches to Human Immune Tolerance* Asilomar, California, 9–12 March 1986; organized by S. Strober and R. Hoppe, Stanford University.

South Florida and R. Parkman, Children's Hospital of Los Angeles) and are 'mast cell-like' in that they contain granules that can be shown to cytotoxic.

The nature of the cytotoxicity has yet to be elucidated. M. Slavin described the suppressor cells induced after TLI in rodents as thymus-independent, non-lymphoid, large and immature, and suggested that the effect of TLI is to cause a reversion of the animal's lymphoid system to the neonatal state. Examining the thymus after TLI, Strober found both histological and functional abnormalities in the medulla (failure of cell proliferation after exposure to interleukin-1 and a marked drop in interleukin-2 production when cultured with the lectin concanavalin A), which he explained by the premature departure of cells from the thymus.

There seemed to be some consensus that the suppressor cells in many experimental models are large granular lymphocyte-like cells and K. Singhal (University of Western Ontario) showed that such cells, isolated from normal bone marrow, can regulate *in vitro* immunoglobulin M responses to several non-transplantation antigens. These cells release a heat-stable, low molecular mass glycolipid that is suppressive *in vitro* if antigen is present from an early stage. The view was expressed that the role of natural suppressor cells is primarily to assist with the functional deletion of self-reactive clones, but they could also have great significance in protecting the mammalian fetus against destruction by maternal responses. The study by B. Roser (Institute of Animal Physiology, Babraham, UK) on neonatally induced tolerance was, however, a salutory reminder that suppressor T lymphocytes, in this case anti-idiotypic cells acting together with another, as yet unidentified, cell can be critically important in transplantation tolerance.

In summary, the conference left no doubt that approaches towards human tolerance are varied; that the main objective remains both valid and desirable; and that we still have a long way to go. □

Visual information

Do computers need attention?

from Anya Hurlbert and Tomaso Poggio

DESPITE enormous progress in the past few decades, machine vision is still far from achieving the goal that human vision attains with such speed and reliability — in David Marr's words[1], to "know what is where by looking". Recent results on the physiology and psychophysics of visual attention, one example of which is reported on page 693 of this issue[2], accentuate the gap between machines and humans, and provide a first step to understanding why it is so large and what machines must learn to overcome it.

Paradoxically, what appear to be the simplest tasks for humans may be the most difficult for machines. Consider, for example, recognizing your mother in a sketch of her sitting in the kitchen. You could immediately and effortlessly locate her face, match it with your memory and pronounce it a good or a bad likeness. If the sketch were upside-down you could easily right it for a proper view. You would probably expend the most painstaking scrutiny in determining just which feature was slightly off, but even so, your final judgement would be quick. In contrast, a computer, using the most sophisticated face-recognition routine, would perform the task slowly and incompletely, because it would not know where to start. Given the location of the two eyes in a sketch cluttered with dark, round blobs, a computer could be programmed to search for the mouth, nose and chin at the appropriate distances and methodically to match each feature to a virtually identical image in its memory. But failing to find the eyes, the computer could not go on to recognize the face.

Object recognition

The difficulty of the face-recognition problem — and, more generally, object recognition — has called into question one of the main assumptions in the construction of a machine that sees as humans do. The assumption holds that the goal of the first stages in vision is solely to determine 'where' things are, that is, to transform the initial image, an array of intensity values, into a map of the scene which records the distance and orientation of each surface point relative to the viewer (the $2\frac{1}{2}-D$ sketch[1]). In machine vision the $2\frac{1}{2}-D$ sketch may serve to guide a mobile robot around an obstacle or to control its manipulations as it picks up a tool. But, like the raw image from which it is computed, the $2\frac{1}{2}-D$ sketch is itself simply a large array of numbers. Although it may contain preliminary information for object recognition by assigning a colour or texture to each surface point, it does not tell 'what' things are. The critical task in object recognition is therefore to find the object or its crucial part within an array of intensity values or distances. Until now, many attempts to elucidate object recognition (reviewed in refs 3,4) have assumed that the relevant object is already located and isolated in the image.

Unlike machines, humans are adept in spotting the salient features of an object. To understand the mechanisms underlying this ability, psychophysicists have investigated visual attention. Treisman[5] and Julesz[6] have demonstrated that humans are extremely efficient in detecting a part of an image that differs in a single aspect from its background. For example, a red dot pops out in a field of yellow dots, and the same happens for a horizontal line in a field of vertical lines (Fig.1). The time required to detect the unusual item is independent of the number of other items, implying that the search for it occurs in parallel across the entire field. The human visual system obviously possesses a fast, parallel mechanism which can direct attention to salient chunks of the image. (This is sometimes called 'preattentive'. Here, we consider it as part of the entire attention mechanism whose characteristics probably require more complex descriptions than 'serial' or 'parallel'.) Although the possible computational purposes of this mechanism have not been probed by psychophysical experiments, its potential role in object recognition seems critical. For example, in face recognition the attention mechanism may perform two essential steps: first, to locate 'blobs' which could be eyes; and second, to direct processing towards the blobs to verify that they are eyes and thereby to initiate recognition. The role of attention, therefore, may be not only to spotlight distinctive parts of the image but, more importantly, to segment the image into objects or parts of objects, a crucial first step in determining what things are.

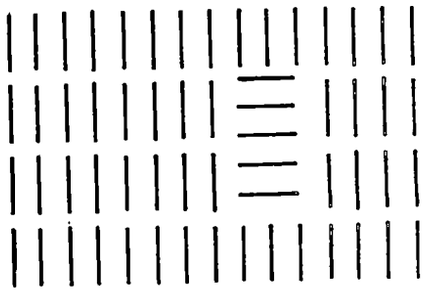

Fig 1. A patch of horizontal line segments pops out in a field of line vertical line segments.

Separable features

An important and still open question is: what are the features or primitives that drive attention? Likely candidates are separable features which, by definition, can be attended to selectively and are processed independently and in parallel. Pop-out and texture-discrimination experiments provide a test for separable features and so far have diagnosed colour, line orientation, line ends (terminators) and possibly crossings among the candidates.

Conjunction experiments test whether two or more separable features can combine to produce a higher-order primitive. For example, when a green T in a field of randomly mixed green Xs and brown Ts is the target, it does not pop out, and the time required to detect it increases linearly with the number of background items. Thus, the detection of a particular conjunction of colour and shape appears to require a search over each item in turn, across the entire field. Conjunction experiments thus reveal another aspect of the attention mechanism, a serial searchlight which appears to operate independently of eye movements and does for feature conjunctions what the parallel mechanism does for features.

Until recently, all conjunctions between known separable features had been shown to require the serial searchlight. The recent results of Nakayama and Silverman[7] reveal a surprising exception to this pattern. In pop-out experiments using fields of small rectangular patterns displayed on a colour television monitor, the authors demonstrate that binocular disparity and motion individually behave as separable features. The conjunction of motion and colour does not; the search for a pattern of blue upward-moving dots is slow and serial across a field of blue-downward patterns and red-upward patterns. Contrary to this trend, conjunctions of binocular disparity and either colour or motion behave as separable features: they are searched for in parallel. (The authors report that when the field splits into two planes, one in front of the other, the search for a conjunction amounts to a pop-out of the unusual item in one plane. Thus, we suggest that it may be possible, using a different kind of motion stimulus, to create separate planes of coherent motion and thereby induce a parallel search for motion-colour conjunctions.)

Experiments

The psychophysical studies on separable features coincide with the recent emphasis on functional localization in visual neurophysiology and neuroanatomy. It is tempting to draw an explicit connection between biology and psychophysics by equating different visual cortical areas with different feature maps; for example, calling area V4 the colour map, MT the motion map and V1 the orientation map. Psychophysics suggests that in a given feature map there exists at each spatial location a collection of neurones each tuned to a different value of the feature (for example, red, green or blue for colour). Although such an organization has not been demonstrated, evidence for segregation of functionally similar neurones in distinct cortical areas is steadily accumulating. From this point of view, the results of Nakayama and Silverman have interesting implications for neurones and feature maps: they preclude the existence of neurones tuned for both motion and colour; predict the existence of neurones tuned to a particular combination of binocular disparity and motion and of neurones tuned to disparity and colour; and suggest that feature maps are replicated at each of several disparity planes. The prediction of disparity–motion-tuned neurones is supported by the recent report[8] of similar neurones in cortical area MT.

Other recent work on visual neurophysiology puts the emphasis on a different aspect of attention. Rather than address computational questions such as 'what are the salient features?' and 'how does the attention mechanism work?' or the psychophysical question 'is feature processing parallel or serial?', the new class of physiological experiments on alert animals seeks to demonstrate the ways in which attention can modulate neuronal responses. In the course of such experiments, insights into the neural circuitry

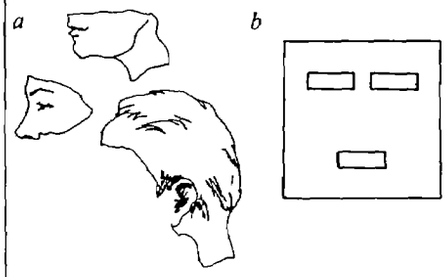

Fig. 2 *a*, each separate set of 'face' features is sufficient to suggest the hypothesis of a face. *b*, It is spatial relation between features and not the features themselves that cue recognition to the face of hypothesis.

and anatomical location of the attention mechanism have emerged. For example, based on studies of attention-mediated modulation in the inferior parietal lobe (area 7), Mountcastle[9] proposed that neurones there are responsible for directing attention to visual targets.

More recent research demonstrates the effects of attention at other levels in the visual pathway. Moran and Desimone[10] have recently shown that, in the monkey, the response of a neurone in V4 or IT to a preferred stimulus (for example, a red horizontal bar) is dramatically reduced when the animal ignores it and instead attends to an ineffective stimulus (such as a green vertical bar) within the same receptive field (which, for IT neurones, may extend at least 12°). The response of the neurone to the preferred stimulus is unaffected when the attended stimulus is outside its receptive field. Thus, V4 and IT neurones are able to filter out an irrelevant stimulus when it competes with a relevant stimulus within the same receptive field. V1 neurones do not have this property, since the monkey cannot even perform the differential attention task when two stimuli are close enough to fit within a single receptive field in V1.

The psychophysical experiment in humans reported in this issue by Sagi and Julesz[2] provides an intriguing complement to the physiological results described above. The authors find that visual attention directed to a random location for an orientation-discrimination task enhances the detection of a test flash presented simultaneously within a certain radius of the target. The area of enhancement, which the authors conjecture to be the area covered by the searchlight of attention, varies from 1.5° at 2° eccentricity to about 3° at 4° eccentricity. Interestingly, these areas are likely to be larger than the average receptive-field sizes in V1.

The above results imply that attention to one region of an image involves both suppression of visual processing in irrelevant domains and enhancement of visual processing in relevant domains. Thus, attention may indeed be responsible for directing a processing focus to specific locations in the initial steps of recognition. Yet although biological research may have found the key to machine vision, it has yet to describe how it opens the lock.

Attention mechanism

Computational results suggest that the attention mechanism is even more complex and powerful than experiments have revealed. Consider again the face-recognition problem. Individual features such as eyes or the curved line of nose and mouth can by themselves lead to the hypothesis of a face (Fig.2*a*). In contrast (Fig.2*b*), features alone cannot be the only cue for recognition. The spatial relationship between the two eye tokens and the closed outer contour can also cue the face-recognition process. Ullman[11] argues that spatial relations must be computed by a mechanism similar to the serial searchlight of attention.

The unravelling of the full complexity of visual attention will clearly involve computational, psychophysical and physiological research. It will influence not only our understanding of visual perception but also the architecture and the control structure of machine vision systems. □

Epstein–Barr virus

Infection and tumour induction

from M. A. Epstein

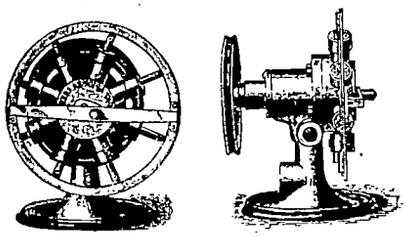
EPSTEIN–BARR (EB) virus, a herpesvirus of man, resembles all other herpesviruses in establishing a persistent carrier state throughout life following initial infection. It has long appeared to infect B lymphocytes exclusively and this specific tropism has been explained by the recent demonstration that the B-lymphocyte C3d receptor CR2 for serum complement also acts as the virus receptor. Infected individuals, however, shed virus into the saliva and the cellular site of viral replication in the epithelium-lined oropharynx has been an enigma. So too has been the oncogenic role of the virus in undifferentiated nasophargeal carcinoma, a tumour whose malignant epithelial cells always carry the viral DNA. The finding of virus receptors on epithelial cells[1] and of a viral transforming gene[2] has now shed the first light on these interrelated problems.

Because only B lymphocytes could be infected experimentally by EB virus it was easy to understand the presence of latent infection readily demonstrable in a percentage of the circulating B cells of infected subjects. For similar reasons, it was assumed that the productive infection responsible for the infectious virions shed into saliva probably arose from infected B cells within the lymphoid tissue of Waldeyer's ring — including tonsils, adenoids, Eustachian cushions and lingual follicles. Hints that epithelial cells might be involved proved difficult to interpret in the absence of a satisfactory mechanism whereby the virus could enter and infect them. But early claims that EB virus replicated in oropharyngeal epithelial cells during primary infection accompanied by infectious mononucleosis were eventually supported and there were also reports that the viral DNA was present in both salivary gland and normal nasopharyngeal epithelial cells. Furthermore, a small proportion of epithelial cells from the human uterine cervix, not usually thought to be associated with EB virus, could apparently be infected after appropriate manipulation *in vitro*.

Striking and unequivocal evidence for EB virus replication in epithelial cells has recently been obtained[3] in the context of the immunological disarray which accompanies the acquired immune deficiency syndrome (AIDS). 'Hairy' leukoplakia of the tongue is a newly described lesion of homosexual males suffering from characteristic immunodepression involving absent or poor responses to antigen skin tests and altered, or frankly inverted, ratios of helper to suppressor T lymphocytes. The patients either have AIDS or are likely to develop it and large numbers of biopsy samples of the tongue lesions have been shown by electron microscopy, specific immunofluorescence tests, and DNA hybridization using EB virus probes in Southern blots, to have EB virus replicating in prickle cells[3]; a papillomavirus was frequently also present, sometimes even in the same cells.

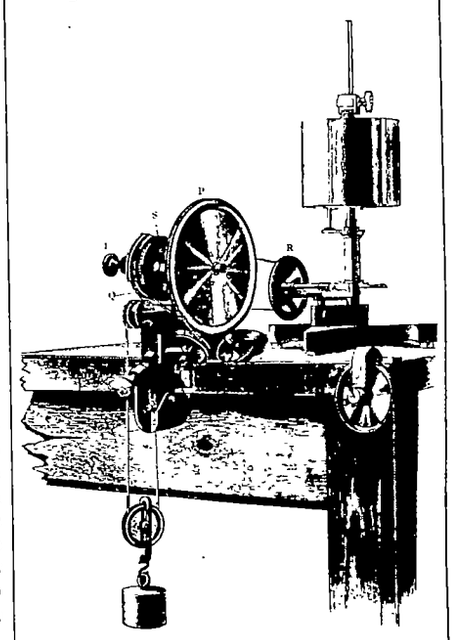
The crucial importance of specific cytotoxic T cells in maintaining the virus-host balance in the life-long EB virus infection has come to be recognized in the past few years. The balance is delicate, and impairment of T-cell surveillance predisposes to virus-induced pathology. It has been demonstrated repeatedly that transplant recipients on immunosuppressive therapy to prevent graft rejection have depressed numbers of cytotoxic T cells and increased amounts of EB virus shed from the mouth; they also have a heightened incidence of EB virus-associated lymphomas. There is thus a clear parallel with certain aspects of AIDS in which cytotoxic lymphocytes are depleted, unusual EB virus production takes place as seen in the epithelial prickle cells of "hairy" leukoplakia[3], and lymphomas carrying EB virus are common. It is of great interest that attacks of falciparum malaria are likewise accompanied by a fall in T-cell numbers and inversion of the ratio of helper to suppressor T cells, since the hyperendemic form of this disease has been recognized for many years as an essential co-factor in the induction of virus-related endemic Burkitt's lymphoma.

Interactions between EB virus and epithelial cells are no longer mysterious. Using two monoclonal antibodies against different epitopes of the complement C3d CR2 EB virus receptor, Young and colleagues[1] show that the receptor molecules are present on the cells of oral and nasopharyngeal squamous epithelia and, in view of the hairy leukoplakia findings, it may be significant that on the tongue the receptors appear to be restricted to the prickle cell layers. All the evidence now supports the view that permissive productive replication of EB virus takes place in oral and pharyngeal epithelial cells, which fits well with the ten-year-old observation that malignant epithelial cells of nasopharyngeal carcinoma, which carry the virus genome, can be readily induced to produce infectious virus both in tissue culture and in nude mice.



If entry of EB virus into epithelial cells can now at last be understood, what of its role in changing them into cancer cells? As far as nasopharyngeal carcinoma is concerned, nothing has hitherto been clear.

100 years ago



Power in Laboratories

IN connection with the admirable devices for the distribution of driving-power in laboratories, illustrated in *Nature*, vol. xxxiii. p. 248 (shown opposite), the description of a novel and very effective form of water-engine, with which I have been experimenting for several months, will be of interest.

One of these motors is set up in the cellar of our science hall, where it is supplied with aqueduct-pressure of sixty pounds to the square inch, and the power is transmitted from it by means of rubber belting led over

"idle pulleys" to the upper stories of the building, where a small engine-lathe and dynamo are driven. A word will suffice to explain the very simple construction of the motor-system of radial cylinders, with their bases at the centre of the motor, through which runs the driving-shaft. The pistons in these cylinders are single-acting, and the water is admitted to them in succession by the rotary valve which forms part of the main shaft. The pistons, thus, in pressing outward, exert their force against a strong ring, to which is bolted a crossbar which engages the crank of the main shaft. Thus the ring, in turning the shaft, has the vibratory motion of an eccentric, and returns the opposite pistons to the bases of the cylinders, at the same exhausting the water through the interior of the rotary valve.

From *Nature* **34**, 121; 10 June 1886.

although racial, genetic and environmental co-factors are necessary. On the other hand, enough has been learned about EB virus in relation to endemic Burkitt's lymphoma for a persuasive theory to have emerged[5].

Thus, it has been suggested that latently infected B cells undergo unusually abundant virus-driven replication, no doubt because of impaired T-cell control resulting from recurrent attacks of falciparum malaria, such that one or other of three specific chromosomal translocations occurs, each being a cause of c-*myc* oncogene activation. Serious doubts have been raised, however, as to whether cellular oncogenes are relevant at all to the induction of cancer[6], and certainly c-*myc* alone cannot render cells cancerous[7].

New information on a key EB virus gene promises to reconcile these conflicting views. The gene for the virus determined membrane protein of latently infected cells has been identified and cloned, and after transfection into quite alien cells expression of the product has been shown to confer tumorigenicity[2]. This transforming gene explains the ability of EB virus to cause malignant tumours rapidly and directly in susceptible animals[8], and clearly plays a major role in the chain of events leading to the development of endemic Burkitt's lymphoma, whether with or without interaction with an activated c-*myc* oncogene. Discovery of this gene also provides a first and important indication as to how EB virus might be involved in causing nasopharyngeal carcinoma and, indeed, the other epithelial tumours in which preliminary investigations have indentified the viral genome. □

Plant ecology

Pesticides and pollination

from Peter D. Moore

INTERDEPENDENCE in nature is often regarded as a source of strength and stability, but it can also become a point of weakness when one member of a complex chain of interactions is affected by catastrophe. In the case of insects involved in flower pollination, for example, there are evident evolutionary advantages in specialization that involve interactions between individual plant species and specific vectors, but such relationships may lead to problems if the vector population becomes depleted as a result of catastrophe. And catastrophe in insect populations is a far from unlikely event in these days of broad-spectrum pesticides. This problem is the subject of a recent study on the consequences to the reproductive success of plants in a New Brunswick forest of pesticide spraying (Thomson, J.D., Plowright, R.C. & Thaler, G.R. *Can. J. Bot.* **63**, 2056; 1985).

In the coniferous forests of New Brunswick, the spruce budworm (*Choristoneura fumiferana*), a defoliation agent of balsam fir (*Abies balsamea*), is an economically significant pest. Various pesticides have been sprayed onto the forests in the past 25 years in efforts to control the budworm, but concern has been expressed about the possible effects of spraying on other, non-harmful insect species and even economically beneficial species, such as the bees involved in pollination, and therefore fruit production, in the blueberries (*Vaccinium* spp.) that grow in the same area. P.G. Kevan (*Biol. Conserv.* **7**, 301; 1975), studying the pesticide fenitrothion, provided evidence that such effects can indeed be harmful.

Thomson and his co-workers investigated the effects of spraying Matacil, an anti-budworm agent which, because it is less toxic to bees, has replaced fenitrothion. When they tested the effects of Matacil on the mortality of a range of wild insect species, Thomson *et al.* found that the most pronounced effects occurred among the smaller bees (Andrenidae, Halictidae and Anthophoridae) and one fly family, the Syrphidae. These families are important pollinators of some of the understorey plants such as the Canada mayflower (*Maianthemum canadense*) and the red-osier dogwood (*Cornus stolonifera*). But the question to be answered is whether the spraying influences the populations of these insects to a degree that affects the breeding success of these plants.

By studying fruit sets in *M. canadense*, *C. strolonifera* and the creeping dogwood (*C. canadensis*) both inside the sprayed area and in control plots outside the influence of the spray, Thomson *et al.* obtained an estimate of fecundity, expressed as a percentage of the total flowers on an individual achieving fruit set. In *M. canadense* and *C. stolonifera* they found a significant reduction in fecundity within the sprayed area (means of 4.6 and 8.8 per cent, respectively) compared with the control sites (9.7 and 24.6 per cent). But in *C. canadensis* there was no significant difference (spray mean of 13.1 per cent and control mean of 11.6 per cent). The discrepancy between the two *Cornus* species could be caused by the fact that *C. canadensis* is also pollinated by larger bumblebees (*Bombus* sp.) which are not affected by Matacil spraying. These results add weight to the argument that spraying where the pollinator is sensitive decreases fecundity.

The question of whether the decrease in plant fecundity actually influences its overall population stability still remains unanswered. Much depends on the degree to which the plant requires the seed as a survival and/or dispersal mechanism. If vegetative growth and dispersal are available as alternative strategies for a species, then the decrease may be of little consequence. Although there are exceptions, such as the pin cherry (*Prunus pensylvanica*) (Marks, P.L. *Ecol. Monogr.* **44**, 73; 1974), most woodland understorey species are long-lived perennials with little dependence on their seed set.

Where the effects I have described here are likely to have the most profound impact is in plants which have a limited geographical range, are out-breeding, perhaps dioecious, short-lived, have no capacity for vegetative propagation and are specific in their pollination vectors. A plant which answers to most of the elements in this description is the hop tree (*Ptelea trifoliata*), a rare plant that colonizes shorelines on the northern side of Lake Erie in Canada. J.D. Ambrose, P.G. Kevan and R.M. Gadawski (*Can. J. Bot.* **63**, 1978; 1985) have studied the reproductive biology of this species and conclude that it is dioecious, is entirely dependent on wind-dispersed seeds for its spread and exhibits a rapid population turnover. Its breeding would therefore seem particularly susceptible to any catastophic disruption such as that in the New Brunswick forests. But there is one factor in its favour — a considerable diversity of insect vectors in its pollination system. Ambrose *et al.* found that the flowers were visited by Hemiptera, Coleoptera, Diptera and Hymenoptera, totalling at least 102 species from 37 families. In this particular respect, what seems to be a vulnerable plant has a survival strategy and the ability to withstand the almost inevitable impact of pesticides on its pollination vectors. Perhaps we should give special attention to the conservation of those plant species which lack this key factor in their defences against human environmental disruption. □

Iodine-131 in human thyroids in Britain following Chernobyl

SIR—On 2 May 1986 raised atmospheric levels of radioactive material were detected in the southern United Kingdom, apparently due to the Chernobyl reactor accident. Some activity persisted subsequently, but at a level considerably lower than the initial peak[1]. One of the most serious consequences believed to result from the accidental release of fission products from irradiated fuel is irradiation of the thyroid gland by ^{131}I (ref. 2). Thus, particularly because a substantial component of the radioactivity detected was identified as ^{131}I, it seemed desirable to carry out some direct measurements of ^{131}I in human thyroids. Between 10 May and 22 May we carried out a series of measurements on the thyroids of adults and children resident in the southern United Kingdom (predominantly South London) during the period of exposure.

Measurements were taken in a chalk-shielded room with a low radiation background, using a high purity germanium detector, collimated to be sensitive mainly to the thyroid region and with an overall counting efficiency for ^{131}I of 0.27%. Of necessity, subjects were chosen on the basis of availability and willingness and consequently consisted predominantly of departmental staff and students, together with five children of staff. None of the individuals for whom data are reported here had been occupationally exposed to ^{131}I in the recent past. However, to check for the possibility of inadvertent contamination in the hospital environment, we carried out identical measurements on three staff employed full time in our clinical radioisotope dispensary and found their ^{131}I levels to be within the range observed for the test group. Measurements were commenced over the weekend of 10–11 May and continued thereafter. Measured values of activity in the test group of subjects, and corresponding dose-rates calculated using data of International Commission on Radiological Protection[3–5], are presented in Table 1. From these data it seems reasonable to conclude that the peak in thyroid activity for most subjects occurred in the period between 14 and 19 May.

To estimate, from the measured activities, the time integral of dose commitments to the thyroid that may be expected to result from these exposures, we have made use of the data from a parallel set of measurements that we have carried out — commencing on 8 May and using similar measurement technique — on ^{131}I concentrations in milk delivered by a local dairy. The results of these measurements are presented in Table 2 and appear to be consistent with those observed at Chilton (some 100 km north-west of Sutton) which peaked on 6 May at 54 Bq l^{-1} and were made on farm-fresh milk[1]. If it is assumed that approximately 0.5 l of milk, ingested in the 24 hours following each day's delivery, was the main source of ^{131}I in the subject group[1,6], then the data are consistent with the ICRP model in which 30% of ingested ^{131}I is deposited in the thyroid, where it remains with half-life of 7.6 days[4,5]. On this basis the appreciable increases in thyroid activity (10–65%) during the week following 10 May further suggest that the peak activity in milk delivered in Sutton did not arrive until some 2 days following that observed for the Chilton farm, coinciding with the start of our own measurements on 8 May.

Accepting these assumptions, and assuming also that dietary activity hence-

Table 2 Iodine-131 activity measured in milk from a Sutton dairy

Date of delivery	Activity (Bq l^{-1})
8 May	41 ± 5
10 May	34 ± 5
12 May	21 ± 5
13 May	13 ± 4
14 May	11 ± 4
15 May	9 ± 4
16 May	8 ± 4
17 May	8 ± 4
19 May	7 ± 3
20 May	5 ± 3

forth decays with the half-life of ^{131}I, it is possible to estimate the time integral of thyroid activity resulting from the incident. Such a calculation, consistent both with our limited measured data on thyroids and also with similar measurements following the Windscale reactor accident in 1957[7] (made later in the time variation in activity), points to a total dose commitment from the incident equivalent to that from the peak dose rate, in each individual, acting over a period of about 26 days. Values derived in this manner (using the highest observed dose rate) are listed in the final column of Table 1. These values can be compared with a figure of approximately 1,000 μSv for the population mean annual dose to the thyroid that arises from natural sources[8]. These values are close to the estimates of ^{131}I dose to thyroid that resulted from the intensive series of nuclear weapons tests in 1961[9].

Prior to the Chernobyl incident, one of the world's most serious reactor accidents appears to have been that at Windscale (subsequently renamed Sellafield) in 1957. On that occasion, ^{131}I measurements were also made for the population centred

Table 1 Iodine-131 radioactivity measured in the neck region (Bq)

Subject	Age(sex)	Measurement date (May 1986)													Assumed mass of thyroid[3]	Highest observed dose	Estimated dose commitment

on Sutton (including one of the present subjects) and showed peak levels of ^{131}I thyroid activity at that time ranging up to 300 Bq in adults[7]. The present values are clearly an order of magnitude lower.

It may also be of interest to note that our measurements (made using a simpler, screening procedure) on five UK citizens on their return from residence in Warsaw during the week 28 April–4 May showed levels of ^{131}I in the thyroid (at 4 May) ranging from 40 to 150 Bq. Measurements made on the same date on two individuals returning from residence in Kiev showed thyroid ^{131}I levels of 1,100 and 1,700 Bq. In contrast, the levels in 11 individuals returning from Leningrad and Moscow and two from parts of West Germany were all below the 40-Bq detection limit in our screening measurement.

Do mammals need P elements?

SIR—In a recent *News and Views* piece, Andy Flavell describes a way by which the *Drosophila* P element has been engineered to eliminate the germ-cell specificity of synthesis of the P transposase and allow transposition of P elements in somatic cells[1]. As he says, these modified elements may well direct synthesis of transposase in mammalian cells, and cause transposition of P elements around mammalian genomes. Would this then give vertebrate molecular biologists all the advantages given by P elements to *Drosophila* geneticists? The answer, I fear, is no.

The P elements have proved to be yet another powerful addition to the already well-equipped armoury used in solving the problems of developmental biology of *Drosophila*. They provide tools for both isolating and analysing genes. It is the prospect of easy transposon tagging of mutations and a high efficiency of production of transgenic animals that has tempted mammalian developmental biologists and geneticists (myself included) to yearn for a P-like element in mammals. However, sober reflection suggests that even if this were come about, we would be only slightly, if at all, better off.

None can doubt the enormous potential of *Drosophila* biology for adding to our understanding of the genetic control of development of a complex animal. Much of this potential stems from the wealth of mutations which affect development in surprisingly precise ways. With this fount providing the raw material those who work on *Drosophila* can count their further blessings; the use of polytene chromosomes to correlate genetic with physical maps, the small genome which facilitates cloning and chromosome walking and the tricks of the P elements. It is, however, the genetics of *Drosophila* upon which all else hangs, and this genetics in turn has become so well-understood because of two key factors: the small size of the animal and its rapid generation time which permit the analysis of many thousands of individuals and crosses.

Amongst the vertebrates only mice have a comprehensive and manipulatable genetics and are small enough to enable large numbers to be maintained. But the two main benefits brought to *Drosophila* by P elements, transposon-tagging and gene integration, already exist in mouse molecular biology. The rate-limiting steps in the advance of these experiments lie elsewhere, in the handling and analysis of large numbers of animals.

Retroviruses have been used as transposon tags for isolating mouse genes for a number of years. Natural infection of the germ-line has produced at least one coat-colour mutation, and allowed DNA from the region to be isolated[2]. Infection of embryos *in vitro* has been used as a method of generating insertional mutants, and their subsequent isolation[3]. Additionally, a spin-off from producing transgenic mice, which have insertions of foreign DNA, has also been the isolation of mutations caused by the insertion event[4,5]. These methods are all technically difficult and slow. More efficient *in vitro* viral infection of embryos would speed things up and methods have been described which yield about 10% of offspring with new viral inserts in the germ line[6]. *In vivo*, appropriate crosses between Swr and RF mice — in a sense analogous to a dysgenic cross of *Drosophila* — result in 0.35 to 0.67 new retroviral inserts per animal[7], a rate that begins to approach that of P-elements.

Testing carefully for new recessive mutations caused in the mouse by DNA insertion entails a great deal of cross-breeding, DNA preparation and Southern blotting, but there is a good chance of identifying embryonic lethals[4] (rather few of which are likely to be 'developmental' mutations). Setting up sib-crosses without DNA analysis and simply waiting for a new recessive mutation to reveal itself would reduce the work required. Of course this would only allow identification of viable mutations, and is extremely inefficient as even under the best circumstances the vast majority of crosses would be between animals not carrying any inserts. If one were to look for a *specific* mutation caused by an insertion the logistics become daunting to say the least. If one were to take all the offspring of Swr/RF crosses 'blind', and backcross them to a tester stock, assuming a target size for mutation of 20 kilobases and a genome size 100,000 times that, a rate of new insertion of 50% overall would produce the desired mutant once in 200,000 mice. Using a multiple tester stock carrying ten or twenty interesting genes would hardly reduce the scale of the task to one which the average worker would tackle. Few mouse facilities house more than twenty thousand animals in total. Even if only ten thousand crosses were needed (routine in a *Drosophila* lab), this would occupy a good sized room and several animal technicians for a couple of years. We would have to be confident indeed that the gene being tagged was truly interesting to justify such efforts.

Introduction of foreign genes into the mouse genome by microinjection of the embryo is now a widely used method of analysis of gene function. Despite early setbacks it now seems that most intact human or mouse genes will function after microinjection[8]. The efficiency at which injected embryos integrate the foreign DNA varies between 5 and 30%, which is about the same as the efficiency of P-mediated integration after injection. There is, at the moment, no marker which allows identification of transgenic animals, other than DNA analysis. The rate-limiting step, however, is the number of embryos which can be readily handled. It will always be a very skilful task to handle, inject, culture and replace the embryos into foster mothers.

Integration mediated by the P transposase almost always results in only a single integrant. Transgenic mice very frequently have multiple, tandem inserts, although there seems to be no correlation between insert number and expression of the genes[8]. Retroviral vectors can be employed to produce transgenic mice with only single inserts[6] but there are size restrictions on the DNA that can be introduced in this way. It is here that appropriately modified P elements may be most useful, allowing the easy generation of single-insert transgenics.

All this said, even if transposing P elements onto the mouse genome and having them jump around there will not push mouse biology into the same league as *Drosophila* biology, it would be worth-

while and informative. Moreover, it sounds like fun!

Initiating boiling with ice

SIR—When an observation in the physical world appears to be paradoxical, running counter to one's intuition, experience and learning, it usually provides an opportunity to achieve some valuable scientific insight. Such a case began with the observation by one of us (R.L.D.) that a large spoon that had been kept in the freezer would initiate boiling in water that had been heated in a cup in a microwave oven, which the other one of us (R.E.A.) suggested might occur because crystals of ice initiate boiling in overheated water.

Water is said to be overheated or 'superheated' when its boiling temperature for a given pressure is surpassed without transformation to the vapour phase. This can be brought about by heating a drop of water as it rises in a heated column of oil. Using this technique, water can be heated to as high as 279.5°C at atmospheric pressure before explosive boiling occurs[1]. This extreme superheating occurs because there is no free vapour/liquid interace, the water being immersed in oil. Even if there is a free interface, significant superheating is possible[2] because the internal temperatures can rise above the boiling temperature which occurs at the interface where vaporization occurs. (The true definition of boiling relates to vaporization at a flat liquid/vapour interface, and, therefore, is not defined by the onset of vapour bubbles.) 'Bumping' occurs when clean water is heated and boils unevenly but can be avoided by the presence of a boiling 'chip' or a piece of Teflon, which contains many gas-entrapping crevices.

We found that the temperature that could be achieved by tap water in a beaker heated on an oven-top burner was 100.75 ± 0.25°C, close to the boiling temperature. But when tap water was heated in a microwave oven, the temperature measured by a thermocouple was briefly in excess of 110°C and there were more sustained periods of 105–106°C. To ensure that our thermocouple did not trigger boiling, we put it in a glass well that contained cooking oil. The tip of the glass well was positioned in the centre of the tap water held in a Pyrex beaker. The leads to our thermocouple were not attached to the voltmeter while the microwave was running, because the radiation would cause spurious readings. Our chromel/alumel thermocouple was calibrated with a crushed ice-water bath, and checked at the boiling temperature using water brought to a rolling boil (using a large chunk of Teflon).

Several kitchen objects were used to check the hypothesis that ice crystals nucleate boiling in ordinary tap water. When a stainless-steel or silver serving spoon was used, it would only nucleate boiling when cooled in a freezer (where some ice crystals could form). Glass, a screwdriver, and a plastic utensil behaved in the same way. If small boiling chips were added to the water before it was heated, we could not produce enough superheating, and inserted objects did not stimulate boiling.

Ice cubes themselves triggered a 'rolling' boil if the temperature rose above about 102°C. At a superheat of about 10°C above the boiling temperature, ice could nucleate boiling for 3–4 s. The time of boiling roughly scales to the number of degrees of superheat. Ice made with degassed water behaved in the same way as ice made with tap water saturated with gas.

It is quite clear that the mechanisms of the phenomena we observed are as follows: the microwave oven heats the water directly and the container indirectly, the opposite of what happens when heating by conduction with a burner. Therefore, the internal temperature can rise above the boiling temperature at positions away from the container's surface which tended to provide sites for boiling. Evaporation at the free surface does not occur rapidly enough to cool the bulk of the sample. When an ice cube is introduced, its crevic-ed crystalline structures, which can hold gas or water vapour, stimulate film boiling on local parts of the surface of the ice cube. The vapour film acts as a partial thermal insulation, slowing down the heat transfer between the ice cube (at about −15°C) and the water (at 110°C). When the water temperature immediately around the ice cube drops below 102°C, or so, the observed boiling ceases.

When our experiments are repeated with water in a plastic cup, a much smaller degree of superheat is achieved, primarily because the water wets plastic much more poorly that it does Pyrex glass, and therefore boiling on the surfaces of plastic is much more active, cooling the interior and preventing significant superheating.

One word of caution. We used extremely fine, insulated thermocouple wire, which allowed us to close the microwave oven door and not risk radiation leakage. Similar precautions should be taken by those who desire to repeat our experiments.

In defence of bacterial phylogeny

SIR—In recent correspondence, Woese *et al.*[1] say that our differences on *Archaebacteria* eocytes and photocytes are semantic. Our differences are fundamental and are based on two contradictory evolutionary trees. If one tree is correct the other is not. These trees are our combined photocyte/eocyte tree[2,3] and the tree of Woese[1]. Each relates all extant organisms.

The most widely used and accepted method for selecting a tree is parsimony analysis[4]. The four prokaryotic groups, halobacteria, eubacteria, methanogens and eocytes, can be topologically connected (by unrooted trees) in only three different ways. These correspond to our photocyte tree, to Woese's tree and to a third alternative, shown in Fig. 1. According to parsimony, a tree relating four taxa is supported if a given molecular property is found in two taxa while an altered version of the property is found in both of the other two. Thus "two-and-two" properties are valid. However, if a property is found only in one of the four groups, then it does not support any tree. Hence "three-and-one" properties are invalid.

All of the photocyte molecular properties listed in Table 1 below support the photocyte tree. All are two-and-two and hence are phylogenetically valid properties by the parsimony criteria. The list includes basic cellular properties such as membrane related components [tetraether lipids[5] and fatty acid esters[6]], biochemical pathways [carotenoid synthesis[7] and arginine deiminase pathways[8]] and bioenergetic components [C_{40} and C_{50} carotenoids[9] and 2Fe-2S ferredoxin[10]] in addition to ribosomal RNA sequences and ribosome structure. Contrary to the implication of Woese *et al.*[1], the eocytic 50S lobes found in ribosomes of eocytes and systematically distributed within the methanogens[2,11,12] are also two-and-two. All molecular characters are the same for halobacteria and eubacteria and for methanogens and eocytes, hence they all support the photocyte tree. Many are

deeply integrated into the molecular fabric of these cells. These are precisely the features expected to be good evolutionary markers.

No properties support the Woese tree, including the "founding" ones upon which both the tree and classification were proposed, "membrane, cell walls, rRNAs and tRNAs"[1]. These "founding" properties are listed in Table 1. For example, 16S rRNA oligonucleotide catalogues indicate that the eubacterial pattern is different, but they do not identify which group the eubacteria are closest to. All of their characters are three-and-one and cannot support any tree. When judged by standard evolutionary procedures and tests, the same "founding" properties which prompted Woese's taxonomic proposal, fail to support his tree.

Ribosomal RNA sequences, as rapidly evolving molecular characters, are subject to artefactual analysis by parsimony. No matter what the correct tree, parsimony and other treeing algorithms can consistently predict a tree which, like Woese's places fast-clock groups (that is, eubacteria and eukaryotes) together[13]. When we analyse the rRNA sequence data using the method of phylogenetic invariants, which is insensitive to this artefact and independent of evolutionary rates, we find support for our eocyte/photocyte trees is significant at greater than the 99% level[14,15].

Woese claims that his proposed classification could be used with any tree. A classification that fits all trees is no classification at all. Consider the arginine deiminase pathway found in the photocytes (eubacteria and halobacteria). We interpret it as having evolved once in the photocytes. Woese's proposed classification, making it a property occurring in two "kingdoms," misdirected others to propose either (1) that it was invented twice, or (2) that it was laterally transferred between "kingdoms"[8]. An incorrect classification has great negative power to obscure and misdirect.

Science and not semantics, then, is the basis of our claims. We see no support for Woese's tree and taxonomic proposal from any molecular properties, whereas deep and fundamental properties support our eocyte and photocyte trees and classification. Viewed through the photocyte tree, membranes, biochemical pathways, and components of biochemical energetics are all natural and logical consequences of evolutionary history. Well integrated molecular biological and metabolic properties support the photocyte and eocyte trees and classifications. In the end, evolutionary connections, and not semantic ones, between organisms give theories true organizational and predictive value.

Table 1 Prokaryotic molecular properties

	Eubacteria	Halobacteria	Methanogens	Eocytes
	VALID BY PARSIMONY (Photocyte)			
Arginine deiminase pathway	+	+	-	-
Tetraether lipid	-	-	+	+
2Fe-2S ferredoxin	+	+	-	-
C40 carotenoids	+	+	-	-
Fatty acid esters	+	+	-	-

Testis size and dizygotic twins

SIR—A recent article in *News and Views*[1] discussed R.V. Short's observations[2] on human testis size and dizygotic twin frequency in Asian, Indian, Caucasian and African ethnic groups.

Large testes were the first clinical feature to be associated with fragile X chromosome-linked mental retardation[3,4]. A mean testicular volume of 48 ml (range 15–127 ml, modal volume 35–40 ml) was observed[5] for adult white fragile X males in whom testicular volume was not a factor in ascertainment. The average testicular volume in unaffected Caucasian males is 20 ml. In an ascertainment of fragile X-affected kindred in Hawaii[6], it was noted that the mean testicular volume (22 ml) of pure Japanese males was less than that (39.5 ml) of pure Caucasian males. This reflected a previously observed difference between unaffected males of these ethnic origins.

A recent Belgian study[7] of 144 obligate female carriers of the fragile X led to the conclusion that such carriers have a high fertility, especially in those who are mentally subnormal (30%). An increase in the incidence of twinning was observed in the 642 progeny of 134 obligate carriers. Of 18 pairs of twins, 12 were dizygotic, and, in the remaining 6, the zygosity could not be determined. This incidence (1 in 35 births) is three- to-four-fold that of the expected incidence of twinning in Caucasians (1 in 80 to 1 in 140 births)[8]. This specialist fragile X-bearing population therefore would appear to express parallel variations to those already observed by your contributors.

Reader Service No.39

THE POLITICS OF CHANGE

How much does your weekly diet of Press, Television and Radio really inform you? How much does it teach you about the true state of British politics? How aware are you of the real options available to government on any policy issue?
Are you satisfied with the current quality of political debate?
Harold Lever, Mary Warnock, Douglas Wass and Ian Gilmour aren't.
That's why they're working for Catalyst, breathing new life into the body politic.

CATALYST

A Journal of Policy Debate
Authoritative Non-Partisan Analysis

The quarterly magazine that's a solid read and a definitive source of reference
It's never too late to improve your reading habits.

'Informative and provocative' – T.H.E.S.

'Indispensable reading for the political commentator' – PEREGRINE WORSTHORNE

'Thank you for helping to get our brains into gear' – AUSTIN MITCHELL

'Deserves to succeed' – DAVID OWEN

'Of great value' – MERLYN REES

'I greatly commend Catalyst' – SIR JOHN HARVEY-JONES

'By far the best discussion that I have seen of the 'British Disease' and its possible remedies' – LORD BLAKE

'Like lighthouse beams into a dark night' – ROY JENKINS

'Quite excellent' – DAVID STEEL

'Absolutely indispensable... difficult to imagine how one got on without it' – STEWART STEVEN

SUMMER 1986 ISSUE, OUT NOW: **CHOICE AND THE ENVIRONMENT.** AVAILABLE FROM: UNIT 8, GROVE ASH, BLETCHLEY, MILTON KEYNES MK1 1BZ. ANNUAL SUBSCRIPTION (4 ISSUES): £15 (UK); £19-50 (EUROPE); £22-50 (USA); £4 (SINGLE ISSUES).

Keep up to date with

CANCER SURVEYS

Editor: **L M Franks,** *Published for the Imperial Cancer Research Fund by Oxford University Press*

Brings you critical and comprehensive reviews of the latest research. For clinicians, cell and molecular biologists, and epidemiologists.

DRUG RESISTANCE *Volume 5 Number 1*

Edited by **G Stark** and **H Calvert,** Imperial Cancer Research Fund, London, and the Institute of Cancer Research, Sutton, UK.

Contents

DNA amplification in drug resistant cells and in tumours **George R Stark**

Multidrug resistance **James H Gerlach, Norbert Kartner, David R Bell and Victor Ling**

Membrane transport alterations as a mechanism of resistance to anticancer agents **D W Fry and R C Jackson**

Biochemical and cellular determinants of bleomycin cytotoxicity **Branimir I Sikic**

Clinical aspects of drug resistance **A Sobrero and J R Bertino**

Circumvention of resistance to anthracycline by calcium antagonists and other membrane-perturbing agents **David Kessel**

In vitro human tumour model systems for investigating drug resistance **Bridget T Hill**

Cancer Surveys focuses on a new topic every quarter. Each edition provides a definitive and up-to-date account of the present state of knowledge in the chosen area. Guest Editors, with specialist knowledge of that field, provide general assessments. Contributors review the areas where they have made important contributions, include research which may not have been published elsewhere and relate epidemiological and laboratory research to clinical problems.

Each issue costs £13.50(UK), US $29 (N. America), £15.50 (Elsewhere) or take out a year's subscription: £47 (UK), US $95 (N. America), £53 (Elsewhere). Cancer Surveys is published quarterly.

All Previous issues are available. Details on request.
The next issue in the series is BIOCHEMICAL MECHANISMS OF ONCOGENE ACTIVITY: Proteins Encoded by Oncogenes, edited by Harold E Varmus and J Michael Bishop

Unnatural science?

Marie Jahoda

Profiles of Social Research: The Scientific Study of Human Interactions.
By Morton Hunt. *Russell Sage Foundation, New York:1986. Pp.324. Distributed by Basic Books, hbk $17.50, pbk $8.95.*

LONGSTANDING readers of this journal on both sides of the Atlantic may raise their eyebrows at the very title of the book here under review. Natural scientists often deny the legitimacy of using the word "science" in conjunction with social research, a view shared by some people in high places. But surely nobody can doubt that the social world is as much part of nature as the world studied by natural scientists, equally there to be observed, understood, measured, occasionally manipulated in experimental fashion, conceptualized and perhaps even explained.

The denial of scientific status for social research cannot rest on these generally accepted criteria for science. Indeed it does not. The verbal quibble is a substitute for an appreciation of some genuine differences between the natural and the social sciences beyond the unquestioned difference in achievements. There is a distinction between the phenomena in the social and the physical worlds. The regularities social scientists discover are subject to change. Those in the natural sciences are not; they are assumed to hold for all times and through the entire Universe. This has implications for the development of theories on both sides of the fence. In the natural sciences, a new theory should encompass the regularities a previous one has explained. No such demand can be met in the social sciences, because the regularities themselves may have altered. So, while there is no shortage of theories in the social sciences, there are no cumulative explanations, at least not so far. Social scientists must deal with their complex subject matter in an extended "Now", the duration of which is unknown.

The relatively low public prestige of the social sciences is, however, less grounded in this feature of the subject and more in another ineluctable fact: while no lay person can pronounce on the unification of the four forces, not even on a single particle, everybody has daily experience of the social world and holds implicit or explicit theories about it. Depending on such personal views, one and the same social scientific formulation is regarded by some as trivial common sense, by others as false.

Morton Hunt's competent and lively description of several social research projects, their methods, achievements, difficulties and public reception, addresses these issues not directly but by example. The volume was commissioned by the Russell Sage Foundation of New York, in celebration of its 75-years-long support for the social sciences. It deals understandably but regrettably almost exclusively with American research, but social scientists elsewhere will have no difficulty in recognizing their subject, apart from the incomparably greater funding available in the United States. The book is based on published research and interviews on aspects of the research process that are not normally included in the written record. Hunt conveys above all something that should appeal to natural scientists: the intellectual quality and commitment to high standards that outstanding social scientists invest in their efforts.

Popperfoto

Boston, September 1974 — racial hatred erupts as whites protest against the court-ordered integration of public schools through the bussing of students to different parts of the city.

Part I gives an illustrated overview of the standard methods of social research, paying due attention to their assets and shortcomings as well as to the ethical problems that inevitably arise when people are the subject of study. Neither advocacy nor critique, this is a fine presentation of the state of the art in social research.

Part II contains detailed descriptions of five major projects, including their internal histories, costs, methods, results and, in one dramatic case, the wide-reaching public consequences that followed publication. This was James Coleman's famous — according to some, notorious — large-scale survey of school segregation and its effects. Coleman's study was commissioned by the government in 1965, with a budget of $1.5 million, and Hunt describes it by skilfully interweaving the research issues with an account of the social and legal context, an intellectual biography of Coleman and the views of various social scientists on the question of whether social research should remain "pure" by choosing its own topics, or try to answer questions raised by policy-makers. After describing the conceptual and practical problems of conducting a survey of more than 600,000 children in 4,000 schools, Hunt presents the computer-produced results. They shocked the civil rights movement, which had confidently expected they would show that more money spent on desegregated schools would reduce, if not eliminate, the achievement differential between black and white children. Coleman's conclusions were different. For example, he found that parental economic status had more to do with achievement than race or quality of school. Uproar followed: simplified press accounts, congressional hearings, attack and defence in popular journals. At that time the controversial bussing policy was introduced — and failed. White parents took their children from the integrated city schools and moved out into the suburbs, or put them through private education. And Coleman, re-analysing his data after several years, acknowledged publicly that the original data already contained evidence for "white flight" as a result of desegregation.

It is to Hunt's great credit that he presents this confusing story without minimizing the intellectual and political passions it aroused, nor the mistakes made on all sides, and yet shows convincingly the potential power of social research to illuminate controversial issues. One question, however, he leaves unasked: is it in the best interest of social scientists or policy-makers to demand quick answers to immediate problems?

Case histories of two further government-initiated studies allow Hunt to enlarge on the assets and vicissitudes of social research. One was the decade-long, real-world experiment on negative income-tax, better described as income maintenance for the very poor. Economists, statisticians, sociologists and social psychologists cooperated in this complex project. Hunt uses it as a basis for a sophis-

ticated exposition of the research process, its relation to theory and, in this case where time was not pressing, for the demonstration that the amount of thought and expertise invested in such research has its intellectual pay-off and its social uses. The other government-initiated study, the Survey of Income and Program Participation (in social welfare programmes), gives Hunt occasion to trace the history of survey research and indicate what is considered to be current best practice.

A fourth case takes the example of a social psychological laboratory experiment with undergraduates to illustrate the great power of this method, which dominates American social psychology, and its inherent problems: Do the results apply to the world outside the laboratory? Is the desire for experimental precision responsible for all too many elegant trivialities in the literature? A final case exemplifies the methods of longitudinal panel research through analysis of some studies, designed to continue for 20 years, of aging in an originally healthy middle-aged sample.

Altogether this is an engagingly and clearly written book. It presents social science as it is, warts and all. Social scientists could well use it as a textbook. Natural scientists may gain from it insight into the intellectual challenges social scientists face, and respect for their efforts in meeting them. □

Marie Jahoda is Emeritus Professor of Social Psychology at the University of Sussex, Falmer, Brighton BN1 9QG, UK.

Inflamed appeal

Gerry Higgs & Brendan Whittle

The Inflammatory Reaction. By Henry Z. Movat. *Elsevier:1985. Pp.365. Dfl.260.*

THE inflammatory reaction continues to be a centre of interest in the medical sciences, largely because of the high incidence of inflammatory diseases throughout the world. One in three people in the West can expect to suffer from some sort of chronic inflammatory disorder during the course of their life. This book, however, is devoted essentially to the acute inflammatory reaction and here Professor Movat has dealt very thoroughly with the subject. He makes no apology for his somewhat idiosyncratic approach, drawing heavily upon his own research findings to illustrate and explain the events of inflammation. This is not to say that the book lacks objectivity. It is an impressive review of current knowledge, with an extensive bibliography that takes up more than a fifth of the text.

The study of inflammation was for many years considered the province of pathologists and has only recently been hijacked by pharmacologists and immunologists. Professor Movat emphasizes the need for integration of the disciplines concerned, but, as a pathologist himself, he is well placed to lead his readers through the historical developments and on to current ideas. Not surprisingly then, he places inflammation in the context of the structure and function of the tissues affected. Beginning with the anatomy of the microcirculation, he goes on to describe the vascular and lymphatic changes occurring as a result of inflammatory injury. The morphological and functional aspects of leukocyte activation are dealt with in a similar way. This approach provides a good basis for the chapters on mediators and mechanisms.

The longest chapter, occupying almost a quarter of the book, tackles the formidable list of mediators that are known to contribute to the vascular phenomena of acute inflammation. Another chapter deals with substances which stimulate leukocyte emigration. The problem with categorizing inflammatory mediators is that they are rarely involved in discrete functions. For example, the prostaglandins, leukotrienes and complement-derived factors contribute to vascular as well as cellular responses in inflammation. Professor Movat has overcome this difficulty by demonstrating the relative importance of individual mediators in processes such as vasodilation, vascular permeability, chemotaxis and degranulation. This has not been achieved without cross-referencing between chapters, which in places is confusing. The picture that emerges, however, is that inflammatory reactions are initiated and amplified by the actions and synergistic interactions of a large number of mediators.

It is a little disappointing that the mechanisms of chronic inflammation are not touched upon until the penultimate chapter of the book. Also, discussions of the treatment of inflammation or the mechanisms of anti-inflammatory drugs have been deliberately avoided. Nevertheless, this is the most comprehensive and up-to-date text available on the subject of acute inflammation, and as such it will prove useful for reference. A large part of the book is based on experimental findings and this aspect should appeal to the post-graduate and post-doctoral workers in inflammation research. Professor Movat should, therefore, succeed in his objective of stimulating the young investigators to whom this monograph is primarily addressed. □

Gerry Higgs is Head of the Anti-Inflammatory Section and Brendan Whittle Head of the Department of Mediator Pharmacology at the Wellcome Research Laboratories, Langley Court, Beckenham, Kent BR3 3BS, UK.

Engineered viruses out of doors

D.H.L. Bishop

Genetically Altered Viruses and the Environment. Edited by Bernard Fields, Malcolm A. Martin and Daphne Kamely. *Cold Spring Harbor Laboratory: 1986. Pp.362. $63.*

THE use of genetically altered viruses in medicine or veterinary practice is, of course, old hat. Since the late eighteenth century and Jenner's pioneering work on smallpox, attenuated genetic variants of disease-causing viruses have been employed to protect man and domestic animals from infection by virulent viruses.

Such vaccine strains of viruses have been obtained by serendipity. What then is the concern about genetically altered viruses in the environment? With modern technologies and precise knowledge of the genetics of viruses (genome sequences and coding strategies), not only can we now achieve the objectives of earlier scientists by direct and specific genetic engineering, but we can go much further in custom-designing viruses for new purposes. It is against this background that the symposium that spawned this book was organized. The issues raised are both broad and far-reaching, and are of importance not only to scientists but also to the public, especially local and national regulatory authorities.

The initial chapters of the book describe the US legislative and regulatory frameworks pertaining to the use of genetically engineered viruses. Corresponding frameworks in other countries are not considered, limiting the interest of this information to the international audience, though one appreciates from these accounts the problems that have arisen in the United States where regulations are being applied to a subject that goes beyond the concepts involved in originally formulating the legislation.

The development and use of genetically engineered viruses in agriculture and forestry will open up new tracts of science, and will doubtless have irreversible environmental consequences. The question of risk assessment is therefore a central one, but there is only restricted discussion of this subject in the book. It was, for example, a major oversight of the organizers that there is a detailed report neither of the use in Australia of the South American myxomatosis virus to control rabbit populations, nor of the domino effects of the introduction of the virus to continental Europe and the United Kingdom. Likewise our extensive knowledge of the use of viral insecticides to control pests of agriculture and forestry is given

short shrift. Chapters are devoted to the subject of virus spread between hosts by vectors, or water or airborne transmission, topics which bear strongly on potential environmental effects. But there is much more to the issues involved than can be covered in each of these short contributions.

In a section on virus tropisms, the genetic basis of the cell–organ selectivities exhibited by certain viruses is discussed succinctly, as is the role of cellular receptors in determining particular virus tropisms and the penetration processes used by viruses to invade cells. Similarly, the genetic elements involved in the control of virus replication and expression of particular viral phenotypes are well reviewed. The complicated matter of virus–host interactions is covered in four chapters dealing with virus persistence and variation, and host responses to virus infection, with particular reference to genetically altered viruses such as the attenuated virus vaccines. The final section of the book is devoted to accounts of virus vectors that are of value for the expression of foreign genes (vaccinia, bovine papillomavirus, adenoviruses, *Autographa californica* nuclear polyhedrosis virus). This is a topical subject, in that such vectors are being developed by the biotechnology industry for the production of foreign gene products. Again, however, there is little mention of their use (and impact) in the environment.

All in all, it is evident that the original meeting was a thought-provoking and worthwhile exercise. Unfortunately, the resulting book provides only sketchy outlines of selected areas of the subject matter, and I would question its value to either the specialist or the more general reader. □

D.H.L. Bishop is Director of the Natural Environment Research Council's Institute of Virology, Mansfield Road, Oxford OX1 3SR, UK.

A manifold mind

John C. Marshall

The Citadel of the Senses and Other Essays. By Macdonald Critchley. *Raven: 1986. Pp.277. $32.50.*

MACDONALD Critchley is one of our most senior and distinguished neurologists, and a man for whom "retirement" means an opportunity to work harder than ever. His current collection of essays, some reprinted, many previously unpublished, bears witness to an undimmed interest in all aspects of neurological disease and an acute awareness of the rich variety of humankind, its triumphs and its foibles. The volume is appropriately prefaced by a novelist's *bon mot*: "Somerset Maugham regarded old age as the time to undertake those tasks shirked in youth because they would have taken too long".

The title essay, "The Citadel of the Senses: The Nose as its Sentinel", restores to olfaction the high ground usually occupied by the visual and auditory systems. Some brief remarks on the comparative anatomy of the nose introduce a vignette on the role of smell in medical diagnosis; but lest such odours seem unduly fetid, we are also treated to extracts from "Vins et Vignes de France", "La Psychologie du Parfumeur", and the adventures of Flush amidst the redolent aromas of spring in Florence. The protean world of touch is equally well represented in a chapter on haptic perception; here Critchley ranges from the skills of the silk mercer, through the neuropsychology of braille reading, to disorders of tactile discrimination and localization consequent upon damage to the peripheral and central nervous system. Disorders of the visual system likewise provoke a wealth of anecdote and differential diagnosis: in what terms should we describe and explain how some patients with adequate sight nonetheless fail to recognize objects (visual agnosia), or how yet other patients apparently cannot see two objects at the same time (simultanagnosia)? What are we to make of the aurae in migraine or the bizarre visual hallucinations that may precede an attack? Was the terrifying abyss that Blaise Pascal purportedly saw plunging to his left a symptom of ophthalmic migraine? (Neurologists are almost as keen as psychoanalysts to diagnose the famous dead.)

Although most of the papers collected here are essays for the left hand, intended to stimulate thought rather than solve problems, one does occasionally long for a more extended analysis. For example: Critchley claims that "it is a vain pursuit to seek to isolate various subtypes of visual agnosia, e.g., for colours or for faces". Yet there are many well-documented case-reports, with extensive testing and more than adequate controls, that do seem to indicate the existence of high-level perceptual disorder in which an impairment of colour or face recognition is disproportionately severe. What *specifically*, one wants to know, does Critchley find inadequate about the investigation and interpretation of these cases? Similarly, in his discussion of claims that there are subtypes of specific developmental dyslexia, Critchley writes: "To medical men like myself such efforts are not impressive and seem premature and speculative". Those of us who have attempted to provide solid, empirical evidence for a typology of dyslexic impairment would welcome criticism more detailed than the blank assertion that "to make a rigid parcellation within the clinical picture of developmental dyslexia is going too far".

Throughout the volume Critchley wears his prejudices and his enthusiasms on his sleeve. Particularly generous and appealing are his biographical sketches of esteemed neurologists: Hughlings Jackson, Newman Neild and Josef François Babinski. How refreshing it is to discover that the last of these was a person, not merely a reflex. I was especially happy to learn of Babinski's term for "confused, obscure, or imprecise" writing — "chieurs d'encre" (ink-shits, as Critchley forthrightly puts it). The enthusiasms that Critchley recommends for study by the young neurologist include the physiology of laughter and smiling, the transcendental states that music can provoke, and the sensory skills of the blind; on occasion an enthusiasm and a prejudice will interact, as when Critchley advocates the study of aphasias in African, Asian and Amerindian languages, but tells the student to take no notice of "contrastive linguistics"!

From *The Citadel of the Senses*

Sole stimulation — the Babinski sign, reported in C.r. Séanc. Soc. Biol. *in 1896. "Here at last", writes Critchley, "was a clinical shibboleth which would distinguish the organic from the hysteric, the genuine from the counterfeit".*

One final foible: in this, as in most of his collections, Critchley refuses to give references, a habit that is decidedly unhelpful to those whose knowledge and memory cannot match Critchley's own. As it happens, I do have the "original" reference for "Anton's syndrome" (1899), a condition where a cortically-blind patient denies his blindness. But I'd appreciate chapter and verse for the claim that the circumstance "had been described with the utmost lucidity by Seneca centuries ago". □

Whales: transition in translation

Samuel A. McLeod

General Features of the Paleobiological Evolution of Cetacea. By G.A. Mchedlidze. *Balkema:1984. Pp.139 + plates. Dfl. 65, £16.50, $26.*

FOR the general reader there is, surprisingly, still no overview of cetacean evolution to replace Kellogg's 1928 *History of Whales*. Despite its title, Mchedlidze's book will not suffice as a successor to Kellogg's work. Specialists, on the other hand, will find this to be a very useful volume, though they will also need access to Mchedlidze's 1970 monograph (published in Russian) and his 1977 English-language summary of some of his ideas on cetacean evolution. Mchedlidze's monographs are separate publications, not generally available; this translation provides a much-needed introduction to some of the Soviet fossil cetacean faunas (including important Azerbaidzhan and Georgian fossils discovered over the past two decades), together with several rather idiosyncratic essays on particular morphological transformations.

The descriptions of the fossil cetaceans alone make the book invaluable, though a couple of them are confusing. *Oligodelphis azerbajdzanicus* and *Kelloggia barbarus* were both originally described in a 1968 manuscript by Mchedlidze and his erstwhile Russian collaborator, S.M. Aslanova, but by the rules of zoological nomenclature those species names are available only as of 1976. *Kelloggia barbarus* is also said to have "intercostal plates", reminiscent of the now-disproven cetacean "armour" of Kükenthal and Lydekker. In 1970 Mchedlidze described a new genus and species, *Mirocetus riabinini,* but in the 1976 work, and this translation of it, the species name appears as *M. rjabinini.*

The drawbacks of the book for the unwary reader are several. For example, while Mchedlidze cites most of the pertinent Western palaeontological research, he seems unaware of, or ignores, the general systematic literature. His systematic methodology is therefore seriously out of date. Although he uses individual characters to assign species to higher taxa, most of these characters are primitive and the assignments are based on the vague notion that the characters "most closely resemble" those of a higher taxon. His conclusions frequently are not borne out by the anatomy of the specimens in the photographs. Thus he describes *Ferecetotherium kelloggi* and assigns it to the Aetiocetidae (here placed in the Archaeoceti, although the family is now usually classified in the Mysticeti), and considers it transitional to mysticetes. But there is no derived character, beside the supposed lack of a mandibular symphysis (not demonstrable from the plate), that this species shares uniquely with any archaeocete or mysticete. It may be a sperm whale. Many of his interpretations about the origin of mysticetes and the evolution of cetacean dentitions rely heavily on the systematic position of this species.

Mchedlidze initially cites the age of all the Russian fossil cetaceans as Upper Oligocene, but notes they are of different evolutionary stages. Subsequently he mentions that most of the specimens were not found *in situ* and that they may actually be of different ages. This problem also affects his systematic conclusions in terms of which taxa might be ancestral to other cetaceans. A different sort of chrono-evolutionary difficulty appears when Mchedlidze uses the old and extreme gradualistic argument that there was not enough time for the evolution of the various cetacean groups from their closest but more primitive reputed relatives. Most particularly, he believes the direct ancestors of cetaceans are "archaic [presumably Late Cretaceous] placental mammals".

Many of Mchedlidze's essays are adaptive scenarios for the origin and evolution of various cetaceans. This is a thought-provoking approach, but it depends directly on the soundness of the systematic conclusions; these, in my opinion, are the book's greatest failing. Several bizarre ideas, some initially espoused by such zoologists as W. Kükenthal, R. Lydekker and A.B. Howell, are re-cycled. Noteworthy is Mchedlidze's resurrection of the idea that odontocete skull asymmetry evolved because of increased swimming speed. More astounding is his statement that the dorsal position of the external nares allows cetaceans to remain "out of sight of predators for longer periods of time"!

The translator, editor and publisher have done a fine job on the book, correcting some mistakes, adding several text citations not in the original bibliography and, most particularly, reproducing the plates more clearly. The disparity between the number of specimens listed in the legends and those on the plates remains, however, and the genus *Mirocetus* appears in three places instead of the original *Microcetus,* which changes the author's meaning.

This book is indispensable for the specialist. It will also be of interest to Western zoologists more generally, but they should treat its conclusions with great caution. □

Tip splitting without interfacial tension and dendritic growth patterns arising from molecular anisotropy

Johann Nittmann* **& H. Eugene Stanley†**

* Etudes et Fabrication Dowell Schlumberger, 42003 St. Etienne, France
† Center for Polymer Studies and Department of Physics, Boston University, Boston, Massachusetts 02215, USA

Two growth mechanisms of considerable recent interest are related to a single statistical mechanical model. Tip splitting without interfacial tension occurs when a fluid pushes into another miscible fluid of higher viscosity. Dendritic growth occurs when anisotropic molecules aggregate—a common example is the snowflake. We find that both structures are fractal objects, and can be obtained from a single statistical mechanical model, implying that there is a relation between the underlying physical processes involved.

GROWING structures have fascinated mankind for centuries, and today the field of growth phenonena elicits interest from many disciplines, ranging from medicine and biology to fluid mechanics. Two growth forms that have attracted recent interest are the following:

(1) Dendritic growth[1-9]. No two snowflakes are identical; each is assembled by the random aggregation of water molecules. Yet every child can distinguish a snowflake from other growth forms. The key scientific question is by what mechanism the anisotropy of a water molecule becomes amplified from its weak 'local' effect at the molecular level to its pronounced 'global' effect at the macroscopic level of the snowflake.

(2) Tip splitting[10-20]. A classic experiment in fluid mechanics concerns the splitting of a low-viscosity body of fluid which results when it is forced under pressure into a high-viscosity fluid. If the two fluids are immiscible, then the interfacial tension between them serves to establish a length scale at which tip splitting occurs. When the two fluids are miscible there is no interfacial tension, yet tip splitting nonetheless occurs. Thus an important question concerns the physical mechanism which determines the point at which the finger splits.

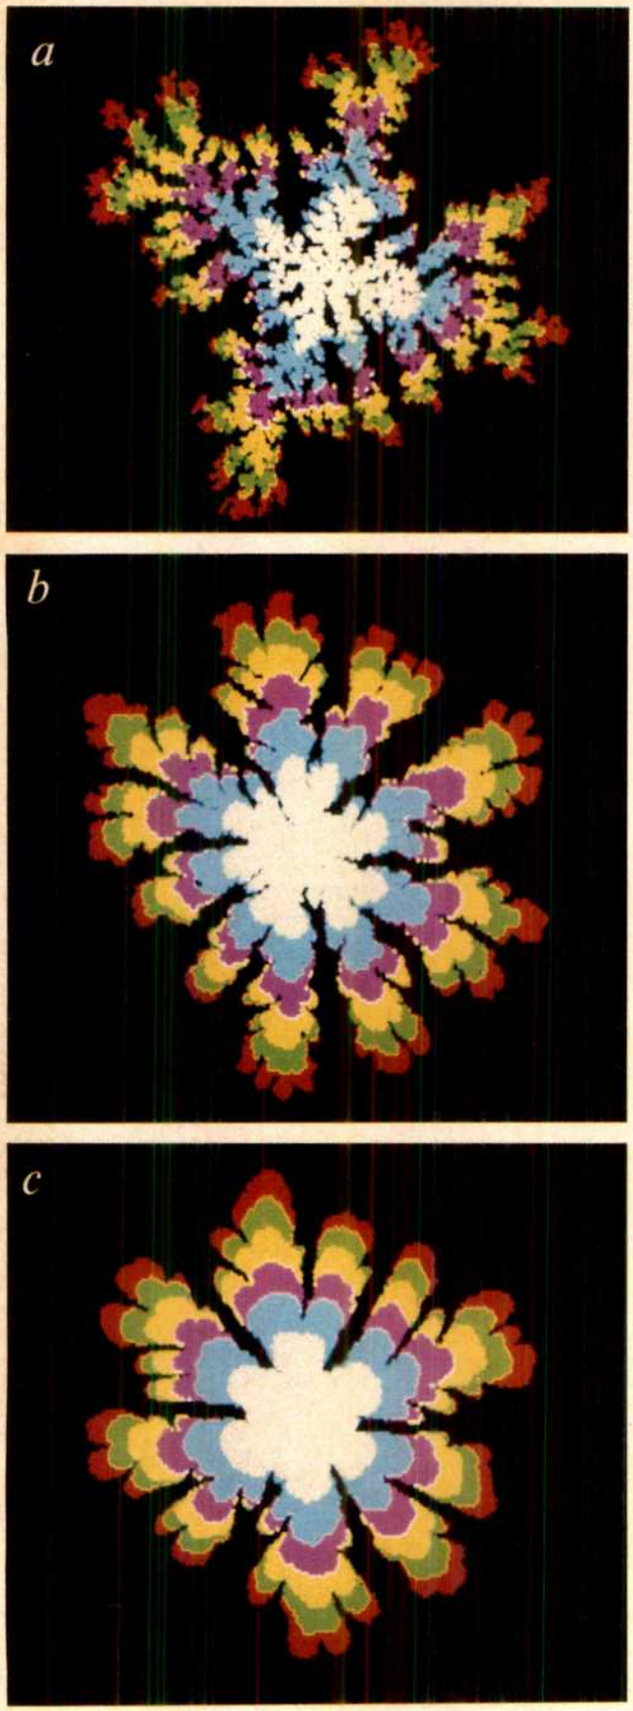
The scientific questions in (1) and (2) have been the object of research for many years, in part because our present state of understanding is so incomplete[21] that even a little progress would be valuable. The two categories of growth mechanism (1) and (2) have been considered to be quite different, in the sense that the physical basis for one has no relation to that of the other. Here we develop a statistical mechanical model which incorporates both dendritic growth and tip-splitting, thereby relating two disparate fields of enquiry.

Relation between noise and tip splitting

The model is most clearly explained if we begin with the dielectric breakdown model (DBM) of Niemeyer *et al.*[22] on, for example, a triangular lattice. We first place a seed particle at the origin of a large circular domain of radius R. If we think of this seed particle as being the source of a fluid of infinitesimally small viscosity, which is being forced under pressure to displace a fluid with much higher viscosity[23,24], then the interface must move according to Darcy's law:

$$v_n = -\mathbf{n} \cdot \nabla P \tag{1}$$

Here v_n is the velocity component normal to the interface, $\hat{\mathbf{n}}$ is the normal unit vector and P is the pressure field. P is constant in the less viscous fluid and, because $\nabla \cdot \mathbf{v} = 0$, P satisfies the Laplace equation



$$\nabla^2 P = 0 \tag{2}$$

in the more viscous fluid. Hence the relevant boundary conditions are $P(r, \theta) = 1$ anywhere in the low-viscosity body of fluid, and $P(R, \theta) = 0$ along a circle of radius R.

In a perfect medium with radial symmetry and no pressure fluctuations, the interface will spread out in concentric circles. However, because there is always some noise in the system, a fluid-dynamical instability[25] will occur and irregularities in the interface will grow. This noise phenomenon is reproduced in the DBM, which includes fluctuations by means of the following algorithm. First, ∇P is calculated at every perimeter site of the cluster; this is done by solving equation (2) with an overrelaxation technique. At step 1 there is a single seed on a triangular lattice with six perimeter sites. As all sites have equal values of ∇P, the first perimeter site is mapped to the numerical interval $[0, \frac{1}{6}]$ the second to $[\frac{1}{6}, \frac{2}{6}]$, the third to $[\frac{2}{6}, \frac{3}{6}]$ and so forth. Next, a random number generator is used to choose a number in the interval $[0, 1]$. Suppose that this random number is 0.2603238: the second perimeter site is then occupied, and the procedure iterated. For this two-site cluster, ∇P is calculated at the eight perimeter sites, the values are normalized to unity, a new random number is chosen, and one of the eight sites occupied. Such a DBM cluster is characterized by a high degree of noise: as each growth step is determined by only one random number, it is always possible that the random number chosen corresponds to a perimeter site with an extremely small value of ∇P, which by equation (1) should almost never grow. Thus the DBM violates the fundamental Darcy law due to the noise inherent in the algorithm.

We now describe a procedure whereby this noise can be systematically reduced in a controllable fashion. Clearly we need an algorithm such that perimeter sites with extremely small values of ∇P are extremely unlikely to be chosen. This is accomplished by advancing to a new perimeter site only after it has been chosen s times, where s is a parameter which can be tuned. Each perimeter site has a counter which registers how many times that particular site has been chosen. As $s \to \infty$, the growth of the interface will approach Darcy-law growth, in which any point of the interface grows according to the true local pressure gradient. In the Darcy 'zero-fluctuation' or 'mean-field' limit[26] ($s \to \infty$), the interface would be a perfect circle if there were no underlying lattice.

Figure 1*a–c* shows the results of calculations for successive values of s. We find that Fig. 1*b* and *c* resemble tip splitting as observed in the viscous fingering of both newtonian (refs 19, 27; J. D. Chen, personal communication; R. Lenormand, personal communication) and non-newtonian[10,12,18] fluids. When $s = 2$ (Fig. 1*a*), the structure resembles the DBM both qualitatively (although the branches look thicker) and quantitatively

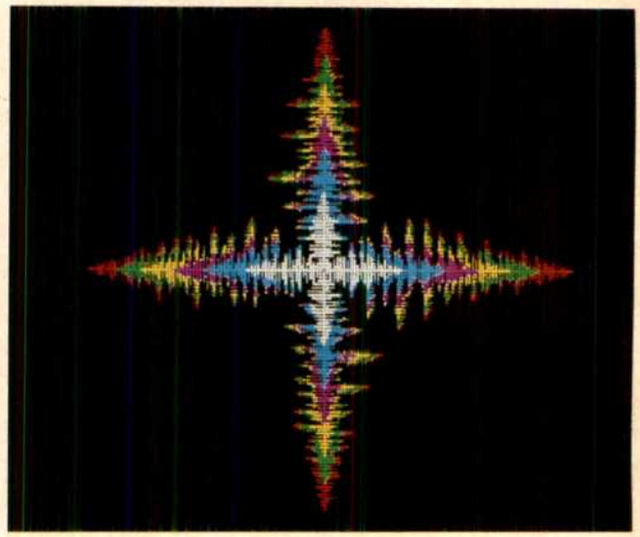


Fig. 2 A typical fractal structure on a square lattice with $s = 50$ and a microscopic anisotropy (defined by equations (6), (7)) of $k - 1 = 10$. The colour coding is the same as in Fig. 1.

($d_f = 1.7$). Here d_f is the fractal dimension obtained, for example, from the slope of a log–log plot of the mass against the caliper diameter. For large s (for example, $s = 20$; Fig. 1*b*), the qualitative appearance appears to differ: the system appears at first sight to cross over to a new 'universality class', with a larger value of d_f. However, when we extrapolate the apparent fractal dimension to large cluster sizes we find that $d_f = 1.7$ for all values of s; that is, the growth forms are quantitatively identical, independent of the degree of noise reduction.

Note that tip splitting always occurs by the same mechanism. First a cluster grows 'smoothly', without tip splitting. However, as the radius of curvature increases, the interface becomes 'rough', with both positive (outward) and negative (inward) fluctuations. The positive fluctuations are not significant, as they are soon damped out; however, the negative fluctuations persist (Fig. 3). This is because, for a charged fractal object, the electric field inside a single notch is very small, and the equation relating the electric field to the gradient of the potential is formally identical to the Darcy law relating growth velocity to the gradient of the pressure. Hence, the tiny notch is not likely to be filled in so quickly as one would expect if interfacial tension were present (Fig. 3*d*). The tiny protrusions on both sides of the notch see a much larger field than does the notch, so they attract mass. The tiny notch thus becomes the terminus of a long fjord (Fig. 3*e*). A fjord is almost perfectly screened, and so is almost never filled in. In Fig. 3, $s = 50$. If $s > 50$ (less noise), then the same tip-splitting mechanism will apply but a negative fluctuation (notch) will decay more efficiently: the system is less susceptible to negative fluctuations and a fjord is formed only when the cluster has reached a larger radius of curvature.

Although the asymptotic fractal dimension d_f is independent of s, the finger thickness W_f clearly increases with s. Moreover, our model explains the existence of a well-defined W_f: the less the noise, the thicker the finger (see Fig. 1). We find the quantitative law:

$$W_f \simeq 4.5 \log s + 2 \qquad (3)$$

Fig. 1 Examples of fractal structures generated when the anisotropy parameter k is held fixed at unity, but the noise parameter $1/s$ is decreased. In *a*, *b* and *c*, $s = 2, 20$ and 200, respectively. For all finite values of s, we find that the fractal dimension is equal to the DBM value, $d_f = 1.7$, providing we take care to extrapolate the apparent mass dependence of d_f to its asymptotic limit. The colour coding is as follows: the first one-sixth of the sites are white, the next sixth are blue, followed by magenta, yellow, green and red.

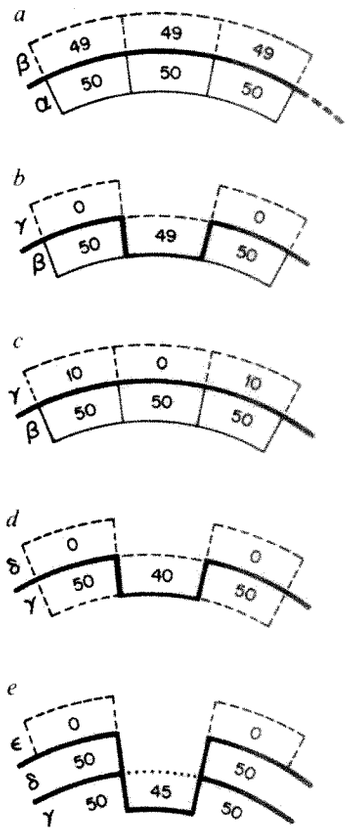

Fig. 3 Schematic illustration of the difference between an outward ('positive') and an inward ('negative') interface fluctuation. A positive fluctuation tends to be damped out rather quickly, as mass quickly attaches to the side of the extra site that is added. On the other hand, a negative fluctuation grows, in the sense that mass accumulates on both sides of the tiny notch. The notch itself has a lower and lower probability of being filled in, as it becomes the end of a longer and longer fjord. This is the underlying mechanism for the tip-splitting phenomenon when no interfacial tension is present. *a* shows the advancing front (row α) of a cluster with $s = 50$. The heavy line separates the cluster sites (all of which were chosen 50 times) from the perimeter sites (all of which have counters registering less than 50). In *a*, no fluctuations in the counters of these three sites have occurred yet, and all three perimeter counters register 49. *b* shows a negative fluctuation, in which the central perimeter site is chosen slightly less frequently than the two on either side; the latter now register 50, and so they become cluster sites in row β. The perimeter site left in the notch between these two new cluster sites grows much less quickly because it is shielded by the two new cluster sites. For the sake of concreteness, let us assume it is chosen 10 times less frequently. Hence by the time the notch site is chosen one more time, the two perimeter sites at the tips have been chosen 10 times (*c*). The interface is once again smooth (row γ), as it was before, except that the counters on the three perimeter sites differ. After 40 new counts per counter, the situation in *d* arises. Now we have a notch whose counter lags behind by 10, instead of by 1 as in *b*. Thus the original fluctuation has been amplified, due to the tremendous shielding of a single notch. Note that no new fluctuations were assumed: the original fluctuation of 1 in the counter number is amplified to 10 solely by electrostatic screening. This amplification of a negative 'notch fluctuation' has the effect that the tiny notch soon becomes the end of a long fjord. To see this, note that *e* shows the same situation after 50 more counts have been added to each of the two tip counters, and hence (by the 10:1 rule) 5 new counts to the notch counter. The tip counters therefore become part of the cluster, but the notch counter has not yet reached 50 and remains a perimeter site. The notch has become an incipient fjord of length 2, and the potential at the end of this fjord is now exceedingly low. Indeed it is quite possible that the counter will never pass from 45 to 50 in the lifetime of the cluster. In our simulations we can see tiny notch fluctuations become the ends of long fjords, and all of the above remarks on the time-dependent dynamics of tip splitting are confirmed quantitatively.

We also find that W_f is independent of the magnitude of the pressure field. To see this, we varied the global pressure gradient by changing the size of our computational grid from 200 to 25 units and found no variation of the finger thickness. This discovery is explained if one considers that the ratio of the local pressure gradient between a site at a finger tip and a site within a fjord does not change if the global pressure gradient is changed: this in turn is a direct consequence of the fact that the pressure field satisfies a Laplace equation.

Previous work on tip-splitting phenomena has focused on explaining the non-zero value of the finger thickness W_f as arising from the presence of interfacial tension σ (ref. 28; see also ref. 29). However this explanation cannot be applied to miscible fluids, such as those used in recent experiments[10,12,18,27,28], because in this case, by definition, $\sigma = 0$. In our model interfacial tension does not exist (that is, σ acts only on the length scale of a single fluid element or 'pixel'); our observed finger thickness is thus related solely to the concept of noise.

Before proceeding further we note that in the limiting case $s = 1$ the DBM is equivalent to diffusion-limited aggregation[30–32] (DLA). The diffusion analogue of the DBM for $s > 1$ is a DLA-type model in which growth occurs only after a perimeter site has been hit by s random walkers. If all the counters are reset to zero after each growth step, then we have the Meakin model[33] or the Kertész–Vicsek model[8], in which growth of the positive fluctuations (the tips) is amplified because a tip of size 1 pixel is more likely to experience the next growth event—so the apparent value of d_f decreases toward unity as the cluster grows. The DLA-type analogue of our DBM-type model in which the counters are not reset to zero after each growth event is the Tang model[26], for which it is not the positive fluctuations (the tips) that display amplified growth but the negative fluctuations (the notches). Amplified growth of negative fluctuations is the characteristic feature of DLA, explaining our result that d_f has its DLA value for all finite values of s.

Thus we conclude that noise reduction—arising from suppression of fluctuations—does not change the overall 'universality class', but does introduce a characteristic finger thickness.

Local anisotropy and dendritic growth

Real growth phenomena are never perfectly isotropic. In fact, anisotropy appears to dominate dendritic crystal growth; thus, for example, a snowflake is recognized by its six-fold anisotropy, although the noise is also reflected in the variability from one snowflake to another[9]. No two are alike, although the eye immediately recognizes the pattern of a snowflake.

The problem of understanding the growth of a snowflake has a rich history. A large class of models has focused on introducing anisotropy in a 'global' or macroscopic fashion by introducing angular variables and assuming that the growth depends sensitively upon these variables[2–4]. Although the resulting patterns have, by virtue of their rules of construction, the requisite six-fold symmetry, their resemblance to real snowflakes is not striking. Moreover, they lack the random variations that seem to characterize real snowflakes and also fractal objects.

A snowflake grows by successive landings of water molecules, and we have therefore focused our attention on how microscopic irregularities in the landing surface can be translated into the macroscopic structure of the snowflake. To reflect the presence of these microscopic irregularities, we must incorporate into our model the essential fact that the landing sites seen by an incoming molecule are not all equivalent. Hence we replace equation (1) by

$$v_n = -\mathbf{n} \cdot (k \nabla P) \tag{4}$$

where the conservation of mass condition $\nabla \cdot \mathbf{v} = 0$ implies that equation (2) is replaced by

$$\nabla \cdot (k \nabla P) = 0 \tag{5}$$

with the same boundary conditions as for $k = 1$. Here the anisotropy parameter $k = k(x, y)$ would be the permeability in a fluid problem.

Consider a square lattice. One simple choice for $k(x, y)$ is (see Fig. 2)

$$k(x, y) = 1 \tag{6}$$

for x or y even,

$$k(x, y) = k > 1 \tag{7}$$

otherwise equations (6) and (7) express mathematically the fact that the surface affinity for incoming water molecules depends on the spatial coordinate: the incoming particles do not see a perfectly smooth and homogeneous 'landing surface'.

Moreover, our anisotropy is fundamentally different from that considered in, for example, refs 4 and 11. Schematically, in these models the interface is moved according to the rule

$$u = f(\kappa) - f(\theta)u_n \tag{8}$$

where u is the growth velocity, $f(\kappa)$ is an interfacial tension term and u_n is essentially the local pressure (or temperature, or concentration) gradient at the interface. The function $f(\theta)$ indicates the extent to which the growth is enhanced along directions separated by an angle θ. In marked contrast, our model assumes that the anisotropy is present on a molecular level at the interface. We assume that along the interface, the affinity for an incoming water molecule alternates from site to site:

$$u = -f(x, y)u_n \tag{9}$$

We believe that our model is more realistic, as an incoming water molecule in snowflake formation cannot possibly sense the angle $\theta = \arctan(y/x)$, but does see a 'landing surface' whose 'attraction' fluctuates from point to point.

Next we consider the effect of tuning the anisotropy parameter k. Figure 5*a–d* shows structures grown with a succession of increasing values of k, ranging from 1.1 to 11. We hold s fixed at the value $s = 50$; if s were too small, then noise effects would complicate visualization of the effect of anisotropy. Figure 5 is for a triangular lattice, for which equations (6) and (7) are replaced by a different rule: we set $k > 1$ for every fifth row of the three principal directions of the lattice (E–W, NE–SW, NW–SE). We see from Fig. 5 that as k increases there is a pronounced change from the isotropic case $k = 1$, and the resulting growth (see, for example, Fig. 5*d*) resembles a 'snowflake' for reasons more subtle than merely the characteristic 6-fold axis of rotation[34]. Using standard methods (for example, all three methods of ref. 18), we measured d_f for this 'snowflake' and found values that decrease with the number of particles used in the calculation. Extrapolating to infinite size, we find[35,36] $d_f = 1.5 \pm 0.1$.

Although the structure at first sight appears to be somewhat ordered, we realize that this is a trick played by the 6-fold axis. In fact, an individual branch is quite disordered, with side branches of all sizes extending from it. The reason $d_f > 1$ is that the side branches occur with many different length scales. This is especially apparent from Fig. 5*d*, where we see from the colour coding that the latest particle to arrive can attach to the side branches as well as to the tip. Figure 5*e* shows real snowflakes with side branches, which show a striking resemblance to the anisotropic simulations of Fig. 5*d*. The differences between Fig. 5*d* and *e* are the subject of current investigation.

We now address the actual structure of the fractal objects in the presence of anisotropy. It is important to note that there are distinct effects that cooperate to generate the final structure obtained. The first effect is the fine structure of the side branches (see Fig. 2), consisting of a set of 'trees' of varying height, as shown schematically in Fig. 4*a*. The trees are mainly without branches, as the anisotropy favours growth only in even-numbered rows or columns of the lattice. However the height of a tree varies widely from one tree to the next, due to the tendency of tall trees to screen shorter trees. An analogous variation in the height of trees has been found by Meakin[37] in his classic studies of DLA on a planar substrate: he found that

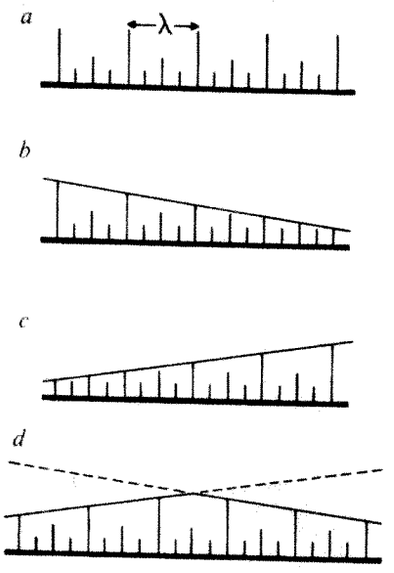

Fig. 4 Schematic illustration to explain the characteristic shape of the four arms of the 'snowflake' cluster in Fig. 2; *a* recalls the fundamental structure of aggregation onto an equipotential surface, first studied by Meakin[37]. For simplicity, the 'trees' are drawn as straight line segments, and the hierachical or fractal distribution of tree height is indicated by a difference of a factor of 2 between successive sizes, together with a spacing, $\lambda(M)$, which increases as M^{1/d_f}, where M is the total cluster mass. *b* shows the modification expected from the fact that the regions of an arm near the centre have more time to accumulate mass than the regions near the tip. *c* shows the effect of the fact that ∇P is much larger near the tip; *d* shows the result of combining *a–c*, and resembles the overall shape observed in Figs 2 and 5*d*.

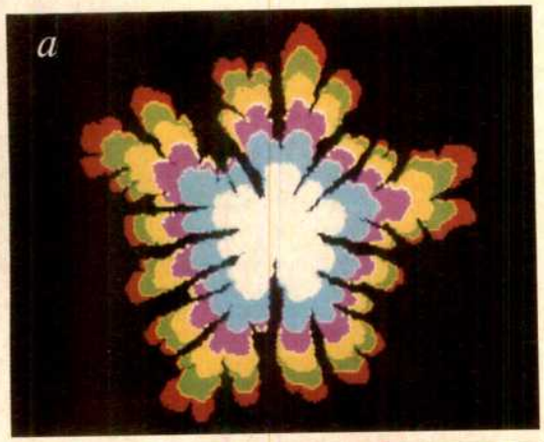
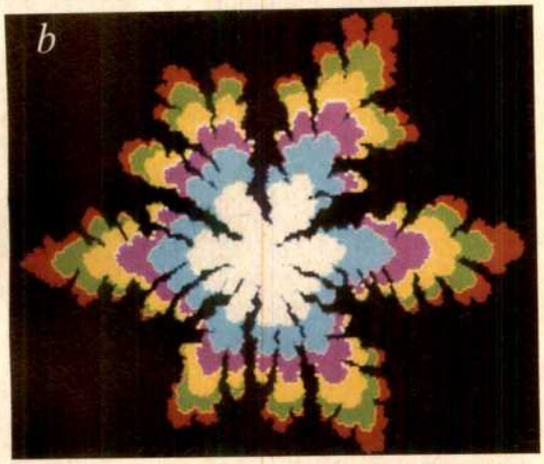
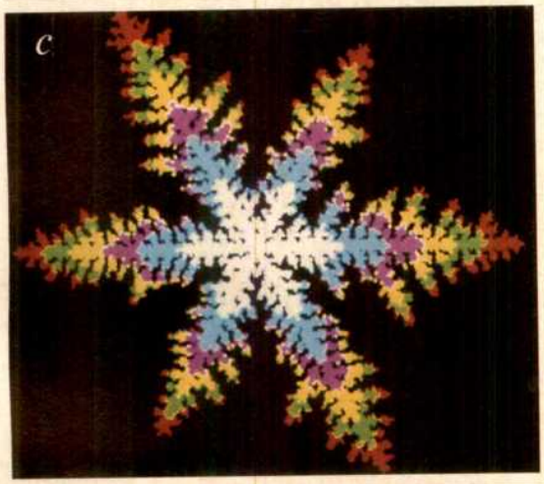


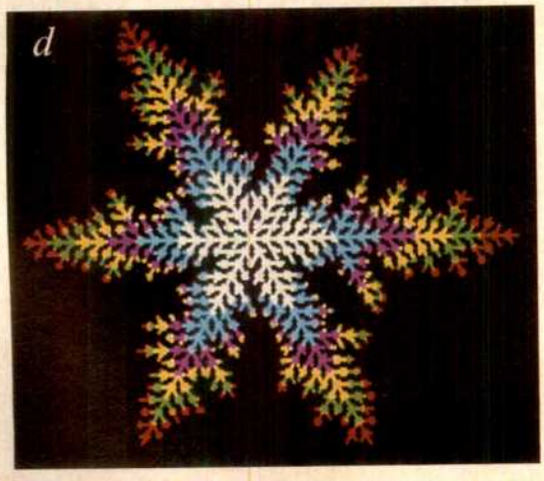
the resulting fractal structure is a 'forest' of trees, with fewer but taller trees surviving at large times due to their tendency to shield the shorter trees.



The main difference between our work and the Meakin (planar substrate) DLA simulations is our lattice anisotropy (parameterized by $k - 1$) and our noise reduction (parameterized by $1/s$), which have the effect of making the trees tall and straight instead of ramified. Consider now the overall profile for the height of the trees in the side branches. This profile can be understood mathematically as arising from the product of two functions. The first, a decreasing function from origin to tip, is related to the fact that the regions of the branches that were formed at early times tend to be larger than the regions of the branches that were formed at late times (Fig. 4*b*). The second, an increasing function, is related to 'screening'; that is, to ∇P, which is larger near the tips and smaller near the origin (Fig. 4*c*). As $v \propto \nabla P$, the growth rate is larger near the tips. The product of the increasing and decreasing functions gives the characteristic profile for the height of the trees in the side branches (Fig. 4*d*).



We also measured as a function of cluster mass: (1) the caliper width of the side branches of Fig. 2, and (2) the caliper diameter of the entire cluster. Both log–log plots are parallel, with slope $1/d_f$.



Discussion

We have shown that two fundamental physical phenomena that are not yet understood, dendritic growth and tip splitting in the absence of interfacial tension, can be related in that both arise from the same statistical mechanical model—a generalization of the DBM[22]. This means that there are physical features common to both phenomena: they differ only in parameter values. In our model we can incorporate in a direct and systematic fashion the crucial role played by fluctuation phenomena

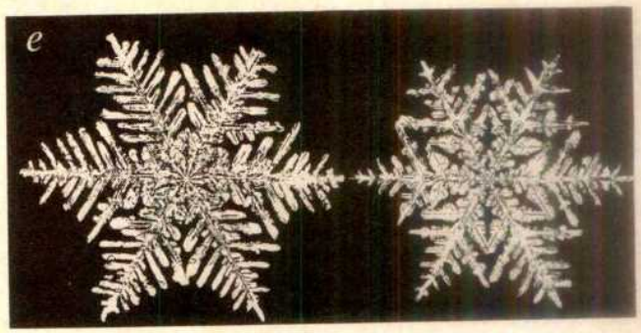


Fig. 5 *a–d*, Examples of fractal structures formed when the noise parameter s is held constant at $s = 50$, but the anisotropy parameter k is chosen to be, respectively, $k-1 = 0.1$, 0.31622, 1.0 and 10.0 (0.31622 interpolates logarithmically between 0.1 and 1.0). The limiting fractal dimension (as mass $\to \infty$) is $d_f \simeq 1.5$, independent of k, for all $k > 1$. The colour coding is the same as in Fig. 1. *e*, Examples of real snowflakes (reproduced with permission from ref. 9) which show a striking resemblance to *d*.

and anisotropy. The physical picture that we have proposed is embodied in two fundamental equations, (4) and (5) (or (1) and (2) for $k = 1$). The second equation describes the spatial change of the pressure field which drives the instability; the first represents the 'growth law', which relates the growth rate of the interface to the pressure field. We have used a generalized Darcy-type law, which enables us to selectively tune both noise and anisotropy.

The overall physical picture that emerges is as follows: Tip-splitting phenomena in the absence of interfacial tension are triggered by microscopic fluctuations (that is, noise). Although positive and negative fluctuations of the interface occur symmetrically, the stability (and hence the subsequent growth) of positive and negative fluctuations are totally different: tip splitting is the direct consequence of this asymmetry in the stability of positive and negative fluctuations. A small protrusion of size 1 pixel is much less long-lived than a small notch of the same size; in fact, it is remarkably difficult to fill even the shallowest notch. Zero noise ($s = \infty$) results in a compact (non-fractal) circular object. A very low noise level (large s) has little effect when a cluster is small, but its effect becomes much more pronounced as the cluster grows larger. In the limit of infinite cluster size, an arbitrarily small but non-zero amount of noise is sufficient to make the cluster fractal. The measured fractal dimension is identical to that of DBM and DLA, two models designed to describe phenomena in the limit in which there is a very high noise level.

The tip-splitting phenomena that occur in the case of zero anisotropy are generalized into a fractal hierachy of side branches in the presence of anisotropy. In the limit of infinite cluster size even a tiny degree of anisotropy changes the fractal dimension from the DLA value of 1.7 to the value 1.5.

Thus, the complete phase diagram has $1/s$ on the abscissa and $(k-1)$ on the ordinate. Asymptotically we find that d_f is constant, at the DBM value of ~1.7, everywhere on the x-axis, and d_f is also constant, at the value 1.5, everywhere else in the phase diagram except on the y-axis (zero noise), where $d_f = 1$. Thus noise reduction is not a sufficient perturbation to change d_f from its DBM value, because the negative fluctuations persist for all values of s, and these negative fluctuations control the value of d_f. On the other hand, anisotropy at the microscopic level does change d_f. Further details of this phase diagram suggest an intriguing analogy to critical point phenomena, and this will be the subject of future investigation.

Finally, we return to the question posed in the introduction, of how a tiny anisotropy can become 'amplified' from its local effect at the molecular level to a global effect at the macroscopic

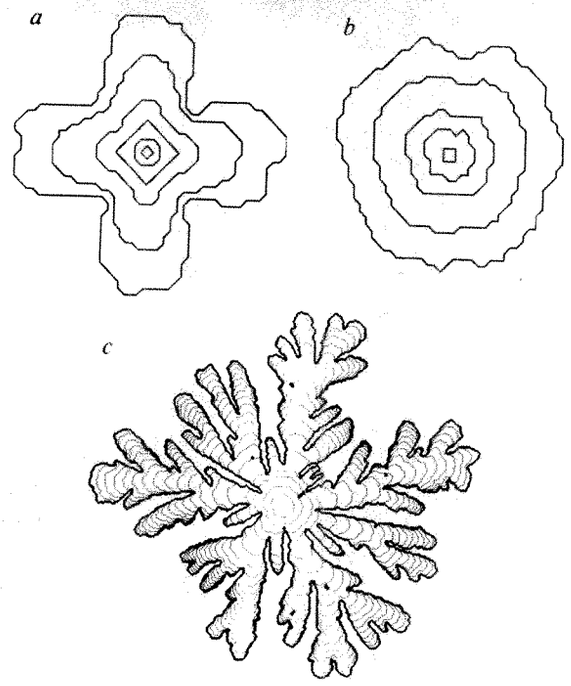

Fig. 6 *a*, Initial growth of an interface on a square lattice for the case $s = 500$. Growth can occur in any of the four space directions (four nearest neighbours). The interface is shown after 5, 21, 85, 200, 500 and 1,000 growth steps. *b*, As in *a*, except that here growth can occur into eight directions (four nearest neighbours and four next-nearest neighbours). The interface is shown after 9, 21, 85, 200, 500 and 1,000 steps. *c*, Viscous fingering structure for $s = 50$, after 15,000 growth steps for eight-fold coordination on a square lattice. The first four contour lines are drawn after 100, 300, 650 and 1,000 steps; subsequent lines are drawn at intervals of 1,000 steps.

level. Our model directly demonstrates this fact: we have shown that in the presence of anisotropy, the resulting fractal dimension is not the DBM value of 1.7, but rather tends asymptotically toward 1.5, a new 'universality class'. Our result is supported by Meakin's very recent calculations for DLA[38] without any local anisotropy, except for that arising from the square-lattice substrate. For this classic and well-studied system, 'pure DLA', Meakin finds the same behaviour that we find in the presence of anisotropy, but only after the cluster size reaches 5 million sites—almost three orders of magnitude larger than the clusters we study! Thus Meakin's local anisotopy, arising solely from the effect of the square lattice itself on the trajectories of random walkers, can lead to a pronounced global effect, altering not only the overall appearance of the cluster but also the fractal dimension itself. As pure DLA is the limit of maximum noise ($s = 1$), we have to wait for an extremely large cluster to see its effect. To support this idea, we systematically reduced s from 50 to 1 while keeping the local anisotropy fixed at the value $k = 2$. When $s = 50$ it is easy to see the snowflake anisotropy pattern, but as s decreases the snowflake vanishes.

To understand better the subtle role played by the anisotropy of the square lattice, we show in Fig. 6*a* the initial growth events for the case $s = 500$, $k = 1$. The early stage of growth is characterized by the competition of 'lattice anisotropy', which attempts to pull the interface into the four principal directions of the plane, and 'interface smoothing' (due to the decay of positive and negative fluctuations), which initially prevents splitting. The competition between these two contradicting tendencies leads to an oscillation of the interface: the structure of the interface alternates between a circle and a diamond-shaped cusp until, eventually, the weak anisotropy of the lattice dominates. As in real systems, no cusp singularities[39] occur: the noise in our systems smooths the sharp corners of the initial cusp as interfacial tension would do. A well-defined finger thickness has developed. The larger the value of s, the smaller is the noise and the larger is W_f. To weaken the lattice anisotropy, which results from the rule that growth is possible only in one of the four space directions (nearest neighbours), we can also allow growth into the four diagonal directions (next-nearest neighbours). Figure 6*b*,*c* shows that such growth is initially almost circular until it reaches a critical radius, after which negative fluctuations are no longer filled in. This gives rise to the characteristic fingering structure shown in Fig. 6*c*. Thus this model seems to represent both qualitatively and quantitatively the viscous fingering phenomenon for the case of miscible fluids (zero interfacial tension).

We thank G. Daccord, R. Lenormand and J. D. Chen for sharing their experimental results with us before publication, and we also thank them and F. Rondelez for helpful discussions. We thank David Kamins for generous and patient assistance with colour computer graphics, and the Boston University Academic Computer Center for generous computer time on the mainframe IBM-3090 computer.

When a chimaeric soybean leghaemoglobin gene was introduced into the genome of another legume species, Lotus corniculatus, *nodule-specific expression of the chimaeric gene was found in root nodules formed on fully regenerated plants inoculated with the* Lotus *microsymbiont,* Rhizobium loti. *Expression under control of the 5′ upstream region of the soybean gene was regulated at the level of RNA and followed the correct developmental timing. This indicates a conserved induction mechanism for leghaemoglobin genes in legumes.*

THE symbiotic association between soil bacteria of the genus *Rhizobium* and plants of the family Leguminosae results in the formation of a unique specialized plant organ—the root nodule. Fixation of atmospheric dinitrogen by the bacterial nitrogenase enzyme within this organ enables the plant to grow without external supply of reduced nitrogen. The interaction between the symbionts is generally very specific and has been used to subdivide the bacterial genus into species and the legumes into cross-inoculation groups[1]. *Bradyrhizobium japonicum* will thus infect soybean while *Rhizobium loti* infects *Lotus corniculatus.* Normal root nodule formation occurs only after invasion of the plant root by the compatible bacteria. Successful invasion initiates a series of developmental events in the plant. Root cortex cells re-differentiate into meristematic cells that proliferate and differentiate to form the organized tissues[2]. Around 30 different plant encoded-polypeptides ('nodulins') are specifically synthesized or present in higher concentration during this development[3,4]. Biochemical function has been assigned to genes encoding glutamine synthetase[5], uricase[6,7] and leghaemoglobin polypeptides[8].

Four leghaemoglobin proteins, Lbc_3, Lbc_2, Lbc_1 and Lba, are synthesized in soybean nodules[8]. The corresponding genes together with a pseudogene and a truncated gene are organized in two clusters with intergenic regions of some 2 kilobases (kb) separating the individual genes[9,10]. Induction of the four active *lb* genes occurs in a sequential manner during nodule development. Transcription of the lbc_3, lbc_2 and lbc_1 genes starts slightly before the appearance of visible nodules while transcription of the *lba* gene is delayed for another day or two[11]. Later in development, transcription of the *lba*, lbc_3, lbc_1 genes is drastically increased at the same time as several other nodulin genes are activated, indicating common features in the regulation of nodule-specific genes[11]. Typical eukaryotic promoter sequences homologous to sequences required for optimal transcription of a mammalian β-globin gene are located 5′ to each of the coding sequences of the four active genes[12,13], but β-globin gene expression is also dependent on downstream sequences[14]. In order to analyse the role of 5′ upstream and 3′ downstream sequences in the specific regulation of leghaemoglobin genes, we have transferred a chimaeric gene (*lbc_3 5′3′-cat*) with the composition 5′ lbc_3-chloramphenicol acetyltransferase (CAT) coding sequence-3′ lbc_3 to a heterologous legume species, *Lotus corniculatus* (bird's-foot trefoil), using the Ri plasmid of *Agrobacterium rhizogenes* as gene vector.

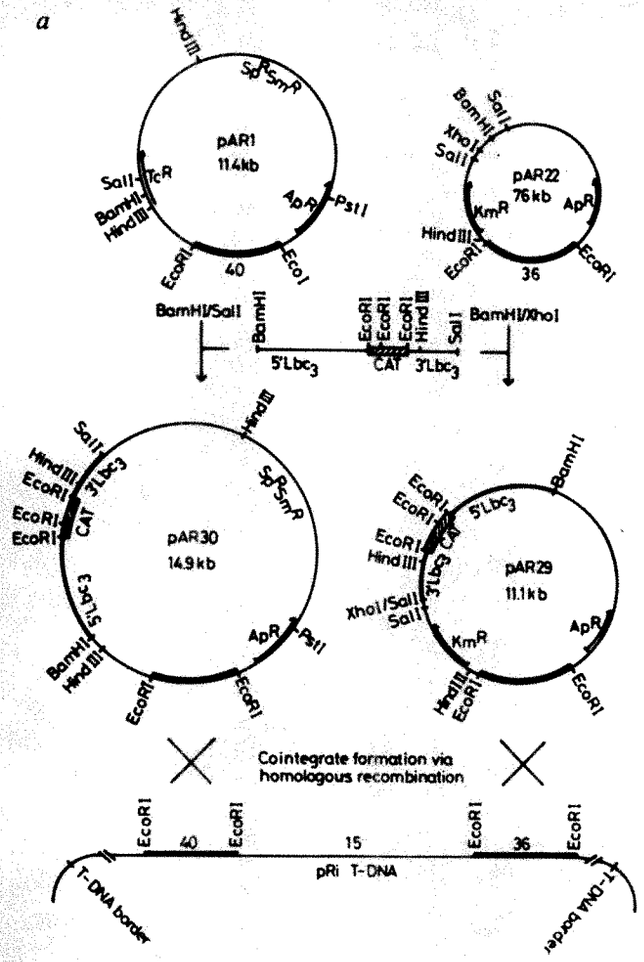
Here we describe the nodule-specific expression of the chimaeric soybean *lbc_3 5′3′-cat* gene in root nodules formed on fully regenerated plants of a member of the legume family. We further show that the expression is regulated at the level of RNA and that the correct transcription initiation signals are used. Finally it is shown that the chimaeric gene is activated at the correct stage of nodule development.

Transformation system

The minimal requirement for the study of the expression of transferred genes in root nodules is a legume transformation and regeneration system that allows transformed cells to differentiate into roots. Such a system was developed using the capacity of *Agrobacterium rhizogenes* to induce root formation in transformed plant cells. For this particular study an approach leading to the integration of a complete 'intermediate cloning vector'[15] carrying the chimaeric gene in the T-DNA region of the Ri plasmid was chosen. Figure 1*a* shows the two intermediate vectors, pAR29 and pAR30, used to integrate the chimaeric *lbc_3 5′3′-cat* gene into *A. rhizogenes* T-DNA. Homologous recombination through the pRi *Eco*RI fragments 36 and 40 was obtained after conjugation[16] of the two 'intermediate vectors' from *Escherichia coli* to the *A. rhizogenes* 15834 strain[17]. Transconjugants underwent Southern blot analysis to demonstrate the presence of the chimaeric gene and of co-integrate formation through the homologous T-DNA sequences (data not shown). Roots formed after wound site infection of *L. corniculatus* seedlings were cultured *in vitro* and freed from the infecting bacteria by treatment with antibiotics (500 μg ml^{-1} Claforan). Whole plants were regenerated from root cultures through somatic embryogenesis or organogenesis[18]. The structure of the co-integrate T-DNA region transferred to *L. corniculatus* lines L6-23 and L5-9, as deduced from recombinant constructions and confirmed by Southern blot analysis, is given in Fig. 1*b*. Figure 2 demonstrates the presence of the *lbc_3 5′3′- cat* gene in the L6-23 line.

The number of T-DNA inserts in the two plant lines were estimated from the number of *Eco*RI or *Hin*dIII restriction fragments hybridizing to the left T_L-DNA border in genomic DNA Southern blot analysis. An *A. rhizogenes* T_L-DNA-derived probe shown below Fig. 2 was used to recognize the various restriction fragments generated after insertion of the T_L-DNA into the plant genome. Two T-DNA inserts were found in L6-23 while only one insert was present in the L5-9 line. These values reflect the minimum copy numbers for the *lbc_3 5′3′-cat* gene. Regenerated plants were transferred to growth cabinets and

* Present address: Department of Molecular Plant Pathology, Université Louis Pasteur, 67083 Strasbourg, France.



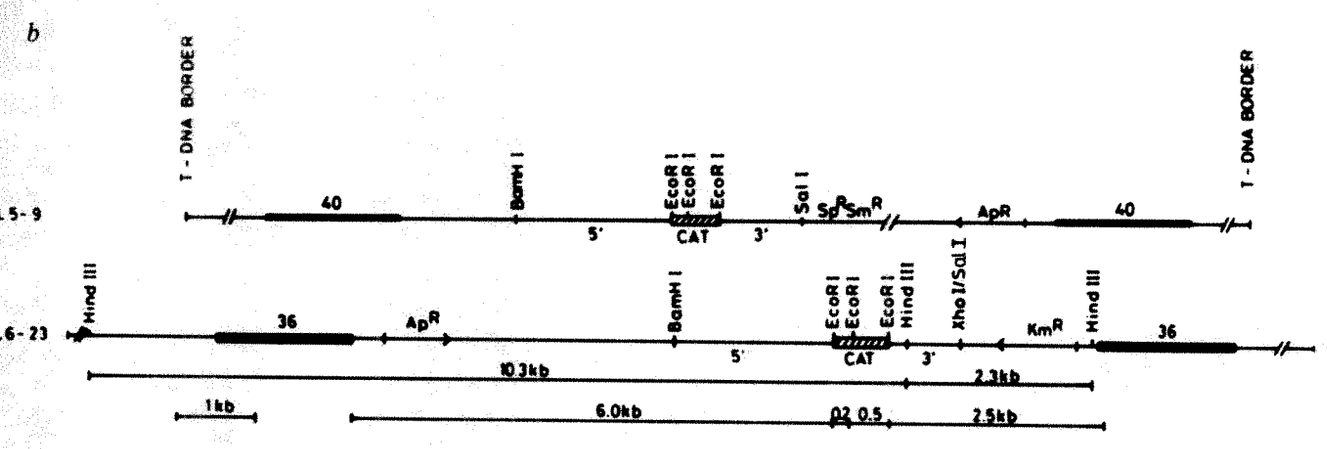


Fig. 1 *a*, Integration of the chimaeric *lbc*$_3$ *5'3'-cat* gene into the *A. rhizogenes* T_L-DNA region. *b*, Structure of the T_L region after integration of the chimaeric *lbc*$_3$ *5'3'-cat* gene.
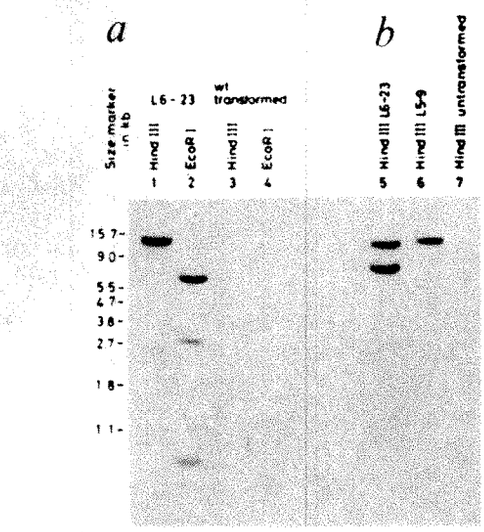
Methods. *a*, Two *Eco*RI fragments (36 and 40) from the T_L (T-left) T-DNA region of the agropine pRi plasmid 15834 were chosen as integration 'sites'. The ColE1 replicons pAR1, pAR22 J.S.J. unpublished) carrying the corresponding subcloned *Eco*RI fragments were therefore used as 'intermediate cloning vectors'[15] for the *lbc*$_3$ 5'3'-*cat* 3.6-kb *Bam*HI/*Sal*I fragment[37]. The resulting plasmids pAR29, pAR30 were then separately conjugated to a rifampicin-resistant (rif^R) *A. rhizogenes* 15834 using a plasmid helper system[16]. Transconjugants carrying co-integrates were selected on LB medium containing rifampicin (100 μg ml^{-1}) plus spectinomycin (100 μg ml^{-1}) plus streptomycin (100 μg ml^{-1}) or kanamycin (300 μg ml^{-1}). ColE1 plasmids are unable to replicate in *Agrobacterium*. Selection for plasmid resistance markers will therefore select co-integrates formed after homologous recombination through the region offered. The chimaeric *lbc*$_3$-*cat* gene consists of a 2-kb *lbc*$_3$ promoter region terminating 7 bp upstream of the *lbc*$_3$ initiator codon, CAT coding sequence including 5-bp 5' and 31-bp 3' untranslated sequence and 0.9 kb of the *lbc*$_3$ 3' flanking region starting 3 bp after the *lbc*$_3$ stop codon. See ref. 37 for further details. *b*, The presence and orientation of the chimaeric gene within the pRi T-DNA was determined by Southern analysis of total DNA from *A. rhizogenes* co-integrate strains. Integrity of the inserted plasmids and the position of generated restriction sites within the T-DNA was also confirmed. The figure shows the deduced structure of T_L-DNA transferred to the transformed *L. corniculatus* lines L6-23 and L5-9. See *a* for restriction sites not indicated. The lines below the L6-23 structure indicate the fragments generated after *Hin*dIII and *Eco*RI digestion of DNA from transformed plant lines. The same fragments are shown in Fig. 2. Subcloning and plasmid preparation were according to Marcker *et al.*[11]. The procedure of Van Haute *et al.*[16] was used for conjugational transfer of plasmids. Total DNA was extracted and analysed according to Dhaese *et al.*[44].



inoculated with the *Rhizobium loti* strain NZP2037[19]. Nodules for analysis were harvested 3–6 weeks later.

Nodule-specific expression

Chloramphenicol acetyltransferase activity was measured in 3–6-week-old nodules excised from the roots of L6-23 and L5-9 transformed *Lotus* lines. Root tissue as well as leaf plus stem fragments derived from the same transformed plant were also extracted and CAT activity measured. Conversion of ^{14}C-chloramphenicol to the acetylated forms followed by thin layer chromatographic separation was used to assay CAT activity. Data from *Lotus* lines L6-23 and L5-9 are presented in Fig. 3, together with data from untransformed *Lotus* plants and from a line transformed with the complete *lbc*$_3$ gene. No CAT activity could be detected in any tissue from untransformed or *lbc*$_3$-transformed plants. High enzymatic activity was, however, expressed from the chimaeric *lbc*$_3$ *5'3'-cat* gene in root nodules of the L6-23 line. Neither root nor leaf plus stem tissue from this same line contained any CAT activity. The *lbc*$_3$ *5'3'-cat* gene is therefore expressed in an organ-specific manner. Similar results were obtained with the L5-9-transformed line. A remarkable result is the lack of expression in any of the other major tissues tested. Even prolonged exposure of the autoradiogram did not reveal any CAT activity in transformed leaf stem or root tissues. The CAT assay conditions used would have detected an activity 5,000 times lower than the activity observed in root nodules.

Expression regulated at RNA level

The nodule-specific expression of CAT from the soybean *lbc*$_3$ *5'3'-cat* gene may be the result of transcriptional, translational or post-translational control. In order to distinguish among these

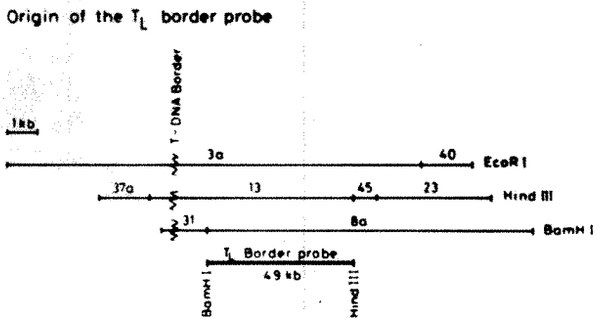


Fig. 2 *a*, Southern hybridization analysis of the transformed *L. corniculatus* line L6-23. Lanes 1 and 2 contain ~10 μg *Hin*dIII or *Eco*RI-digested DNA from leaves of L6-23 plants. Lanes 3 and 4 contain corresponding digests of DNA from *L. corniculatus* plants transformed with the *A. rhizogenes* wild-type strain. The size of the fragments hybridizing to a *lbc*$_3$ *5'3'-cat* probe are indicated below the diagram of the co-integrate structure in Fig. 1*b*. *b*, Estimation of copy number of the *lbc*$_3$ *5'3'-cat* gene in L6-23 and L5-9 *Lotus* lines. A *Bam*HI/*Hin*dIII fragment adjacent to the left T_L border was used in Southern hybridization to visualize the *Eco*RI and *Hin*dIII fragments generated after insertion of the T_L-DNA into the plant genome. The restriction map[45] below shows the exact position of the *Bam*HI/*Hin*dIII restriction fragment used as probe and give the size of *Eco*RI, *Hin*dIII restriction fragments hybridizing to this probe within the pRi plasmid itself. Lanes 5–7 contain *Hin*dIII digests of L6-23, L5-9, and untransformed *Lotus* plants, respectively. Copy numbers were estimated by counting the hybridizing bands. Total plant DNA was extracted and digested according to Dellaporta *et al.*[46].

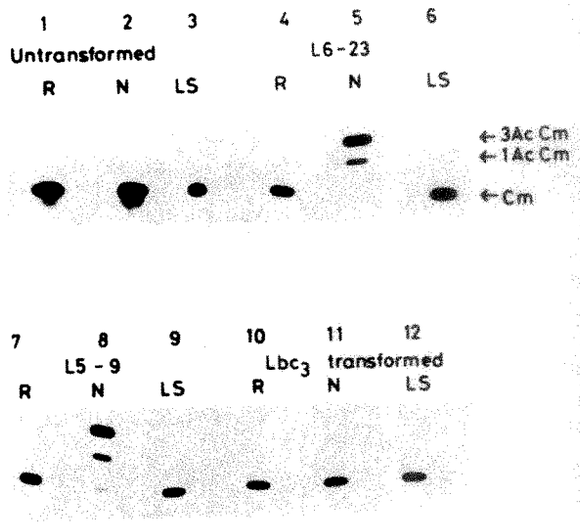

Fig. 3 Expression of the chimaeric *lbc*$_3$ *5'3'-cat* gene in various tissues from transformed and untransformed *Lotus* plants. Equal amounts of tissues were homogenized in a mortar and CAT activity measured by conversion of ^{14}C-chloramphenicol (Cm) to acetylated (Ac Cm) derivatives. Lanes 1–3 demonstrate the lack of CAT activity in root (R), nodule (N), and leaf + stem (LS) tissue of untransformed plants. Lanes 4–6 and 7–9 show the CAT activity in corresponding tissues of the L6-23, L5-9 *lbc*$_3$ *5'3'-cat* transformed lines. Conversion of chloramphenicol in lanes 5 and 8 demonstrate the organ-specific expression of the chimaeric gene in root nodules. Lanes 10–12 show the assays of *lbc*$_3$ transformed control tissues. Reconstruction experiments showed that CAT enzyme from root nodule extracts are stable when mixed with root and leaf plus stem extracts (data not shown).

Methods. Tissue was homogenized with mortar and pestle in 50 mM Tris *p*H 7.5 1 mM EDTA, 400 mM NaCl, 2 mM phenylmethylsulphonyl fluoride buffer (1:1 w/v) at 0 °C. The crude extract (50 μl) was diluted 10-fold into reaction mixture (450 μl) containing 200 mM Tris *p*H 7.5, 0.5 mM acetyl coenzyme A and 0.5 μCi ^{14}C-chloramphenicol and incubated for 1 h at 37 °C. Samples were extracted with 5 ml ethyl acetate and analysed by thin layer chromatography using chloroform/methanol (95:5). The chromatograms were autoradiographed and CAT activities quantitated by counting corresponding regions by liquid scintillation. Standard assays contained 100 μg protein.

possibilities total RNA was extracted from nodule, root and leaf plus stem tissues from L6-23, L5-9 and *lbc*$_3$ transformed control plants. The RNA was separated on agarose gels, transferred to nitrocellulose and hybridized with a probe from the CAT coding sequence. A strong hybridization signal was detected with L6-23 and L5-9 nodule RNA while none of the RNA preparations from any other tissue tested showed hybridization (Fig. 4*a*). Expression of the *lbc*$_3$ *5'3-cat* gene is therefore clearly controlled at the level of RNA. The gene for ubiquitin, a histone-associated protein, is constitutively expressed in a range of eukaryotes including plants[20,21]. Hybridization of a heterologous ubiquitin cDNA to the various RNA preparations was therefore used as an internal standard. Figure 4*b* shows the constitutive expression of endogenous *Lotus* ubiquitin genes in the tissues tested.

Lotus corniculatus plants contain endogenous leghaemoglobin genes, and cross-hybridization with soybean leghaemoglobin sequences was detected in Southern blot DNA hybridizations (data not shown). A hybridization signal was also detected in Northern blots. Figure 4*c* shows the signal obtained with a full-length cDNA probe for the soybean *lba* gene. The steady-state level of transcripts from the chimaeric *lbc*$_3$ *5'3'-cat* gene is more than 200-fold higher than the lowest level detectable with the Northern hybridization technique used here.

The size of the CAT hybridizing transcript is approximately 900 nucleotides, which corresponds well with the 860 nucleotides between the *lbc*$_3$ cap site and the *lbc*$_3$ polyadenylation site on the chimaeric gene. The endogenous soybean *lbc*$_3$ has a cap site 51 nucleotides upstream of the ATG codon[22] (position +1). To test whether the heterologous host *L. corniculatus* recognizes and faithfully utilizes the 5' soybean *lbc*$_3$ promoter, the transcription initiation point of the CAT transcript from L6-23 nodules was determined. Total nodule RNA was subjected to oligo(dT) chromatography and subsequently used in a primer extension assay. An oligonucleotide primer (5'CAACGGTGGTATATCCAGTG3') complementary to nucleotides 15–34 in the CAT coding sequence was used. Figure 5 shows the resulting 85, 86, 87, 88 and 90 nucleotide long cDNA species generated. These sizes correspond well with the distance between the cap site (+1) and the 5' end (+83) of the primer. The cDNA species of 85, 87 and 88 nucleotides correspond exactly to endogenous

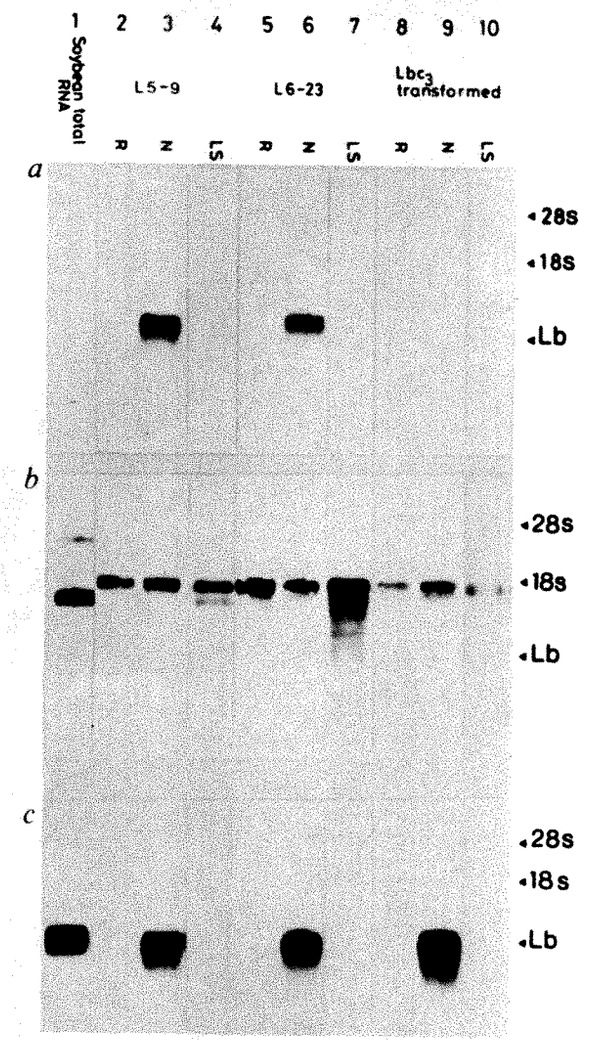

Fig. 4 Northern analysis of transcripts from tissues of *lbc*$_3$ *5'3-cat* transformed and *lbc*$_3$ transformed *Lotus* lines. Five μg of total RNA extracted from root (R), nodule (N) or leaf+stem (LS) tissue was separated in formaldehyde-containing agarose gels and blotted onto nitrocellulose (Gene Screen). Lane 1 contains total RNA from 20-day-old soybean nodules. Lanes 2–4 total RNA from roots, nodules or leaf+stem of the *lbc*$_3$ *5'3'-cat*-transformed L5-9 line. Lanes 5–7 contain total RNA from root nodules, roots or leaf+stem of the L6-23 line while lanes 8, 9 and 10 contain RNA from an *lbc3* transformed line. The complete CAT coding sequence was used as a probe in *a* and demonstrates the presence of the *lbc*$_3$ *5'3'-cat* transcript in L5-9 and L6-23 nodules. In *b* the transcript for the constitutive ubiquitin genes is visualized using a cDNA probe for the human ubiquitin gene[20]. Nodule-specific expression of the endogenous *Lotus lb* genes is shown in *c*. A cDNA probe for the *lba* gene was used in this hybridization. Total RNA was extracted and analysed according to Marcker *et al.*[11] except for leaf+stem RNA which was extracted in 100 mM Tris *p*H 8, 50 mM EDTA, 500 mM NaCl, 5% β-mercaptoethanol, 1.4% sarkosyl at 65 °C for 15 min.

soybean *lbc*$_3$ cap sites determined by S_1 mapping at lower exonuclease concentrations[22].

Developmental regulation

Vertebrate β-globin genes are regulated by a gene-switching mechanism that ensures transcription of only one gene in embryogenic, fetal and adult tissue[23]. The four active leghaemoglobin genes (*lba*, *lbc*$_3$, *lbc*$_2$, *lbc*$_1$) are also induced at different stages of nodule formation, but all four genes remain active throughout the lifetime of the nodule. The *lbc*$_3$, *lbc*$_2$ and *lbc*$_1$ are expressed at a low level immediately before the nodule turns pink. At this developmental stage there is a strong and abrupt increase in transcription of the *lbc*$_3$, *lbc*$_1$ and *lba* genes. A number of 'nodulin' genes are induced at this stage while the bacterial nitrogenase genes are induced even later[11]. CAT activity from the chimaeric *lbc*$_3$ *5'3'-cat* gene in L6-23 was therefore followed throughout nodule development. Figure 6 shows the induction kinetics of the chimaeric gene relative to nodule development and nitrogenase activity. The lack of CAT activity in small white nodules (panel 2 in Fig. 6), the low level of activity in white nodules (panel 3) and the strong increase in activity in pink nodules with high nitrogenase activity follow the kinetics of the native *lbc*$_3$ gene. Correct developmental regulation of the *lbc*$_3$ promoter is thus maintained in the *L. corniculatus* transformants.

Discussion

Agrobacterium Ti plasmids have been used as gene vectors for plant transformation by a number of investigators. Protoplasts[24], leaf disks[25], callus[26] and wounded plants[27] have been infected and transformed tissue was recovered by screening or selection[28]. The transferred genes are functionally expressed and expression in complete regenerated plants has so far been achieved in tobacco[29–34], petunia[31,34–36] and tomato plants[25]. Chimaeric genes consisting of the T-DNA-derived nopaline synthase promoter and coding sequences specifying resistance to chloramphenicol, kanamycin and methotrexate respectively were initially used for transfer and expression in model studies[29,32]. More recently, chimaeric genes derived from genes encoding the chlorophyll *a*/*b* binding protein[33,36] were transferred, organ-specifically expressed and shown to maintain their photoregulation upon transfer.

The transferred *lbc*$_3$ *5'3'-cat* gene is specifically expressed in root nodules of the heterologous *L. corniculatus* host and is regulated at the level of RNA. We therefore infer that the DNA sequences responsible for the nodule-specific expression of the *lbc*$_3$ gene are located on the 2-kb 5'-flanking or 0.9-kb 3'-flanking region of the chimaeric *lbc*$_3$ *5'3'-cat* gene and that interactions at these sequences control the activity of the *lb* promoter. The most reasonable explanation of our results is that the regulation

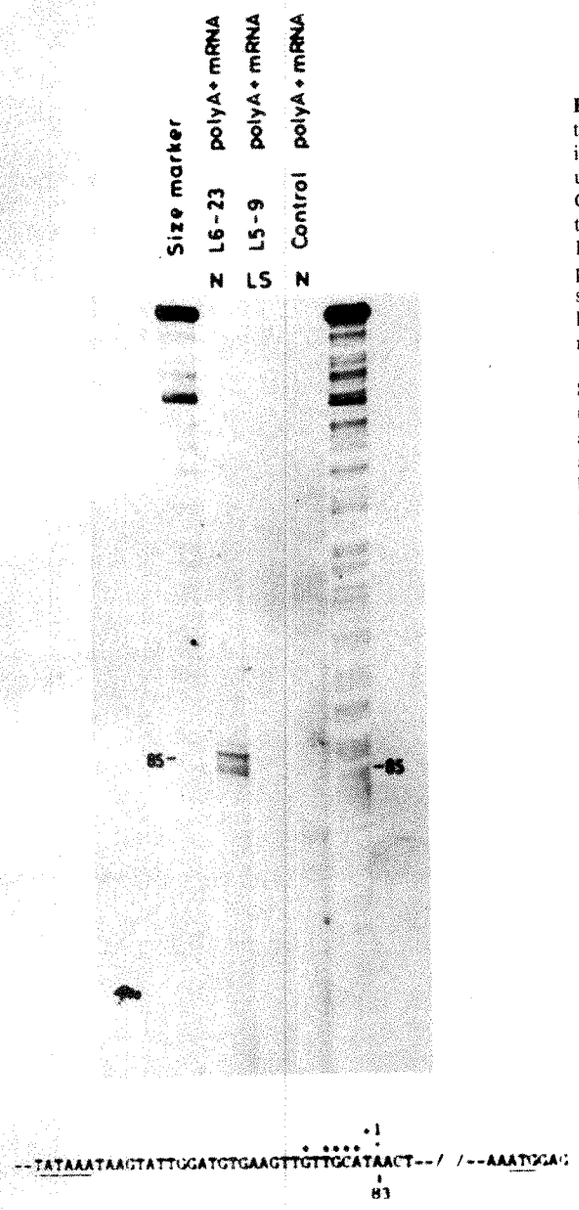

Fig. 5 (Left) Determination of the transcription initiation site for the lbc_3 *5'3'-cat* gene in *L. corniculatus* root nodules. Total RNA isolated from nodules or leaf+stem was oligo(dT) purified and used in a primer extension assay. A synthetic oligonucleotide 5' CAACGGTGGTATATCCAGTG 3' complementary to nucleotides 15 to 34 of the CAT coding sequence was used as primer. Lane 2 shows the cDNA species resulting from extension of the primer on the CAT transcript present in L6-23 nodules. Lane 3 shows the negative control using leaf+stem mRNA from the L5-9 line and lane 4 the negative control with mRNA from untransformed nodules. No other specific cDNA species were detected. Lanes 1 and 5 show the sequence ladder used to size the cDNA. A cDNA 83 nucleotides long would be expected if the soybean cap site at (+1) was used. The cap sites corresponding to the 85, 86, 87, 89 and 90 nucleotide long cDNA species generated are indicated with asterisks on the partial sequence of the lbc_3 *5'3'-cat* 5' region given below. The translation initiation codon of the CAT coding sequence and the TATA box of the lbc_3 promoter are underlined. The primer was end labelled with ^{32}P using polynucleotide kinase and the extension assay was according to Boel *et al.*[47].

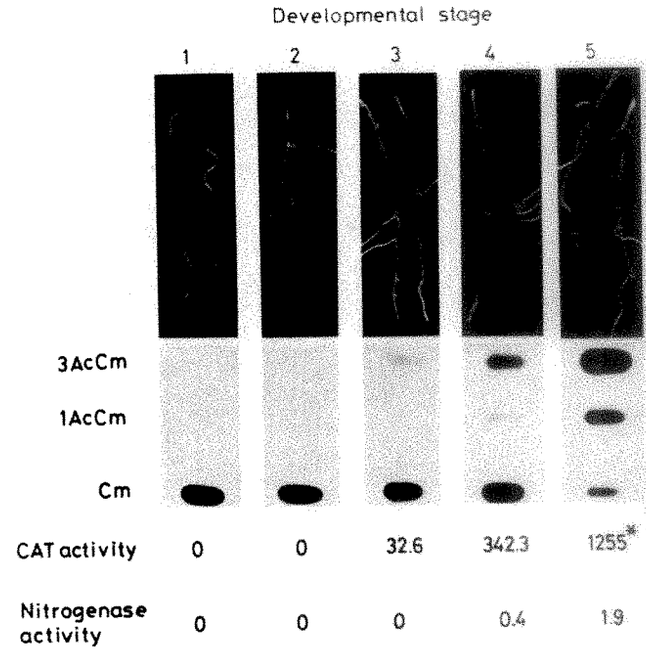

Fig. 6 (Above) Comparison of the lbc_3 *5'3'-cat* gene expression in developing root nodules. CAT and nitrogenase activity were measured on root pieces with nodules in different developmental stages. Stage one shown in panel 1: no visible nodules. Stage 2, panel 2: emerging nodules. Stage 3, panel 3: distinct white nodules. Stage 4, panel 4: small pink nodules. Panel 5 shows nodules in various later states of maturity. The CAT activities and nitrogenase activities follow the developmental control of *lb* gene expression in soybean root nodules. *, This enzymatic activity is only valid for the substrate-limited reaction shown.

Methods. 400 mg root tissue carrying appropriate nodules was analysed for each developmental state. CAT activity was determined in half of this material according to the previously given procedure. The other half was used to measure acetylene reduction capacity of the nodules. Roots and nodules were incubated for 1 h with an atmosphere of 10% acetylene in Suba Seal-stopped 7 ml Bijoux bottles. Ethylene was measured on a gas chromatograph and nitrogenase activity determined as nmol ethylene per μg protein per h. CAT activity is in c.p.m. per μg protein per h.

of the *lb* promoter is exerted on the initiation of transcription, but other models for regulating the level of RNA cannot entirely be ruled out.

Haem, the prosthetic group in globin proteins, controls the efficiency of lbc_3 *5'3'-cat* mRNA translation in yeast[37]. A similar translational control of leghaemoglobin gene expression might therefore also exist in root nodules, but this has not been investigated here.

Sequences required for expression of photoregulated genes are present in 5' flanking regions[33,36,38–40]. A short 33-base-pair (bp) sequence located between the TATA box and the transcription start site is sufficient to confer light induction on the ribulose 1,5-biphosphate carboxylase *rbcS-E9* gene[39] while the *rbcSss3.6* gene has light-responsive and enhancer-type regulatory sequences upstream of the TATA box[41]. Organ specificity and light-induction control regions are both located on a short DNA fragment derived from the pea chlorophyll *a*/*b* binding protein gene[33]. The available evidence, therefore, suggests that DNA sequences controlling organ specificity are closely linked to the promoter. We therefore expect that the regulatory sequences involved in nodule-specific expression are located on the lbc_3 5' flanking region. The correct initiation of transcription and organ-

specific expression of the lbc_3 promoter in the distantly related legume *L. corniculatus* has further implications concerning the control of nodule expressed genes. *Lotus corniculatus* belongs phylogenetically to the tribe Loteae while soybean belongs to the Phaseoleae[42]. The microsymbiont *Rhizobium loti* is a species separate from the soybean symbiont *B. japonicum*[1] and nodulates plants from a different cross-inoculation group. It appears therefore that both a putative bacterial induction signal and DNA sequences involved in nodule-specific expression of plant 'nodulin' genes are conserved in the legume *Rhizobium* symbiosis. Efficient nodulation of different plant species by broad host range isolates of *Rhizobium* and the wide susceptibility of certain host plants, support this idea[1,43].

We thank Dr A. Petit and Professor J. Tempé, Orsay, for introducing us to the *Lotus* system, and A. Kühle and D. Abildsten for technical assistance. We have developed a method for the partial automation of DNA sequence analysis. Fluorescence detection of the DNA fragments is accomplished by means of a fluorophore covalently attached to the oligonucleotide primer used in enzymatic DNA sequence analysis. A different coloured fluorophore is used for each of the reactions specific for the bases A, C, G and T. The reaction mixtures are combined and co-electrophoresed down a single polyacrylamide gel tube, the separated fluorescent bands of DNA are detected near the bottom of the tube, and the sequence information is acquired directly by computer.

THE structural analysis of DNA has an increasingly important role in modern molecular biology. About 4×10^6 bases of DNA have been sequenced since the introduction of the enzymatic method of rapid sequencing developed by Sanger and co-workers[1,2] and the chemical method developed by Maxam and Gilbert[3]. Typically, four separate reactions are performed on the particular DNA segment to be analysed. In the enzymatic method, these reactions produce DNA fragments terminating in either adenosine (A), cytosine (C), guanosine (G) or thymidine (T). In the chemical method fragments terminating in G, G+A, C+T, or C are typically produced. In both cases the four sets of reaction products are electrophoresed in adjacent lanes of a high-resolution polyacrylamide gel. An autoradiographic image of the gel is produced which can be examined to determine the relative lengths of the DNA fragments generated in each of the four reactions. The DNA sequence is inferred directly from this information. Both these techniques are highly effective but are also very labour-intensive, fairly expensive and involve the use of radioisotopes. For these reasons, and because many genes remain to be sequenced (there are 3×10^9 bases in the human genome alone), we have undertaken the development of an automated and non-isotopic method of DNA sequence analysis.

Strategy

Our approach has two major aims. The first is to acquire, store and analyse sequence information directly by computer. Doing this in real-time during the gel electrophoresis eliminates the

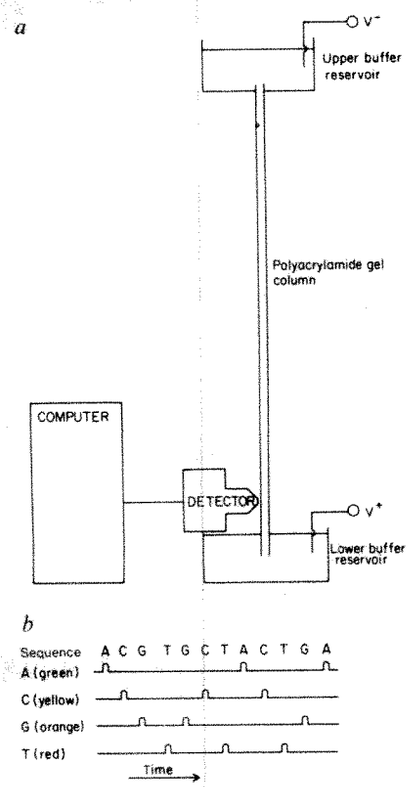

Fig. 1 *a*, Simplified diagram of the automated DNA sequenator. *b*, Idealized output from the automated DNA sequenator.

transfer of information from gel to film (autoradiography), the tedious manual analysis and the need to run several overlapping gels; instead, a single gel can be run for as long as resolvable sequence is obtained. The second aim is to avoid the use of radioisotopes, which are hazardous, costly and unstable.

With these considerations in mind, we have developed a strategy for the automated sequence analysis of DNA which is based on two key points (proposed initially in ref. 4). First, fluorophores are used for detection rather than radioisotopes. Fluorescence provides sufficient sensitivity for real-time optical detection of the small amounts of DNA present in DNA sequencing gels ($\sim 10^{-15}$ mol per band) (see the discussion below). Second, four different fluorophores are used, one for each of the base-specific reactions. The reaction products are combined and co-electrophoresed, and the DNA fragments generated in each reaction are detected near the bottom of the gel and identified by their colour. These fluorescence data are continuously acquired and stored by computer during the electrophoresis. The data may then be analysed by computer to yield the DNA sequence. An idealized version of this process is depicted in Fig. 1.

We applied this strategy to Sanger's enzymatic method of DNA sequence analysis. We use chemically synthesized fluorescent oligonucleotide primers to label the DNA fragments. When these fluorescent primers are used instead of the usual underivatized primer in the enzymatic sequencing reactions, the DNA fragments generated in the reactions are fluorescent.

Chemistry

The first step in implementing this strategy was to develop chemistry for the synthesis of the fluorescent oligonucleotide primers[4,5]. Briefly, we synthesized a derivative of thymidine which contains a phosphoramidite moiety at the 3′ carbon and a protected amino group at the 5′ carbon. When this molecule is used in the final addition cycle of oligonucleotide synthesis by the phosphoramidite method (see ref. 6 for review), the product after deprotection and cleavage from the solid phase is an oligonucleotide containing a single aliphatic amino group

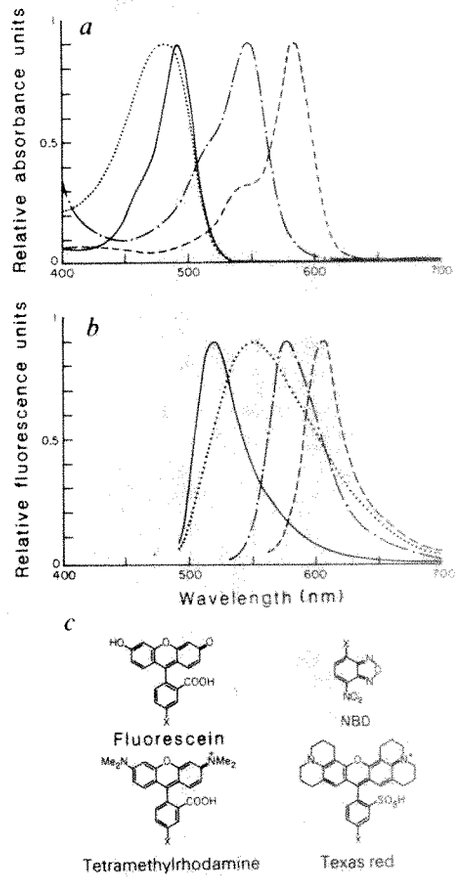

Fig. 2 *a*, Absorption spectra of the four dyes used in the DNA sequenator: ——, fluorescein; ·····, NBD; -·-·-, tetramethylrhodamine; - - - -, Texas Red. *b*, Florescence emission spectra of the four dyes; the same line types as in *a*, are used to denote the dyes. *c*, Chemical structures of the four dyes. X, The moiety to which the dye is bound, for example, an oligonucleotide primer. **Methods.** All spectra were obtained in 10 mM sodium carbonate buffer, *p*H 9.0; absorption spectra were taken on an H/P 8451 spectrophotometer; fluorescence spectra were taken on a Perkin-Elmer MPF4 spectrofluorimeter (uncorrected). The following dye derivatives were used for measurements: fluorescein isothiocyanate (FITC), NBD aminohexanoic acid, Texas Red (all from Molecular Probes, Junction City, Oregon); and tetramethylrhodamine isothiocyanate (Research Organics, Inc., Cleveland, Ohio).

at the 5′ terminus. This material may then be conjugated readily to any of various commercially available amino-reactive fluorescent dyes to yield the corresponding oligonucleotide derivative.

The selection of a set of four fluorophores was central to development of the DNA sequenator. Several criteria were used in the selection of these fluorophores. (1) The absorption and emission maxima had to be in the visible region of the spectrum, as far to the red end as possible, to minimize scattering and fluorescence background. (2) To be able to distinguish between the dyes effectively, their emission maxima had to be well resolved from one another. (3) The dyes had to be highly fluorescent to provide sufficient detection sensitivity. (4) The dyes should not significantly impair the hybridization of the oligonucleotide primer, as this would also decrease the efficiency of synthesis in the sequencing reactions. Finally, the electrophoretic mobility of the DNA fragments should not be distorted unacceptably by the presence of the dyes. The chemical structures and absorption and emission spectra of the four dyes we have chosen are shown in Fig. 2. Their absorption and emission maxima range from 486 nm (4-chloro-7-nitrobenzo-2-oxa-1-diazole (NBD) absorption maximum) to 604 nm (Texas Red emission maximum), well within the visible region of the spectrum. The emission maxima are evenly spaced at 30-nm

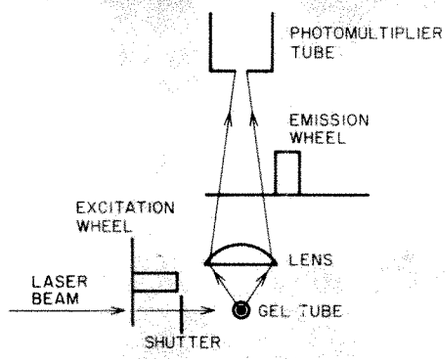

Fig. 3 Diagram of the optical configuration used for within-gel detection of fluorescence at four different wavelengths.

intervals, allowing reasonably good spectral discrimination. All the dyes have good fluorescence sensitivity, and are widely used and readily available. Conjugates of these dyes and an oligonucleotide primer (with the sequence 5′ CCCAGTCACGACGTT 3′, used in the single-stranded M13 phage vectors) were prepared and tested in conventional sequencing reactions using radioisotope detection (see ref. 4 for details). All the dye–primer conjugates were effective in the DNA sequencing reactions. The dyes do, however, affect the electrophoretic mobility of the DNA fragments to which they are bound; this necessitates a mobility correction to the sequence data which is discussed in the section on data analysis. The suitability of these primers in fluorescence-based detection was tested in instrumentation constructed for that purpose, as described below.

Instrumentation

The primary consideration in the design of the fluorescence detection apparatus was sensitivity. We performed preliminary experiments using radiolabelled nucleoside triphosphates of known specific activity to measure the amount of DNA present in a single band of a conventional sequencing gel, and obtained values of the order of 10^{-15}–10^{-16} mol DNA per band. If the DNA is assumed to occupy a volume of 1 mm^3, the DNA concentration is 10^{-9}–10^{-10} M. Therefore, the instrument had to be capable of detecting dye concentrations of that order. This level of detection is readily achieved in commercial spectrofluorimeter systems. However, detection directly within the gel leads to much higher background scatter from the gel and from the circular glass tubing than is normally encountered, leading to decreased sensitivity. We therefore chose to use a laser excitation source in order to obtain maximum sensitivity, and have continued to use the laser source in subsequent work.

Figure 3 shows a schematic diagram of the optics used for detection of the fluorescent bands of DNA in the tube gel. The beam from an argon-ion laser (Lexel 65-0.1) operated in 'multiline' mode is passed through a 1-nm-bandpass interference filter (to select out either the 488-nm or 514-nm laser line for excitation) mounted on a circular 'excitation' wheel and directed into a gel tube (glass or quartz tubing of 1–2 mm internal diameter; typically a 50-cm-long 8% polyacrylamide/6 M urea gel with the laser beam at 40 cm from the top of the gel) suspended between two tanks containing electrophoresis buffer. A single, fast-collection lens (Melles Griot 01 LAG 013, F/0.7) is used to collect the emitted light and focus it through a 10-nm-bandpass filter (Corion S10-*x*-R series, where *x* denotes the bandpass wavelength in nanometres, chosen to match the emission maximum of the dye being used) mounted on a second circular emission wheel, and onto the aperture of a photomultiplier tube (Hamamatsu R928). The optics are mounted on an optical table (MST46 with NN4-28 legs; Newport Research Corporation) enclosed in a dark room which has been painted black, and appropriate baffling is used to prevent stray light from reaching the photomultiplier tube. Four interference filters are mounted at equally spaced intervals on each filter wheel, and a given excitation filter is always used in conjunction with a given emission filter. The filter pairs used are (in the order excitation filter, emission filter) 488, 520; 488, 550; 514, 580; 514, 610. The use of two different excitation wavelengths gives more efficient excitation of the different dyes (tetramethylrhodamine and Texas Red are excited more efficiently at 514 nm, whereas fluorescein and NBD are excited more efficiently at 488 nm) and thereby provides greater detection sensitivity. Neutral-density filters (Melles Griot BK-7 series) are also used in conjunction with the bandpass excitation filters to balance the baseline gel scatter levels obtained in each filter position. Light-emitting diodes and phototransistors are used to sense the position of the wheels. The excitation and emission wheels are accelerated and decelerated between the different filter positions using time intervals between pulses to the stepper motor that have been chosen to yield a constant acceleration. The movement of the wheel from one position to the next took 0.7 s, and the wheel was held stationary at each position for 0.8 s, giving a total time of 1.5 s between data points. A Uniblitz shutter (Vincent Associates) to protect the photomultiplier tube from excess scattered laser light was inserted into the laser beam and appropriate electronics were constructed to close the shutter if the photomultiplier tube (PMT) current exceeded a pre-set limit. Software was written to close the shutter, align both of the wheels into their starting positions, and then to re-open the shutter and commence data acquisition.

Typically, 8,000 points were taken for each of the four filter positions (total of 32,000 points) in a 13-h run; this rate of data acquisition gives 40 or more data points per DNA peak, under the electrophoretic conditions used. Filtering of the data to eliminate high-frequency noise was performed at three levels. First, an analog filter with a 100-ms time constant was used on the phototube output. Second, at each filter position, 200 data points were taken in succession and averaged, to yield a single point which was stored. At the 40-kHz rate of the Tecmar analog-to-digital converter, this required ~5 ms. Finally, the data were smoothed further with a low-pass Fourier filter included in the analysis (see below). Figure 4 shows a set of four-dye data obtained with this system. The raw data are shown in Fig. 4*a*; *b* and *c* show the same data after analysis. The procedures used in data analysis are described briefly below. These data demonstrate the practicality of this four-dye fluorescence approach for automated DNA sequence analysis.

Data analysis

If the raw data obtained with this instrument were as readily interpretable as the idealized data presented in Fig. 1*b*, very little data analysis would be required to determine the DNA sequence. In reality, however, several factors render the analysis of the data more complex. First, the emission spectra of the different dyes overlap substantially (see Fig. 2*b*); because of this, peaks corresponding to the presence of a single dye are seen in more than one channel. To discern the DNA sequence, one must therefore perform a multicomponent analysis to determine the different amounts of the four dyes present in the gel at any given time. The second major factor complicating the analysis is that the different dye molecules impart non-identical electrophoretic mobilities to the DNA fragments (see ref. 4). The fluorescein- and rhodamine-labelled DNA fragments move as if they were approximately one base longer than the NBD-labelled fragments, and the fragments labelled with Texas Red move as if they were approximately $1\frac{1}{4}$ bases longer. These mobility shifts must be compensated for. The third complicating factor in the analysis of the data comes from the imperfections of the enzymatic method of DNA sequence analysis itself. It is well known that the enzymatic method suffers from several anomalous traits, such as substantial variations in the intensity of bands in a given reaction, and occasional areas that prove difficult to sequence (thought to be associated with regions of

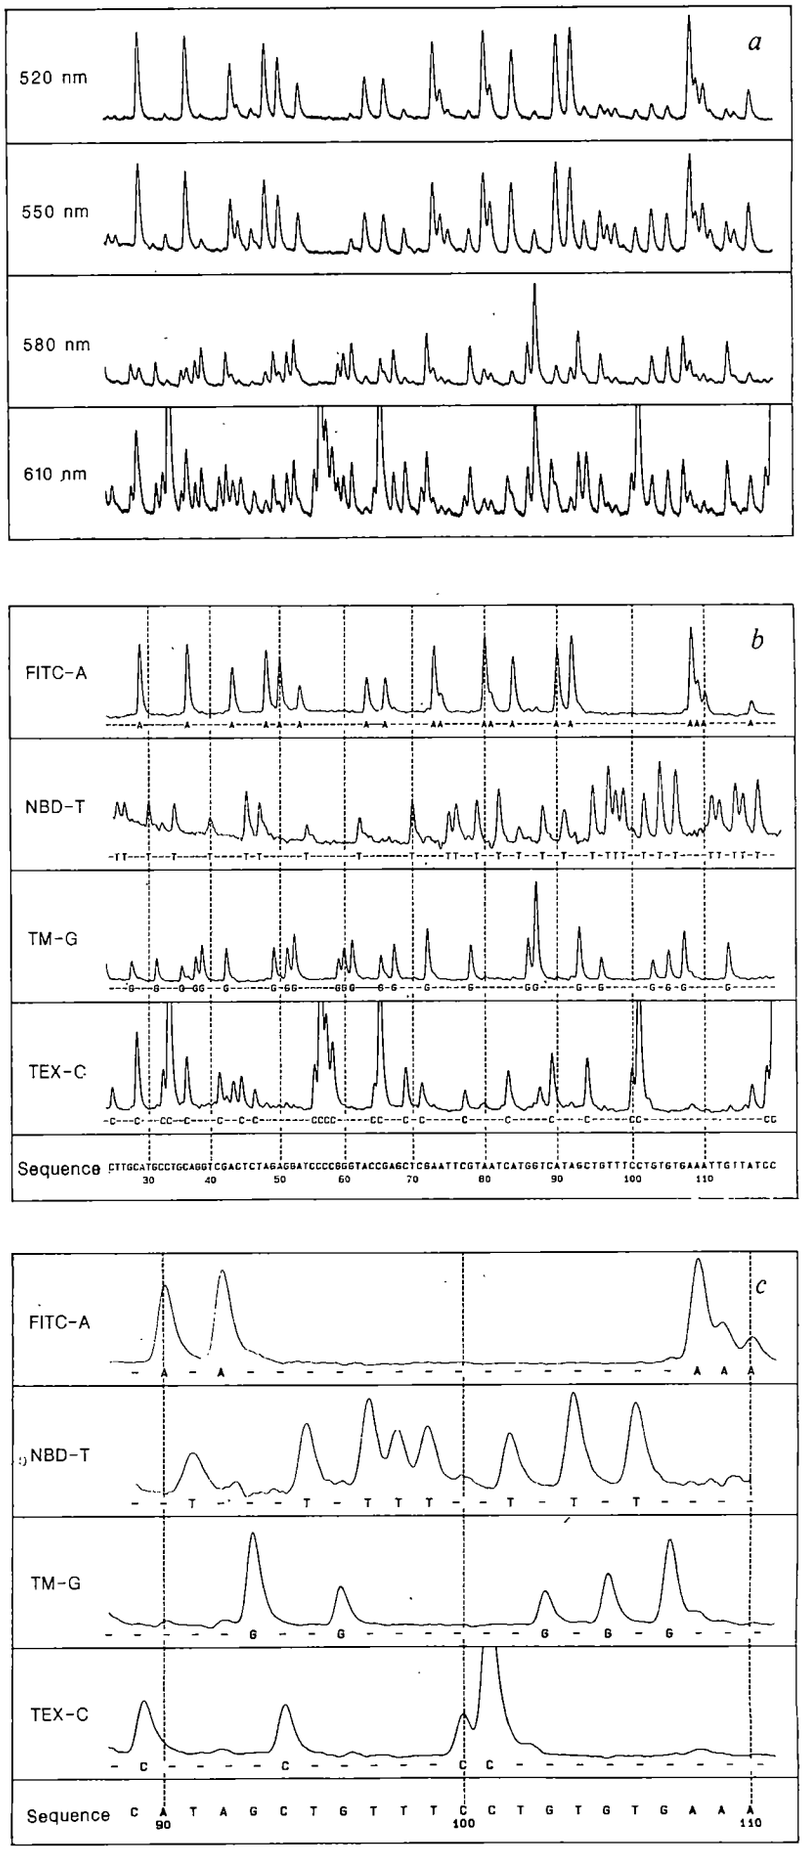

Fig. 4 Fluorescence data (*a*, raw; *b*, analysed) obtained from a mixture of four sequencing reactions. *c*, Expanded plot of 1,000 points of the analysed data. The mixture was applied to a single gel tube (quartz tubing with i.d. 1.3 mm; Heraeus Amersil, Sayreville, New Jersey) and detected using the optical configuration shown in Fig. 3 and described in the text. The relative amounts of each reaction used were chosen to give comparable signal intensities for each dye. This mixture contained 0.025 units of an FITC-A reaction, 0.1 units of Texas Red-C (Tex-C), 0.15 units of tetramethylrhodamine-G (TM-G), and 0.4 units of NBD-T, mixed with one volume of formamide, in a total volume of 14 μl. A unit amount of sequencing reaction contains 0.4 pmol of template DNA and 0.8 pmol of primer DNA. The protocols used in the preparation and loading of the sequencing reactions are given in detail in ref. 6. See text for details of the data analysis.

secondary structure in the DNA itself). These complications must be handled in the analysis.

The procedures we have used in data analysis are described in detail in ref. 5. Briefly, the analysis consists of five steps: (1) High-frequency noise is removed by using a low-pass Fourier filter. (2) The time delay (1.5–4.5 s) between measurements at different wavelengths is partially corrected for by linear interpolation between successive measurements. (3) A multicomponent analysis is performed on each set of four data points; this computation yields the amount of each of the four dyes present in the detector as a function of time. (4) The peaks present in the data are located. (5) The mobility shift introduced by the dyes is corrected for using empirically determined correction factors. Figure 4*b* shows the processed data obtained when these five steps were applied to the raw data of Fig. 4*a*, and Fig. 4*c* shows an expanded plot of a region of 1,000 data points taken from Fig. 4*b*; the DNA sequence is aligned with the data. The correspondence between the sequence and the order of peaks obtained in the different channels is evident.

To date we have successfully executed hundreds of single-dye runs, 20–30 two-dye runs, and about 10 four-dye runs. In single-dye runs we often obtain well resolved and clearly discernible sequence beyond base 400 in ~16 h (data not shown). In four-dye runs we generally have obtained ~200 bases of clear sequence information. Present efforts are directed towards further defining and optimizing the parameters important in obtaining good resolution.

Sensitivity

The question is often raised of how the sensitivity of the fluorescence method compares with the sensitivity of conventional radioactive methods. The comparison is complicated by the fact that in the radioactive detection methods, the signal is integrated (by exposure on film) over long time periods ranging from hours to days. In contrast, the fluorescence approach uses real-time acquisition with integration times of a fraction of a second per data point; sensitivity is naturally much lower when the signal is integrated over such relatively short times. If one ignores this aspect, and simply considers sensitivity to be a measure of the amount of material one can detect over background in either method, the radioactive method clearly has higher sensitivity. The most sensitive of the four dyes we are using is fluorescein, and when small amounts of fluorescein-labelled primers are detected during electrophoresis on short tube gels, we obtain a minimum detectable level (defined here as a signal-to-noise ratio of 1) of ~10 amol (1 amol is 10^{-18} mol). Approximate minimum detectable levels obtained for the other dyes are NBD, 40 amol; tetramethylrhodamine, 20 amol; and Texas Red, 50 amol. These levels are about one order of magnitude less sensitive than those typically obtained with autoradiography[7]. The sensitivity of this method could be increased in several ways (see discussion below), which would be of value for extending the amount of sequence information obtained in a run and increasing the accuracy of the analysis.

Future directions

Here we have demonstrated the practicality of a novel method for the automated non-isotopic sequence analysis of DNA. This work opens up several avenues for further investigation. First, the fluorescence sequencing method that we have described will benefit from optimization of several interacting factors, including (1) the gel itself, including its length, diameter and composition (for example, different acrylamide percentages, gradients), (2) the procedures and reagents used in the sequencing reactions, (3) the electrophoresis conditions (for example, voltage, current and temperature), (4) the optics and electronics used in data acquisition, (5) the chemistry used in fluorescent primer synthesis (for example, attaching multiple dye molecules per primer to increase sensitivity, adding linker arms to the dyes to compensate for their non-identical electrophoretic mobilities, finding new dyes with improved fluorescence characteristics), and (6) the software used in data reduction. We have obtained resolved peaks with good signal-to-noise 400 bases into the sequence in some instances, even with the present relatively unoptimized configuration. It is therefore reasonable to expect that an optimized system would yield sequence information beyond position 500 on a routine basis.

The data analysis methods we have developed to date reduce the raw data into a form which is interpretable by the user. We are presently developing the software to perform the final step of data analysis, the interpretative step of assigning the DNA sequence to the data. This interpretation must take into account the high degree of variability in peak intensity obtained in the enzymatic sequencing reactions (see Fig. 4*b*, particularly the Texas Red–C (Tex–C) reaction), and the possibility of 'false' peaks (see, for example, the false C peaks at base numbers 43, 87 and 116 in Fig. 4*b*). The software will be able to minimize, but not to eliminate, these problems. It is therefore important that bases which cannot be assigned unambiguously are left unidentified, and that the sequence of unknown DNAs is determined on both strands. A reasonable goal for the system accuracy is a 1% error rate for a single strand, which would give a 0.01% error rate or 1 base in 10,000 for the sequence determined from both strands. This level of accuracy is satisfactory for most applications, and is comparable to or better than the accuracies generally obtained in DNA sequence analysis by conventional methods.

It will also be of great value to apply this fluorescence technology to the chemical method of DNA sequence analysis. This is important for several reasons. First, as mentioned previously, there are occasionally regions of DNA that are difficult to sequence by the enzymatic method but which are usually amenable to analysis by the chemical method. Second, whereas the enzymatic method is characterized by significant peak-to-peak variations in intensity, visible in both autoradiograms and in the fluorescence data presented here, the chemical method generates a much more uniform distribution of fragments of different lengths, which would facilitate data analysis. Third, the simple and inexpensive reagents used in the chemical method can be stored easily, and are easier to handle in a machine for automating the sequencing reactions than the delicate reagents (for example, the Klenow fragment of DNA polymerase) used in the enzymatic reactions. Recent advances in solid-phase methods of sequence analysis by the chemical method[8,9] will also be of great value in automating those reactions.

Thus, the practicality of a novel non-isotopic method for automated DNA sequence analysis has been demonstrated. It is our hope that this work will help to eliminate much of the labour associated with the structural analysis of DNA, and thereby allow investigators to focus on the more interesting and important questions of modern biology.

We thank Dr Walter Craig for invaluable advice on the mathematics used in data analysis as well as for critical reading of the manuscript; Dr Steven Fung for helpful advice and discussion; Mr Mike Walsh and Mr Tim Heitzman for technical support in the design and construction of the filter wheel assemblies, as well as much invaluable assistance with hardware; and Mr Frank Ostrander for help in the construction of the instrumentation. The concept of using four different dyes was conceived in conjunction with Mr Tim Hunkapiller of Caltech and Dr Michael Hunkapiller of Applied Biosystems. This research was supported by NSF grant DMB-8500298, the Baxter Foundation, Monsanto Chemical Co. and Upjohn, Inc. L.M.S. was a NIH postdoctoral trainee (HD07257) during part of the work described here.

The X-ray flux of dMe stars is thought to arise from two distinct mechanisms, one involving a continuous 'quiescent' emission from a high-temperature plasma and the other involving the dramatic flare events which have long been known to occur on these stars. We present here some results of simultaneous monitoring of the two flare stars, UV Ceti and EQ Peg, with Exosat and ground-based optical spectroscopy. We observe short-timescale variability in the 0.1–2-keV emission from both these objects and, in the case of UV Ceti, find a strong correlation between the soft X-ray and Hγ fluctuations. The implication is that much of the low-level X-ray flux previously considered 'quiescent' probably originates from small flare events.

Our understanding of coronal structure and of mechanisms for coronal heating in the Sun and stars has evolved considerably as a result of the solar observations of Skylab and the Solar Maximum Mission (SMM) and the stellar observations of the Einstein Observatory and now Exosat. The Skylab photographs of the Sun showed that the soft X-ray emission originated almost exclusively in active-region loops, in larger loops connecting active regions and in X-ray bright points, which are thought to be unresolved, small-scale loops of newly emerging magnetic flux. In place of the diffuse Parker-type hot corona/wind, the closed magnetic loop is now widely thought of as the basic unit of coronal structure[1–3]. By contrast, regions of open magnetic field, called coronal holes, are dark in X rays and appear to be the primary source of the solar wind. Because many of the Skylab and other images emphasize the higher-temperature and more dense structures (the emission for a collisionally excited line is $\sim n(e)^2$), it may well be that there is a significant diffused coronal component, in addition to coronal loops and coronal holes. Whether or not this is the case, the concept of a 'quiet corona' (be it diffuse or the average state of the quasi-steady loop ensemble) has persisted since the discovery of the solar corona. This concept has recently been extended to 'quiet stellar coronae'[4], the dichotomy being one between the quasi-steady evolution of high-temperature, X-ray-emitting structures, on timescales of hours to days to weeks, and the more obvious variability associated with flares. The heating of the 'quiet corona' and the nature and energetics of solar flares have thus historically been viewed as different and distinct problems.

However, recently, using balloon-borne instrumentation, a significant number of solar hard X-ray microflares have been observed[5], presumably produced by bremsstrahlung of non-thermal electron beams in the solar chromosphere and transition region. It was found that the average rate of energy deposition above 20 keV and above the detection threshold amounted to $\sim 10^{24}$ erg s^{-1}. In addition, the integral number of events appeared to vary as the inverse of the peak flux down to their detection threshold, in which case the total rate of energy release, allowing for low-level events, could begin to approach the total quiescent solar coronal X-ray luminosity[6], $L_x \simeq 5 \times 10^{27}$ erg s^{-1}. The timescales for these microflares ranged from seconds to tens of seconds in duration. Elsewhere in the spectrum, short-lived extreme-ultraviolet bursts of subflare magnitude have been observed on the Sun in several transition-region lines; these bursts probably result from the same electron beaming event that creates the hard X-rays[7]. From a re-analysis of Skylab data[8], frequent subflare-like extreme-ultraviolet brightenings have been found near the foot-points of loops, and using the SMM

ultraviolet spectrometer polarimeter, almost continual fluctuation has been seen in the Si IV 1,402.8 Å ($T \simeq 60{,}000$ K) and O IV 1401.2 Å ($T \simeq 160{,}000$ K) lines in a solar active region[9,10]. The timescales for these changes are 10–60 s and the brightenings are sometimes more than a factor of two. The timing of these events is such that there must be an almost instantaneous local heating event followed by radiative cooling. In some cases, a secondary brightening is observed after an impulsive burst, which may be the small-scale analogue of the thermal phase of a flare. More importantly, it has been shown[11] that the incidence of extreme-ultraviolet bursts exceeds that of flares by more than two orders of magnitude, which suggests that, in total, they may be as important energetically as flares. These results, together with our own, suggest that heating due to magnetic field reconnection within an active region is proceeding almost stochastically.

The recent studies of correlations between 'quiescent' X-ray fluxes and stellar U-band flare energy rates for dMe stars are of particular interest as they point to a possible equality between total energy released in flaring and the energy requirements of the quiet stellar corona. The relationships between the time-averaged U-band flare luminosity, $\langle L_{\text{flare; U-band}} \rangle$, and coronal X-ray luminosity, L_x (refs 12, 13), are linear over several orders of magnitude, and imply that $L_x/\langle L_{\text{flare; U-band}} \rangle \simeq 10$–$25$. This result appears to hold not only for the dMe stars, from which it was established, but also for non-emission M dwarfs, and possibly even for the Sun[14]. Because the U-band flare (which is the band most easily measured by optical observers) encompasses only a fraction of the flare energy, it is possible that there is an approximate equality between total flare emission and quiescent coronal emission. However, the mean U-band flare energy is dominated by the relatively large and infrequent flares (>1 per 10 h), and if they are to be the source of coronal heating, it is difficult to see how their energy, once it has been released in a flare, could be stored for times of this order. The present new data demonstrate the importance of continual microflaring on the dMe flare stars.

As part of a coordinated campaign of multi-band observations of stellar flares[15], we observed UV Ceti and EQ Peg on 6 and 7 December 1984, respectively, with ground-based optical telescopes and with the two satellites IUE (International Ultraviolet Explorer) and Exosat. Included among several optical telescopes was the 3.6-m of the European Southern Observatory (ESO), with which intermediate dispersion spectroscopy of the region 3,600–4,400 Å was obtained using the image dissector scanner on the Boller and Chivens spectrograph. Exposures were of 60 s duration with a short delay of ~10 s between spectra. Although these data have not yet been fully reduced, it was possible to determine, in real time, an uncalibrated peak flux value at the wavelength of Hγ. The variation of this peak value will be predominantly due to the Hγ emission line itself; however, some continuum variations will also be included.

Because of Exosat pointing restrictions, it is difficult to obtain, from one site, more than ~5–6 h of simultaneous ground-based coverage. In the case of UV Ceti, Exosat observations were made from 02:00 to 10:45 UT on 6 December 1984, but only the first 3 h could be covered from ESO.

The X-ray (0.1–2 keV) photon counts detected by the channel multiplier array (CMA) of the Exosat low-energy imaging telescope (LE) (using the 4,000-Å-thickness Lexan filter) have been analysed using the reduction package at Mullard Space Science Laboratory, University College London. Some gaps are present in the data where data transmission, or small solar flares, have caused the exposure time to fall below 80% of the nominal value. Although small solar flares do not noticeably increase the flux over the area of the CMA detector containing the stellar image, the increase over the entire image area can be sufficient to overload the detector system and cause a reduction in the effective exposure time.

In Fig. 1*a*, *b* the X-ray data have been grouped into 30-s and 60-s bins, respectively, and Fig. 1*c* shows the time variation of the peak Hγ flux. The data in Fig. 1*a* are binned in successive 30-s intervals; however, to allow a better comparison with the Hγ peak flux, the 60-s X-ray data (Fig. 1*b*) have been grouped into 60-s bins that do not follow on from each other immediately, but rather are as nearly as possible coincident with the windows of the Hγ observations. Therefore, the total counts in the two X-ray plots will not be exactly the same.

Figure 1 shows two important features. First, the X-ray emission appears to be quite non-uniform, with frequent rises of a factor of two or three in flux, lasting for periods of a few tens of seconds to several minutes. Second, five or six of the X-ray events correspond to similar rises in Hγ peak flux. We have investigated this correlation statistically and find that the correlation coefficient between the 60-s data points used to construct Fig. 1*b* and *c* is 0.51, or a Student's *t* value of 7.0. For 143 data points this implies a highly significant correlation between the Exosat and Hγ data, with a probability of

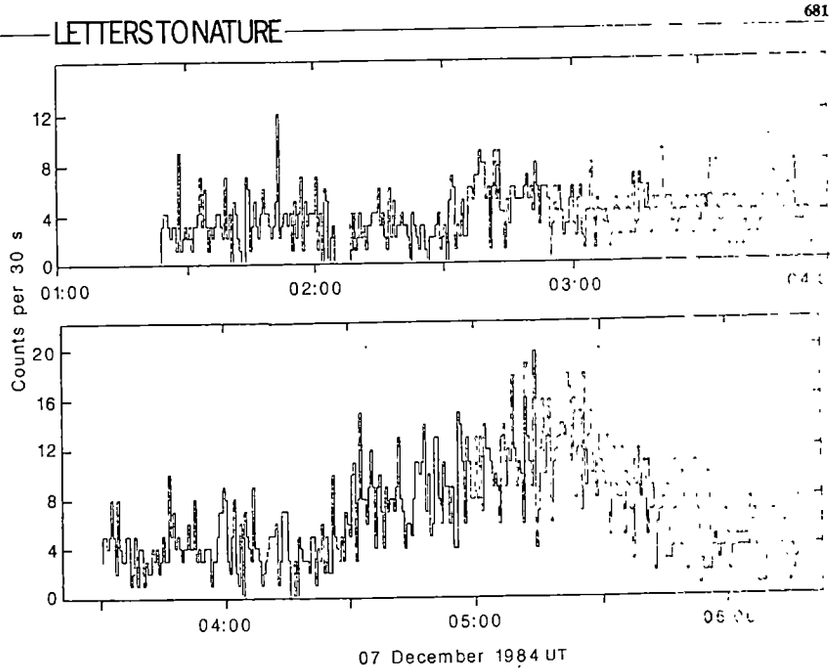

Fig. 3 Soft X-ray flux from EQ Peg. Note the large flare beginning at 04:30 UT. The background level is 0.23 counts per 30 s over the source area.

occurrence by chance of less than 1 in 10^5.

We conclude that the events seen in the X-ray and Hγ fluxes are in fact small flares, which, like flares on the Sun, show increased X-ray emission accompanied by Balmer-line enhancements; the X-rays are presumably due to thermal emission of the flare-heated plasma in one or more loops and the Balmer-line enhancements to chromospheric ablation[16]. While both the soft X-ray events and the Balmer-line enhancements on the Sun last rather longer than these events on UV Ceti, the energies are similar: at a distance of 2.62 pc (ref. 17), the energies in the UV Ceti low-energy X-ray events vary from $\sim$0.5 to 5×10^{30} erg, similar to the energies of compact solar flares.

Figure 2 shows all of the Exosat data for UV Ceti in 30-s bins. Here again we see evidence for an almost continuously variable soft X-ray flux, and to determine whether this variability is statistically significant, we have binned the data with a bin size varying from 10 to 160 s, and compared the observed number of bins with a given population to a Poisson distribution using a χ^2 test. In all cases, the probability of the observed distribution arising from a random arrival of photons from a constant source is $\leq$0.5%. The departure from a poissonian distribution is in the same sense for each trial bin-size, with both more bins with zero or a low number of photons than expected, and more bins with high numbers of photons than expected. The number of bins found with intermediate numbers of photons is correspondingly decreased. This type of distribution could arise from the clumping together of photons from a source which is variable on timescales of 10–160 s.

In Fig. 3, which shows the soft X-ray flux from EQ Peg on 7 December 1984, we again see evidence of continuously variable emission, followed by a substantial LE (soft X-ray) flare, which was also detected by the ME (medium energy) experiment. The flare lasted for $\sim$90 min, with a gradual rise and fall in LE and a more sudden rise in ME. A preliminary analysis of the integrated ME spectral data for the event gave, for effectively zero column density of hydrogen, a best-fit temperature of $\sim2.2\times10^7$ K: this is a typical temperature for the non-impulsive, thermal phase of solar and stellar flares[18,19]. If we adopt the standard calibration of the Exosat detectors[20], and a distance for EQ Peg of 6.41 pc (ref. 17), the total integrated X-ray energy of the flare on EQ Peg is 6×10^{32} erg in LE (0.1–2 keV). This corresponds to the energy of a very large two-ribbon solar flare[21].

Our data for UV Ceti and EQ Peg suggest that the soft X-ray emission of these stars is almost continuously variable, with many surges or microflares lasting from tens of seconds to several minutes. These microflares, which have energies of $\sim2\times10^{30}$ erg in the 0.1–2 keV range, are similar to compact solar flares, but possibly more short-lived. The fact that these microflares occur so frequently in the two dMe stars studied indicates that the concept of a 'quiescent' corona for these stars may be erroneous and that we are seeing, not a quiet, uneventful, low-level emission, but a continuum of flares with energies similar to those of compact solar flares. Most probably, if our detection threshold could be significantly reduced, we could see many even smaller X-ray events. The logical consequence of these results is that what we call stellar coronal emission (the X-ray flux) may be just a succession of microflares.

There are now three other lines of evidence pointing to the possibility that coronal heating in dwarf M flare stars is a direct result of energy input through widespread, low-level microflaring[22,23]: (1) the recently found correlation between time-averaged flare energy release and coronal X-ray luminosity[12,13]; (2) the high-temperature component identified in the two Einstein Observatory solid state spectrometer observations of 'quiescent' coronal emission from the dMe stars[24,25] and in many of the Einstein imaging proportional counter pulse-height spectra of dMe stars which have now been reprocessed (J. Bookbinder, L. Golub, R. Rosner and J. H. M. M. Schmitt, in preparation); and (3) the observed variability on timescales of hundreds to thousands of seconds of practically all reprocessed Einstein coronal X-ray fluxes for dKe and dMe stars (C. Ambruster, S. Sciortino and L. Golub, in preparation).

We thank Drs C. Jordan, C. Ambruster, J. Bookbinder, G. Branduardi Raymont and T. Kiang for useful discussion and the staffs of the ESO and Exosat observatories for their assistance. This work was supported in part by NASA contract NAS5-28409 to the Lockheed Palo Alto Research Laboratory, by a grant from the Piano Spaziale Nazionale of the Italian CNR to the Astronomy Institute of Catania University, and by a grant for International Collaboration in Research from the NATO Scientific Affairs Division.

Metallic ions in cometary comae and plasma tails

W.-H. Ip & W. I. Axford

Max-Planck-Institut für Aeronomie, D-3411 Katlenburg-Lindau, FRG

Ion composition measurements made in the environment of the comet Giacobini-Zinner by the International Cometary Explorer (ICE) spacecraft have shown that H_2O^+ is a major ion species, together with CO^+ ions[1]. The presence of these two cometary ions has long been evident in optical spectra of cometary ion tails[2]. However, the ICE observations were surprising in that they detected ions of mass 23–24 AMU with a relatively high abundance[1]. According to the experimenters, these ions may be either Na^+ or C_2^+, if not both. We suggest here that the ions detected may indeed be in part Na^+ and/or Mg^+ and that these and other metallic ions (especially Si^+ and Fe^+) may be an important component of the cometary ionosphere and central plasma tail. Our reasons are similar, in principle, to those which account for the prevalence of such ions in sporadic E layers in the terrestrial ionosphere, notably the comparatively short timescales for ionization of their neutral parent atoms and the large difference between the rates of dissociative and radiative recombination[3,4].

Because of its strong optical emission, the source strength of C_2 relative to that of H_2O and the scale length for photodissociation and/or photoionization have been well determined. The average values are: $Q(C_2) \sim 4 \times 10^{-3}\, Q(H_2O)$ and $R(C_2) \sim 1.2 \times 10^5$ km, respectively[5]. In comparison, the corresponding scale length for the ionization of the water-group neutrals (that is, H_2O, OH and O) is a factor of 10 larger. It is possible, therefore, that the faster ionization of C_2 radicals in a more limited region could lead to some enhancement of the relative abundance of C_2^+ ions with respect to H_2O^+ ions in a region $<10^5$ km from the tail axis.

Sodium D-line emissions and emissions from other metallic species (Ca, Cr, Co, Mn, Fe, Ni, Cu, V, Si and K) are usually seen most prominently in Sun-grazing comets or bright comets at solar distances <0.5 AU (refs 6, 7). It is often argued that these emissions originate from atoms released by the sublimation of refractory dust grains[8]. At a solar distance of 1 AU, however, the sublimation rate of such dust grains is negligible and essentially no metal atoms should be released. Sodum D-line emissions were detected in comet West (1975n) when it was at a solar distance of 1.4 AU, which gave rise to the suggestion that a component of Na atoms could be embedded in volatile icy grains or matrix in atomic or molecular forms such as NaOH (ref. 9). Although estimates for the production rate of these Na atoms (or their parent molecules) are very uncertain (an upper limit of $Q(\mathrm{Na})/Q(H_2O) \leqslant 10^{-3}$ may be set), such observations, together with the ICE ion composition measurement, call attention to the potential importance of Na^+ ions and metallic ions, in general, in cometary comae and ionospheres. Below, we discuss several implications of metallic ion production in the coma environment and, in particular, emphasize that metallic ions could be a significant component of the central ionosphere and ion tail if their production rates are sufficiently large. The relative (solar) abundances of the most important species concerned are Na (0.06), Mg (1.00), Al (0.08), Si (0.95), Ca (0.07) and Fe (0.85)[10].

Note that, in addition to sublimation from non-volatile dust grains and possibly from volatile material containing their parent molecules, sputtering of dust grains and the nucleus itself by solar-wind protons and the energetic 'pick-up' ion created in the coma should provide a source of secondary neutral atoms (~90%) and ions (~10%)[11]. For a comet with a gas production rate up to that of Halley ($Q = 10^{30}$ molecules s^{-1} at 1 AU) and a dust production rate $\dot{m}_d/\dot{m}_g \sim 1$, the effective cross-sectional area of the dust coma is estimated to be 10^{17} cm^2 assuming a cutoff radius of 1 μm (ref. 12). With a solar-wind flux of 3×10^8 cm^{-2} s^{-1} and a sputtering yield of about unity, the effective sputtering rate of neutral atoms and ions from the dust coma is of the order of 5×10^{24} s^{-1}, which is a factor of 2×10^5 less than the volatile gas production rate. This alone might not be sufficient to account for the relatively high fluxes of ions of mass 23–24 detected by the ICE spacecraft at 2×10^4 km from the tail axis. Nevertheless, secondary ions must be produced by sputtering in the coma and their fluxes may be detectable; there are processes which in any case tend to enhance their fluxes relative to those of molecular ions. Furthermore, the local production rates of sputtered atoms and ions may be larger than we have estimated here if $m_d \gg m_g$ locally (as a consequence of differing expansion speeds of the gas and dust components) and if there is a significant component of dust particles with radii <1 μm.

In general, the solar-wind plasma should not be able to reach the surface of the nucleus but the large gyroradii (~ 1–5×10^4 km) of energetic pick-up ions may allow them to do so. Thus the nucleus and inner coma should be continuously subject to sputtering even when the outgassing rate is large. However, because of the small area of the nucleus ($\leqslant 10^{12}$ cm^2), the production rate of neutral atoms and ions arising from direct energetic particle sputtering is many orders of magnitude less than the sublimation rate of H_2O and other gases. Indeed, only when a comet nucleus is inactive at large solar distances would surface sputtering have a major role in releasing surface material into the surrounding coma region[13,14].

Despite the relatively low production rates of sputtered atoms, it is important to recognize that by virtue of their short photoionization timescales ($\sim 3 \times 10^4$ s at 1 AU (ref. 9) compared with 3×10^6 s for H_2O), together with the fact that a substantial fraction of the sputtered gas is already ionized, metallic ions could become relatively enriched. The very fact that such neutral atomic species as Na appear in the spectra of some comets suggests that their photoions should be abundant. The ionization potentials of these atoms are such that they are photoionized by hydrogen Lyman-α radiation, whereas the more abundant molecules require photons of 12 eV or more for photoionization. In addition to photoionization, metallic ions can be produced by charge transfer reactions such as

$$H_3O^+ + Na \rightarrow Na^+ + H_3O$$

which has a rate coefficient $\leqslant 10^{-9}$ cm^3 s^{-1} (ref. 15); this process may be important in the denser regions of the cometary ionosphere where the H_3O^+ density is $\sim 10^4$ cm^{-3}.

It is difficult to find reactions which can neutralize metallic ions faster than radiative recombination, which with a typical recombination coefficient of 10^{-12} cm^3 s^{-1} is itself unimportant in the present context. To remove metallic ions quickly they

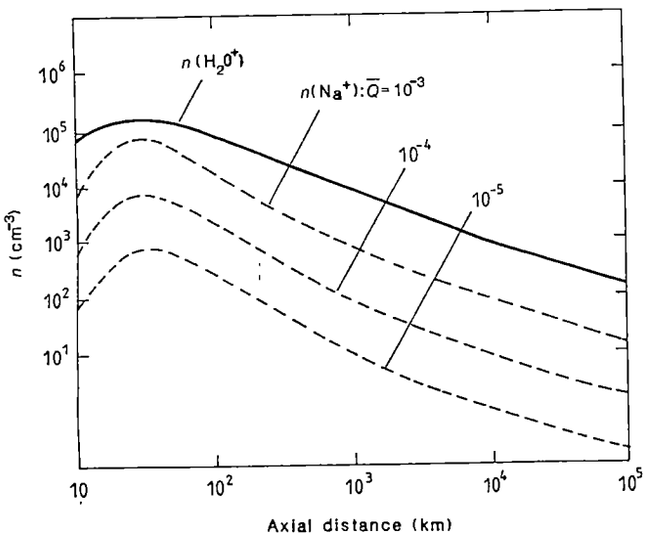

Fig. 1 Comparison of the number density of the H_2O^+/H_3O^+ ions with that of Na^+ (or other metallic ions) for different relative source abundances of the metallic neutrals, $\bar{Q}=Q(Na)/Q(H_2O)$. In the calculation, simulating the free-streaming ionospheric flow along the tail, the flow speed increases linearly from 1 km s^{-1} near the nucleus to 100 km s^{-1} at 3×10^4 km from the nucleus. The metal ion enhancement in this case is entirely the result of the relatively high ionization rate of their atoms in comparison with that of water molecules.

must first be converted to some form of molecular ion so that dissociative recombination is a possibility. However, the rates of formation of such molecular ions are low, except perhaps very close to the nucleus: for example, in the case of Na^+ the process

$$Na^+ + H_2O \rightarrow Na\cdot H_2O^+ + h\nu$$

has a rate coefficient of only $1.6\text{–}6.1\times10^{-16}$ cm^3 s^{-1} at 20 K (ref. 16). This is competitive with radiative recombination in regions where the H_2O density is 10^4 or more (that is, within 3×10^4 km) but provides loss rates for Na^+ ions which are significantly only in regions where the H_2O density exceeds 10^9 cm^{-3} and the electron density is $\geqslant10^2$ cm^{-3}.

In the inner coma, a basic (convective) timescale is determined by the plasma flow characteristics. These are, in turn, controlled by drag which resists motions of plasma relative to the neutrals and by the tension stress created by strongly curved magnetic field lines which pull the plasma inwards towards the nucleus on the upstream side and eventually out along the tail on the downstream side[17]. The flow speeds in the 'ionospheric' region surrounding the nucleus may be quite small, perhaps 10^2–10^3 m s^{-1}, corresponding to convective timescales of 10^4–10^5 s. The tail plasma flow behind the nucleus can be regarded to a first approximation as an expansion of the ionospheric plasma along a quasi one-dimensional tunnel, accelerated by the thermal pressure gradient and magnetic field streams into a region of negligibly small neutral drag. In this manner, flow speeds of 10–30 km s^{-1} may be achieved in $\sim3\times10^4$ km, giving a convective timescale of $\sim10^3$–10^4 s. Detailed calculations are required to analyse these processes fully, involving the ion chemistry as well as the plasma flow dynamics, but the essential features can be demonstrated by a simple approach.

Figure 1 shows results from a model calculation with a range of the relative production rate of the metallic atoms ($Q(Na)/(Q(H_2O)=10^{-5}$, 10^{-4} and 10^{-3}). Ionospheric plasma flow in the tailward direction is simulated here by converting to a one-dimensional geometry with the flow acceleration approximated by assuming $d(\log A)/dx=(2/x)\exp(-x/X_a)$ for the stream-tube area A and an acceleration $dV/dx=(100\text{ km s}^{-1})/X_b$. The scale lengths are taken to be $X_a=3\times10^3$ km and $X_b=3\times10^4$ km. This calculation demonstrates that an enhancement of a factor of ~100 could be introduced into the metal ion abundance simply as a result of more rapid ionization.

There is a second important effect which could enrich the metallic ion component of the cometary plasma: in the sunward region of the ionosphere, which is a region of very low speed flow, metallic ions carried in or produced *in situ* could gradually replace H_2O^+ as the dominant ion as a consequence of their differing rates of recombination (see Fig. 2). The lifetime of ions against recombination is $\tau\sim1/\alpha N_e$, where α is the recombination coefficient and N_e the electron density. For metallic and other atomic ions the (radiative) recombination coefficients are typically of the order of 10^{-12} cm^3 s^{-1}, whereas for molecular ions, which undergo dissociative recombination, $\alpha\sim10^{-6}$ cm^3 s^{-1}. According to magnetohydrodynamic (MHD) simulations (J. A. Fedder, personal communication), ions produced in or brought into the central coma reside for as long as 10^5 s with electron densities of 10^2–10^4 or more; in these circumstances the metallic ions simply accumulate ($\tau\sim10^8$–10^{10} s), whereas molecular ions continually recombine ($\tau\leqslant10^2$–10^4 s). Thus, as plasma is carried through the coma by contraction of the looped magnetic field lines to eventually form the plasma tail of the comet, it should become progressively enriched in atomic, especially metallic, ions to a much greater extent than would be implied by their higher ionization rates alone. The formation of such a metallic ion-rich zone by 'magnetic scavenging' in the neutral atmosphere of a comet is analogous to the occurrence of sporadic E in the Earth's ionosphere, where, following rapid photoionization of metallic atoms, neutral atmospheric wind shears in the presence of the geomagnetic field produce the scavenging effect. This, in turn, leads to the formation of metallic ion-rich layers of high plasma density in which the molecular ions may actually be depleted relative to the surroundings[3,4,18,19].

The ICE spacecraft passed through the tail of comet Giacobini-Zinner along a path very favourable for the detection of metallic ions but unfortunately it was not designed for this purpose and so only a hint of their pesence may have been obtained. However, the Giotto spacecraft has five mass spectrometers of various types which may be able to detect and identify metallic ions. Such ions should be most prevalent in the region immediately surrounding the nucleus ($<10^4$ km) but

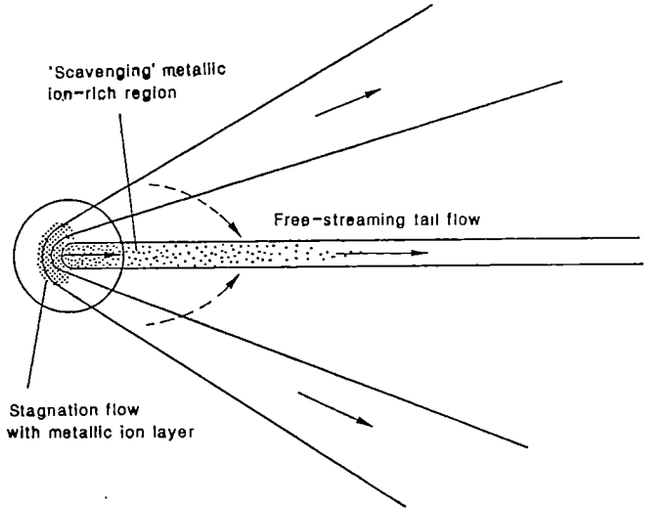

Fig. 2 A schematic view of how the metallic ions might be accumulated in the low-speed flow region of the cometary ionosphere. Metallic ions produced in the coma upstream from the nucleus are carried inwards and concentrated, without suffering recombination losses as do molecular ions, before eventually escaping downstream along the tail.

some should be detectable at larger distances. In some cases, the metallic ions may be submerged beneath large peaks associated with more abundant ions but Fe^+, in particular, may be relatively free of such intereference and hence be more easily identifiable.

Gas-like nature of the sodium anion in solution

Ahmed S. Ellaboudy*, Dolores M. Holton*, Nicholas C. Pyper*, Peter P. Edwards*‡, Brian Wood† & William McFarlane†

* University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, UK
† Department of Chemistry, City of London Polytechnic, London EC3N 2EY, UK

During the past decade a considerable amount of evidence has accumulated for the existence of an anion of sodium, Na^-, as a stable, long-lived entity in certain non-aqueous solvents[1–7]. The term sodium anion refers to a spherically symmetric diamagnetic species in which, in the orbital model of atomic structure, the two valence electrons are accommodated in the 3*s* orbital of sodium[7]. We report here direct measurements of ^{23}Na nuclear spin–lattice relaxation rates for Na^-, coupled with nuclear magnetic resonance (NMR) chemical shift data, which are used to show that Na^- in solution is almost completely decoupled from its environment, behaving as if it were in the gas phase.

The systems chosen for study were solutions of sodium and mixed sodium/alkali metal samples (Na/M, where M = K, Rb and Cs) in the solvent 1, 4, 7, 10-tetraoxacyclododecane (12-crown-4, 12C4; Fig. 1). This solvent has a powerful and specific ability to complex alkali cations. For example, the dissociation of sodium/potassium alloy proceeds through the disproportionation reaction[8]

$$NaK \rightleftharpoons Na^- + K_s^+$$

where K_s^+ represents a complexed or solvated potassium cation.

Metal solution samples were prepared under stringent high-vacuum conditions[8] and ^{23}Na, ^1H and ^{13}C relaxation rates were measured using established procedures.

The frequency of the $^{23}Na^-$ resonance was found to be unchanged to within 0.5 p.p.m. on examining, over a range of temperatures, about 50 metal/12C4 solutions differing in both concentration and counter cation. All these Na^- resonance frequencies correspond to an increase in the electronic shielding of the ^{23}Na nucleus relative to that in the gaseous sodium atom, Na^0_{gas}, by ~2.5 p.p.m., after allowing for bulk-susceptibility corrections. To within the experimental errors arising from relating the solution measurements to the Na^0_{gas} data, the shift in resonance frequencies is the same as that predicted (2.88 p.p.m.) from an accurate calculation[7] of the shielding of a gaseous sodium anion, Na^-_{gas}, relative to that of Na^0_{gas}. This indicates that both the 2*p* and 3*s* electrons of Na^- in solution interact very weakly, if at all, with their surroundings, the resonance frequency of the Na^- ion being diamagnetically shifted relative to that of Na^0_{gas} by the additional shielding generated by the two, spin-paired 3*s* valence electrons.

The shielding of Na^- relative to Na^0_{gas} should be contrasted with the substantial de-shielding of ~60 p.p.m. of Na^+_s relative to Na^0_{gas}, which is considerably larger than the 5.18 p.p.m. de-shielding[7] of a gaseous sodium cation, Na^+_{gas}, relative to Na^0_{gas}. The additional de-shielding of Na^+ in the solution arises from the Ramsey paramagnetic contribution to the shielding generated by the interaction of Na^+ with the environment. Any such paramagnetic contribution is absent in the gaseous atoms and ions.

A detailed examination[9] of the concentration and temperature dependence of the rates of ^{23}Na nuclear spin–lattice relaxation shows that the dominant, but still extremely inefficient, relaxation arises from the interaction of the nuclear electric quadrupole moment (eQ) of the ^{23}Na nucleus with fluctuating electric field gradients. The relaxation of nuclei with spin (I) $>1/2$ is expected to be dominated by this quadrupolar mechanism[10].

Nuclear spin–lattice relaxation rates (T_{1n}^{-1}) for Na^- in 12C4 are very much less than the value of 3,770 s^{-1} for Na^+ in this solvent. The cation relaxation arises from the very large fluctuations in the electric field gradient caused by the asymmetric environment of the Na^+ ion resulting from its strong complexation by the solvent[11]. The very small relaxation rate for Na^- in the solvent 12C4 is comparable with that reported in Table 1 for Na^+ in H_2O, which experiences an environment, the time average of which is centrosymmetric[10,12,13].

It is therefore of interest to compare the Na^- nuclear relaxation rate with those of other ions which are in a centrosymmetric environment[10,12,13]. Note, however, that the experimental spin-lattice relaxation times of Table 1 are not, at this stage, directly comparable because T_{1n}^{-1} is proportional, among other things, to the square of the nuclear electric quadrupole moment $(eQ)^2$, and depends on a theoretically well-established function of the nuclear spin I. Thus, column (2) of Table 1 reports the suitably scaled T_{1n}^{-1} values that would arise if all the ions had the same eQ and I as the ^{23}Na nucleus. This scaling (from column (1) to (2) in Table 1 uses theory of such firmly established validity[10] that these numbers can be regarded as experimental results.

Table 1 Measured and scaled nuclear spin relaxation rates for ions in various solvents

Ion/solvent	(1) Measured T_{1n}^{-1}* (s^{-1})	(2) Nuclear properties (I, eQ)	(3) T_{1n}^{-1} scaled for: Electronic anti-shielding (β_2)	(4) Viscosity (τ_{solv})
Na^+/H_2O	16.2	16.2	191	7,109
$Na^-/12C4$	3.33	3.33	3.33	3.33
Cl^-/H_2O	25	39	1.66	61.66
Cl^-/C_2H_5OH	1,300	2,047	86	716.7
$Cl^-/12C4$	14,100	22,260	935	935
I^-/H_2O	4,600	346	3.58	133
Cs^+/H_2O	0.075	817	15.5	577

* With the exception of relaxation rates in 12C4 these data are taken from refs 12, 13.

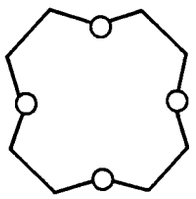

Fig. 1 1,4,7,10-tetraoxacyclododecane (12-crown-4).

The electric field gradient at the ^{23}Na nucleus generated by the environment is magnified by a factor $(1+\beta_2)$, the Sternheimer anti-shielding factor[14], which originates from the additional electric field gradient generated by the electrons belonging to the ion. This additional electric field gradient arises because the external environment distorts the electronic charge distribution away from spherical symmetry. Since T_{1n}^{-1} is proportional to $(1+\beta_2)^2$, the results of column (2) of Table 1 can be scaled to yield the rates that would arise if all the ions had the same Sternheimer anti-shielding factor as Na^-. The resulting data (column (3) of Table 1) are genuine reflections of the differences in strengths of the interactions of each nucleus with its environment external to the ion. Thus, these numbers now reflect the differences in the microscopic structure and microdynamics of the ions in solution.

In any theory of nuclear relaxation in liquids[10], these microdynamics can be characterized by a correlation time, τ_c, defining the rate of fluctuations of the electric field gradient at the nucleus. For all of the ions except Cl^- in 12C4 and Na^+, the molecules in the first solvation shell reorientate independently both of the ion and of each other[12,13]. As this is the first report of the T_{1n}^{-1} data for Cl^- in 12C4, the details of the microdynamics reponsible for this relaxation have not yet been elucidated.

For all of the Na^- solutions, differing in concentration and counter cation, the activation energy (22 ± 1 kJ mol^{-1}) for the process responsible for the Na^- spin-lattice relaxation was found to be essentially identical to that (23 ± 1 kJ mol^{-1}) for the process responsible for the ^{13}C and ^1H relaxation in the pure solvent. As the latter relaxation arises from reorientation of individual 12C4 molecules, our activation energies show that such independent solvent reorientation is the source of the fluctuations in the electric field gradient responsible for the Na^- spin-lattice relaxation. Hence the correlation time governing the Na^- relaxation is the same as that, τ_{solv}, for the reorientation of individual uncomplexed solvent molecules in the neat liquid. This τ_{solv} was derived from the values of T_{1n}^{-1} for nuclei such as ^{13}C and ^1H, whose relaxation is dominated by direct dipolar interactions between the spins. As the correlation time for neat 12C4 thus derived, 130 ps, is much longer than either that (15.6 ps) of C_2H_5OH or that (3.5 ps) of H_2O, the scaled relaxation rates of column (3) in Table 1 for Na^- relaxation in 12C4 would be expected to be much greater than those for the ions in the other two solvents if the strengths of the fluctuating electric field gradients were comparable. The much longer τ_{solv} of 12C4 is consistent with the much greater viscosity[9] (10 cP) compared with that of H_2O (1 cP).

The data in column (4) of Table 1 are derived by scaling those of column (3) by the factor τ_{solv} (12C4), thereby generating the relaxation rates that the ions would have if they all had the same quadrupole moments, nuclear spins and Sternheimer factors as Na^-, and were all in solvents of the same viscosity as 12C4. This scaling markedly increases the rates of column (3) in Table 1, except those for Na^- and Cl^- in 12C4 yielding scaled relaxation rates which illustrate that the strength of the fluctuations of the environment experienced by the Na^- ion is at least an order of magnitude smaller than those for all of the other systems.

Note that the 'raw' experimental relaxation rates of column (1) (which govern the NMR line width) might be incorrectly interpreted to suggest that the interaction of Na^+ with its environment in H_2O is only slightly greater than that of Na^- with its environment in 12C4. However, the present scaled relaxation rates show that this is not the case, and they (column (4)) provide the first conclusive evidence that the sodium anion in these systems is considerably more decoupled from its environment than any of the other common ions. In particular, the interaction of Na^- with its environment is ~280 times smaller than that of the Cl^- ion in the same solvent (12C4).

The chemical shift measurements show that Na^- in 12C4 interacts so weakly with its environment that it behaves essentially as if it were in the gas phase. The nuclear relaxation data also show that Na^- interacts only very weakly with its environment. We have shown not only that this interaction is much smaller than that of halide ions in a variety of solvents, but also that Na^- interacts much more weakly with 12C4 than does the Cl^- ion. It would be inappropriate to attempt to explain here the reasons for this remarkable difference between Na and halide ions.

We thank the SERC for support.

Distribution of atoms at the surface of liquid mercury

Scott W. Barton*, Britt N. Thomas*, Frank Novak*, Peter M. Weber*, Jonathan Harris*, Paul Dolmer†, J. Mati Bloch‡ & Stuart A. Rice*

‡ NSLS, Brookhaven National Laboratory, Upton, New York 11973, USA

Theoretical studies of the anisotropic distribution of atoms in the liquid/vapour interface have led to two conclusions. First, the density along the normal to the interface (the longitudinal one particle distribution function) has different forms in a liquid dielectric and a liquid metal. In a dielectric[1], the density decreases monotonically as one passes from the liquid to the vapour, while in a metal[2] the liquid/vapour interface is stratified for about three atomic diameters into the bulk liquid, Fig. 1 shows examples. Second, the transverse structure factor at the surface of a liquid (the Fourier transform of the in-plane distribution of pairs of atoms) is very similar to the bulk liquid structure factor except near the origin, the difference arising from long-range correlations in the surface[1]. The very few experiments[3,4] that can be interpreted in terms of the properties of the density along the normal to the liquid surface are in agreement with the first set of predictions. There have been no published reports on the transverse structure factor in the liquid/vapour interface. Here we describe the transverse structure factor of the room temperature liquid/vapour interface of mercury, determined using the method of grazing incidence X-ray diffraction[5]. Our experimental results are consistent with the above predictions.

The experiments were carried out at the Cornell High Energy Synchrotron Source (CHESS) using an apparatus that will be

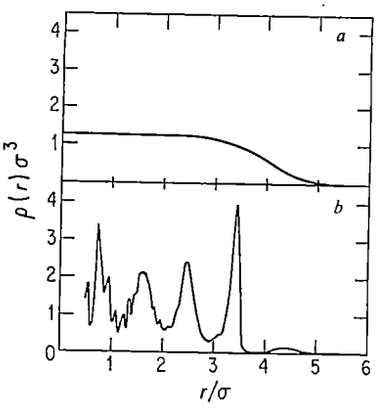

Fig. 1 The density (ρ) along the normal to the surface for: *a*, a typical dielectric liquid; and *b*, liquid Hg as determined in the Monte-Carlo simulations of D'Evelyn and Rice[2]. The density and distance are put in reduced units through the atomic diameter σ. The coordinates chosen assume a free cluster configuration as actually used in ref. 2.

described in detail elsewhere. The geometry used is shown in Fig. 2. The sample is illuminated with X rays of wavelength λ at an angle ϕ which is much smaller than the critical angle for total external reflection, ϕ_c. Given that $\phi_c \propto \lambda$, in our experimental conditions the penetration depth of the X rays, $d \simeq \lambda(2\pi)^{-1}(\phi_c^2 - \phi^2)^{-1/2}$, is independent of wavelength; for Hg it has the value 30 Å. The detector is set with vertical pick-off angle $\phi' \approx \phi_c$ and is scanned as a function of the azimuthal angle 2θ. Let $\mathbf{k}_0$ and $\mathbf{k}_d$ be the wavevectors of the incident and diffracted X rays. Since ϕ' is very small, the scattered wavevector magnitude is given by $|\mathbf{k}| \equiv |\mathbf{k}_0 - \mathbf{k}_d| = 4\pi \sin\theta/\lambda$, the usual Bragg relation. This observation has the important consequence that, since the momentum transfer in the X-ray scattering is parallel to the surface of the liquid, only those atom–atom correlations in planes parallel to the surface are probed in our experiment.

We define the transverse structure factor (excluding polarization and inelastic X-ray scattering effects) by

$$S_{\parallel}(k) = \frac{\int w(\phi, \phi', z) S(k_{xy}; z) f^2(k) \rho(z)\, dz}{\int w(\phi, \phi', z) f^2(k) \rho(z)\, dz}$$

where $w(\phi, \phi', z)$ is a weight factor which describes the X-ray intensity at depth z, $S(k_{xy}; z)$ is the transverse liquid structure factor at z, $f(k)$ is the atomic structure factor and $\rho(z)$ scales as the average number of scatterers at depth z. The normalization is $S_{\parallel}(k) \to 1$ as $k \to \infty$.

Our sample was commercially obtained triply-distilled Hg. It was further purified by hot oxidation of impurities and their subsequent removal by filtering the liquid repeatedly through very long glass capillaries. The Hg was introduced into the beryllium-windowed stainless-steel ultra-high vacuum chamber through a capillary after the base pressure in the chamber had been reduced to 10^{-8} torr or less. Using the same conditions,

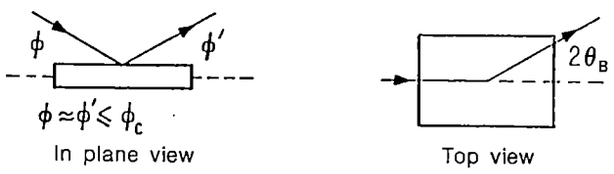

Fig. 2 Geometry of grazing incidence X-ray diffraction experiments.

previous experiments have shown that the liquid Hg surface remains clean for several days[6]. The 8- and 16-keV X rays used were reflected from a double-bounce channel-cut Si(220) crystal and deflected down onto the liquid sample by a Pt-coated float glass mirror, at an angle of incidence of 1.3 mrad. Horizontal slits were used to define the incident beam and the pick-off angle, while vertical Soller slits in front of the detector define the azimuthal angle 2θ to $\pm 0.15°$. An intrinsic germanium energy-dispersive detector was used, which enabled us to separate X-ray fluorescence from X-ray scattering. Corrections for the instrument geometry, and for the decay of incident intensity as the storage ring current decays, were made by scaling the diffraction intensity to the intensity of the 10.1-keV Hg fluorescence line. In our experiment, the intensity of such a fluorescence line is independent of θ. The data were corrected for atomic, anomalous and Compton scattering and polarization (assuming the X-ray beam is plane polarized), and normalized using the Krogh-Moe method[7].

Figure 3 shows the experimentally determined structure factor at 298 K and, for comparison, the structure factor for bulk liquid Hg at 293 K (ref. 8). The error in the bulk structure factor is predicted from counting statistics and is not greater than twice the line thickness in Fig. 3. Note the distinct features: $S_{\parallel}(k)$ for the interface is lower than $S_{bulk}(k)$ in the region from 1 to 2 Å^{-1}; the trough between the first and second peaks in $S_{\parallel}(k)$ is slightly

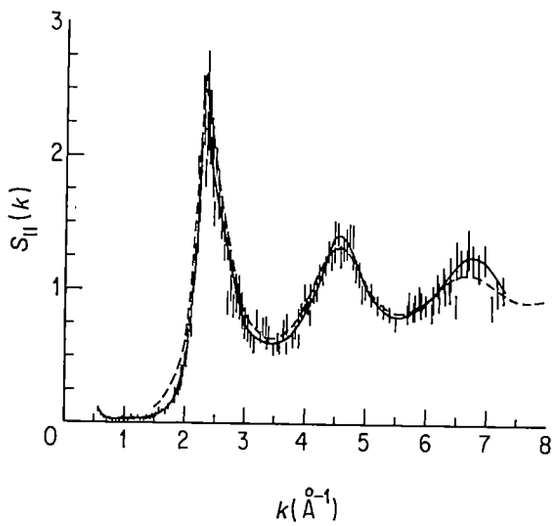

Fig. 3 The transverse structure factor for X-ray scattering from the surface of liquid Hg at 298 K. The vertical lines are out statistical error bars through which we have drawn a solid line to guide the eye. The dashed line is the bulk liquid structure factor at 293 K, from ref. 8.

deeper than in $S_{bulk}(k)$; the second peak amplitude in $S_{\parallel}(k)$ is slightly higher and narrower than the corresponding peak in $S_{bulk}(k)$; there is an apparent increase in $S_{\parallel}(k)$ as $k \to 0$ starting at $k \approx 1$ Å^{-1}.

An examination of the temperature dependences of the structure factors of several bulk liquid metals[7] shows that as the density increases, the low k onset of the first peak decreases and the peak amplitudes are increased. Our results imply that the surface of liquid Hg is more dense than that of the bulk. This further supports the predictions of a stratified liquid/vapour interface density profile; since the total elastic scattering intensity scales as the atomic density, $S_{\parallel}(k)$ will be dominated by the contributions from the high-density strata.

Kalos *et al.*[1] calculated the transverse structure function for the liquid/vapour interface of a model Lennard-Jones system

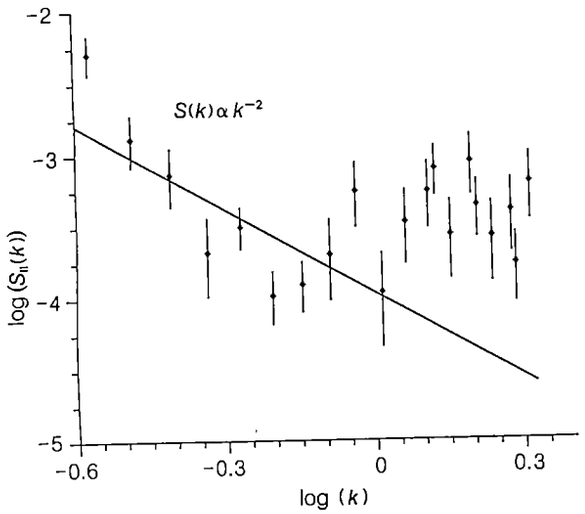

Fig. 4 A log-log plot of $S_{\parallel}(k)$ against k at low k.

with parameters of the potential chosen to describe Ar. They find a divergence in $S_{\parallel}(k)$ as $k \to 0$ with variation as k^{-2}. The theoretical interpretation of this divergence associates it with the existence of long-range correlations in the surface, the absence of any external force acting on the system and the non-vanishing of the derivative of density with respect to displacement along the normal. While our surface transverse factor is different from that of Kalos *et al.*[1] (their factor is given for a thin slice at $z = 0$ and ours is integrated and averaged over a pentration depth), it is assumed that only the first or second uppermost layers will show any long-range transverse correlation; if present, the contribution of such a correlation to $S_{\parallel}(k)$ would overwhelm any contribution to $S_{\parallel}(k)$ from lower layers. Of course, our experiments are carried out in the Earth's gravitational field, which violates one of the conditions used in the theoretical analyses, but that field is so weak that, if everything else is the same, long (but not infinite)-range correlations should still be present.

Although the log-log plot in Fig. 4 shows that some scatter exists for the low k values of $S_{\parallel}(k)$, we believe the k^{-2} dependence of $S_{\parallel}(k)$ is a reasonable fit to our data. At least for the present, there is no reason to disbelieve the predicted k^{-2} dependence of $S_{\parallel}(k)$.

Our results are the first determination of the transverse-structure factor at the surface of a liquid. We expect that the grazing incidence X-ray diffraction technique and its neutron-scattering equivalent will be powerful tools for studying the variation of interface structure when a metal is alloyed, when a liquid supports a film or other structure and, in general, the interaction of a liquid interface and a contact medium.

The research described here was supported by a NSF grant. Some construction funds were provided by a grant from EXXON and we have benefitted from the support of the Materials Research Laboratory at the University of Chicago by the NSF. Efficient solar energy conversion with $CuInS_2$

H. J. Lewerenz, H. Goslowsky, K.-D. Husemann & S. Fiechter

Hahn-Meitner-Institut für Kernforschung Berlin, Bereich Strahlenchemie, 1000 Berlin 39, FRG

The high absorptivity associated with a direct energy gap in the optimum range for solar-energy conversion makes $CuInS_2$ a particularly promising material for efficient solar-energy conversion[1]. Achieved solar-to-electrical conversion efficiencies have been limited to ~6% (refs 2–8). We report here a new heterogeneous polycrystalline *n*-$CuInS_2$ based semiconductor which has yielded conversion efficiencies of 9.7% in an electrochemical cell. The high photoactivity is also evident in a Schottky barrier solar cell configuration. The origin of the improved efficiency is attributed to impurity scavenging by In spheres resulting from a modified vapour/liquid/solid (VLS) growth process[9–11] and the influence of the acidic iodine iodide electrolyte on the cell performances.

Samples with increased In excess exceeding the single-phase region in the phase diagram[12] were prepared. $CuInS_2$ was synthesized from the elements (6 N/Ventron) in a mole ratio of 0.95, 1.05 and 2, respectively. In the growth process, the molten Cu–In alloy reacted with S at $T = 1{,}175$ °C to yield the new material. The resulting boule consists of large-grain polycrystalline material and exhibits a comparably porous structure in its interior. The samples with the highest photoactivity are found in this region inside the boule. Sizes range between 1 and 5 mm^2. A typical surface is shown in Fig. 1. The morphology is characterized by extended steps typical for VLS growth[13]. In addition, small In spheres and In_2S_3 and $Cu_{2-x}S$ occlusions are found and extend up to the surface on some samples.

For photoactivity measurements, electrodes were prepared as described earlier[14] using In–Ga alloy as the ohmic back contact. Figure 2*a* shows the current/voltage characteristic under illumination with simulated AM1 direct radiation (85 mW cm^{-2}) (Oriel Solar Simulator) of *n*-$CuInS_2$ in contact with acidic iodine–iodide electrolyte. Because of the comparably small electrode, area determination was done by scanning laser spot analysis[15–17] to measure the photoactive area accurately. In a two-electrode experiment, the cell converts light to electricity

Fig. 1 Electron micrograph of a typical melt grown $CuInS_2$ sample with In excess; note terraces indicative of VLS growth and In spheres. Scale bar 200 μm.

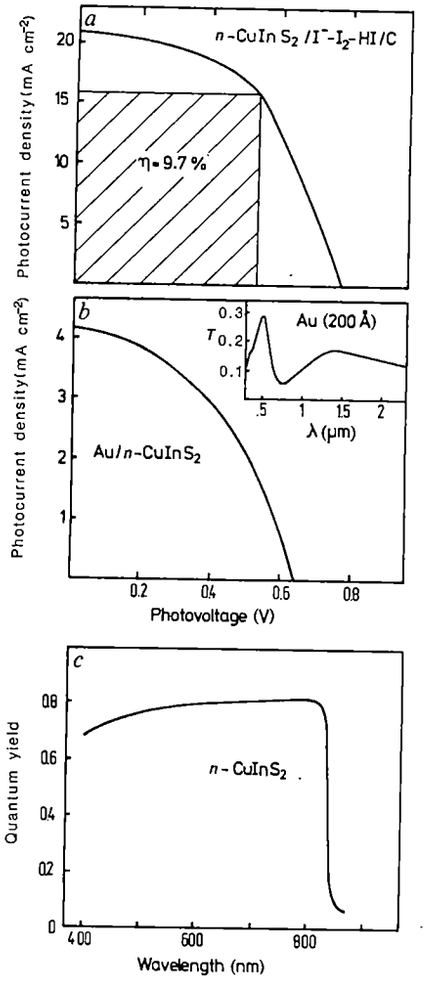

Fig. 2 Photoactivity of heterogeneous $CuInS_2$. *a*, Output power characteristic of the *n*-$CuInS_2$/HI-I^--I_2/C solar cell; electrolyte: 2 M HI, 2.5 M CaI_2, 50 mM I_2; illumination: Oriel Solar Simulator, AM 1 direct (85 mW cm^{-2}). *b*, Output power characteristic of the Au/*n*-$CuInS_2$ solar cell; evaporation of front metal contact after potential cycling in HI-I^--I_2 redox electrolyte; illumination: 64 mW cm^{-2} natural sunlight. *c*, Spectral dependence of the quantum yield; electrolyte: 2 M HI, 2.5 M CaI_2, 50 mM I_2; potential: 0.1 V (SCE).

with an efficiency of 9.7%. The short-circuit photocurrent is stable for ~20,000 Cb cm^{-2}. During the long time testing period no decrease in photovoltage has been found. Figure 2*b* shows the photocurrent/voltage characteristic of a Au/*n*-$CuInS_2$ junction obtained in natural sunlight of 64 mW cm^{-2} (Kipp-Zonen global detector). Before metal evaporation, the sample was polarized in HI-I^--I_2 electrolyte (−0.1 V→ −0.6 V (SCE)) which resulted in an improved cell output compared with untreated electrodes. The spectral dependence of the transmission of the 200 Å thick Au film is displayed in the inset of Fig. 2*b*. The light attenuation for photon energies above the $CuInS_2$ band gap (~830 nm) can be estimated by the area under the transmittivity curve. Since the total transmission is 25% in this energy range, a correction factor of ~4 for efficiency calculation is obtained. This would result in a solar-to-electrical conversion efficiency of ~7.5%.

The spectral dependence of a typical quantum yield is shown in Fig. 2*c*. The experiments were performed in the standard potentiostatic arrangement with a carbon counter electrode and a calomel reference electrode. The quantum yield was obtained by calibrating a photocurrent spectrum with the photon flux of a He-Ne laser at 633 nm. Despite the absorptivity of the iodine-iodide solution and the fact that the distance between electrode and cell window was not optimal, the values exceed 0.8.

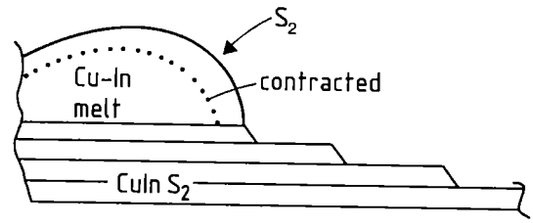

Fig. 3 Schematic representation of VLS growth of highly photoactive $CuInS_2$ (see text).

The photoactivity improvement of the new material can be interpreted based on details of the growth process. An additional advantageous influence of the selected electrolyte is also evident, particularly from the preparation experiments before metal evaporation indicating that surface optimization contributes to the high cell output[18–20]. In VLS (vapour/liquid/solid), growth of $CuInS_2$, a Cu-In melt exists at a given temperature which is supersaturated by gaseous S_2 leading to abrupt contraction of the melt and resulting in the growth of a new terrace[21,22]. This process, schematically shown in Fig. 3, explains the surface morphology shown in Fig. 1. When the growth is interrupted at a time when not all of the remaining sulphur has reacted, the In excess leads to the observed residual In spheres found on these samples (Fig. 1).

The spheres seem to act as a reservoir for impurities, as spark source mass spectrometry (SSMS)[23] and inductively coupled plasma (ICP)[24] analyses show a ~40 times increased Fe content of the metal spheres compared with the neighbouring material[11]. Fe probably substitutes In in the host compound leading to the localized formation of $CuFeS_2$ which acts as a deep trap. Time resolved microwave conductivity (TRMC)[25] and photoluminescence (PL) experiments reveal a drastic reduction in the trap density in the energy gap compared with differently prepared $CuInS_2$ (ref. 10). The prevailing effect of the material heterogeneity thus seems to be the creation of a reservoir for the most deleterious impurities with a material (In) with favourable segregation coefficients, similar to the process of zone refining[26].

We thank Professor H. Tributsch for support and stimulating discussions. The work was in part supported by a BMFT grant No. 03E-8375-A.

Vertical profile of lead isotopic compositions in the north-east Pacific

A. R. Flegal*, K. Itoh†, C. C. Patterson‡ & C. S. Wong§

Ratios of lead isotopes (^{204}Pb, ^{206}Pb, ^{207}Pb and ^{208}Pb) may be used to distinguish leads from different sources in sea water[1–3] in a manner similar to neodynium isotopes[4–8]. The following data from the north-east Pacific include the first vertical profile measurements of lead isotopic compositions in sea water. These preliminary data indicate that lead in offshore (48° N, 141° W) north-east Pacific surface waters (^{206}Pb/^{207}Pb = 1.164) was derived from aeolian inputs of Asian (Japanese) industrial leads (^{206}Pb/^{207}Pb = 1.160) (M. Murozumi, personal communication), but that lead in water immediately (400 m) below it (^{206}Pb/^{207}Pb = 1.211) was derived from North America industrial leads (^{206}Pb/^{207}Pb = 1.222)[9]. This remarkable contrast in isotopic compositions over such a relatively short distance reveals the potential of lead isotopic compositions to resolve the importance of horizontal transport processes on the lead cycle in the oceans, which were recently proposed to partially account for its oceanographic variability in the North Pacific[10].

Seawater collections were obtained along a transect from 48° N, 125° W to 48° N, 141° W in August 1980 (Fig. 1). Surface water samples were obtained from a workboat deployed away from the research vessel, *CSS Parizeau*. Subsurface samples were collected with Caltech 10-1, deep-water samplers[11]. Those samples were then transferred to bottles for storage at 4 °C within a shipboard clean laboratory[12], using trace-metal clean procedures[11].

Isotopic composition measurements by thermal ionization mass spectrometry were made with samples (4 1) after extraction with the dithizone-chloroform procedure described elsewhere[3], as were the lead concentration measurements[11,13]. Coefficients of variation of individual ratios typically were: ^{208}Pb/^{206}Pb ≦ 0.2%; ^{207}Pb/^{206}Pb ≦ 0.01%; and ^{206}Pb/^{204}Pb ≦ 0.3%. Contaminant lead corrections calculated from summations of individually determined contributions of contamination by reagents and containers were ≦2% of the sample lead.

The different sources of lead in north-east Pacific surface waters are established by the differences in their isotopic compositions listed in Table 1, especially the ^{206}Pb/^{207}Pb ratios which are most commonly used as indicators of different lead sources in sea water[2,3]. Isotopic compositions of lead aerosols from industrial sources impacting those waters are also listed in Table 1 for comparison. The ^{206}Pb/^{207}Pb ratios in these north-east Pacific surface waters range from 1.164 in the offshore (48° N, 141° W) waters (Station P-12) to 1.204 in the coastal (48° N, 127° W) waters of the Juan de Fuca Straits (Station P-17). This range in ^{206}Pb/^{207}Pb ratios over 1,900 km in the north-east Pacific is greater than that (1.174–1.196) over 3,300 km in the central (19° N, 158° W to 15° S, 150° W) Pacific[3]. It substantiates reports that the lead in offshore surface waters of the north-east Pacific is primarily derived from Asian industrial lead (^{206}Pb/^{207}Pb = 1.160), and the lead in surface waters of the Juan de Fuca Straits is primarily derived from North American industrial lead (^{206}Pb/^{207}Pb = 1.222)[2,3,11,13]. It is also consistent with ^{210}Pb data from the Pacific, which indicate the predominance of aeolian inputs in oceanic surface waters and of both aeolian and fluvial inputs in coastal waters[14–20].

The vertical gradient in lead isotopic compositions in the

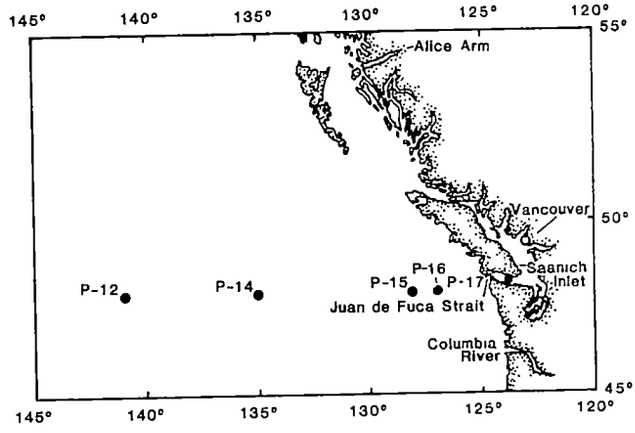

Fig. 1 Sampling locations in the north-east Pacific.

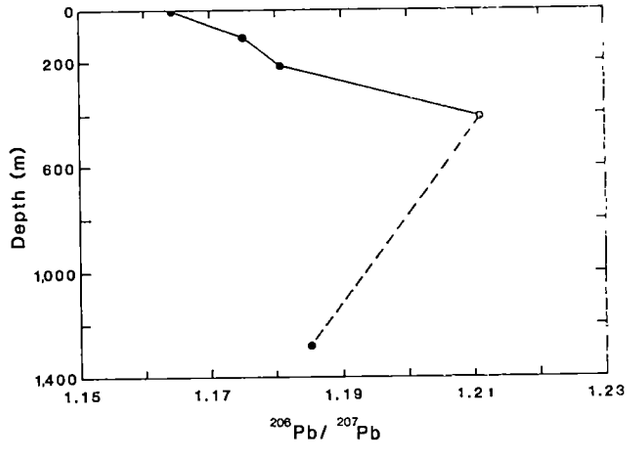

Fig. 2 Lead isotopic ratios (^{206}Pb/^{207}Pb) at 48°N, 141°W in the north-east Pacific.

offshore (48° N, 141° W) waters (Station P-12) is even more pronounced. There the ^{206}Pb/^{207}Pb ratio increases from 1.164 in the surface waters to 1.211 at 400 m, and then decreases to an intermediate value at greater depth (Fig. 2). The relatively large magnitude of this range over the upper 400 m is illustrated by comparison with the previously cited ranges of ^{206}Pb/^{207}Pb ratios in surface waters over 1,900 km in the north-east Pacific and over 3,300 km in the central Pacific. For example, the ^{206}Pb/^{207}Pb vertical gradient (Δ ^{206}Pb/^{207}Pb: Δ km) is more than 19,000 times greater than the horizontal gradient in the central Pacific.

This pronounced vertical gradient in lead isotopic compositions indicates the potential of lead isotope systematics to delineate the element's biogeochemical cycle in the ocean. Specifically, these data indicate that lead isotopic compositions can establish the significance of horizontal transport processes within the ocean, which have been proposed to account for the parallel vertical concentration gradients of lead, bismuth and plutonium in the North Pacific[10]. For example, the subsurface (728 m) lead concentration maximum (68 pmol kg^{-1}) in these subarctic waters is consistent in size and shape with those in more temperate waters of the north-east Pacific[11,13,21,22], but the apparent North American isotopic composition of that lead precludes it from having the western Pacific origins which have been proposed to account for the lead concentration maxima in the more southern waters[10].

Unfortunately, there were neither samples for additional lead measurements nor sufficient oceanographic data obtained on the cruise to resolve adequately the lead inputs at this oceanographically-complex location. Consequently, the subsurface lead may reflect a horizontal input of North American lead

from a southern incursion of the California Undercurrent, the diagenic mobilization of shelf sediments, the nepheloid transport of unconsolidated shelf sediments, or the subsurface decomposition of plankton in coastal waters. Additionally, that lead may reflect a vertical input from a previous aeolian flux of North American lead to the surface waters. Although those potential inputs cannot be resolved with these preliminary data, their multiplicity illustrates the need for additional isotopic data to distinguish different sources of lead in the ocean.

Therefore, the principal significance of these data is that they demonstrate the potential of stable lead isotopic compositions as geochemical tracers in the ocean. The pronounced $^{206}Pb/^{207}Pb$ gradient in this preliminary vertical profile indicates that those ratios can be utilized to determine the significance of different inputs and transport processes on the oceanic lead cycle. It also indicates that those ratios may be utilized as tracers of water masses, as well as of biogeochemical transformations of lead and its analogues (such as calcium) within those water masses.

Basal metabolic rate and energetics of reproduction in therian mammals

Steven D. Thompson* & Martin E. Nicoll†

Departments of * Zoological Research and † Mammalogy, National Zoological Park, Smithsonian Institution, Washington, DC 20008, USA

Traditionally, the fact that reproduction in eutherian (=placental) mammals tends towards prolonged intrauterine development and short lactation has been interpreted as an evolutionary advance over the metatherian (=marsupial) short gestation and prolonged lactation[1]. However, it has recently been postulated that marsupial reproduction involves low initial energy investment and may be advantageous by minimizing energy loss if conditions necessitate early termination[2–5]. Moreover, because marsupials have basal metabolic rates (BMRs) 30% lower than those of most eutherians[6,7], it has been suggested that daily and total energy expenditures during reproduction may also be lower[8]. We have now tested the predictions that low BMR is maintained during reproduction and that initial investment is lower in marsupials. Using indirect calorimetry, we have made the first longitudinal measurements of energy expenditure during reproduction for a marsupial and for two eutherian species with low BMRs[9]. We find that initial investment is lowest in a eutherian and total energetic expenditures were greatest for the marsupial. We also find that, relative to BMR, all three species have increased mean maternal resting metabolic rates (RMRs) during both gestation and lactation; this is the first evidence that mammals with low BMRs can substantially elevate metabolism for prolonged periods during gestation and lactation.

We measured oxygen consumption ($\dot{V}O_2$) and body temperature (T_b) in five South American short-tailed opossums (*Monodelphis domestica*, Metatheria: Marsupialia: Didelphidae), three elephant shrews (*Elephantulus rufescens*,

BMR = per cent of expected as calculated from Kleiber[9]. kcal per day = [resting oxygen consumption (ml h^{-1}) × 0.0048 kcal ml^{-1} oxygen × 24 h] + kcal stored as mass in young. X-cost = incremental cost over BMR, as a multiple of BMR, per day. Total incremental cost = duration × X-cost. Per cent increase in mother's % Kleiber = (mean % Kleiber)/(BMR % Kleiber).

* S.D.T., unpublished data.

Eutheria: Macroscelidea: Macroscelididae) and one tenrec (*Echinops telfairi*, Eutheria: Insectivora: Tenrecidae). Earliest marsupials are thought to have been reproductively similar to small modern didelphids[10] and tenrecs are among the most primitive of extant eutherians[11]. To this extent the comparison reflects the potential for energetic differences having been involved in the evolutionary divergence of the two groups. Respirometry allowed maternal metabolism to be separated from that of the offspring during lactation, avoided the inclusion of activity costs usually included in studies of caloric intake, and thus allowed us to distinguish among net investment (growth of young), the cost of allocating that investment (mother's respiration) and maintenance costs for the growing litter (litter's respiration). Specific basal (or resting) metabolism ($\dot{V}O_2$ g^{-1} h^{-1}) was determined within thermoneutrality for each female before reproduction (BMR), during gestation (RMR_g), during lactation (RMR_l) and after weaning (BMR).

During gestation, females were placed in a Perspex chamber and submerged in a circulating water bath for at least 2 h at a maximum frequency of once weekly; room air was metered through the chamber at 40–150 ml min^{-1}. During lactation, measurements were made first on the mother and young together, then the young were removed and the female was immediately measured alone. $\dot{V}O_2$ was determined using an open-circuit respirometry system with a Beckman G-2 oxygen analyser calibrated using nitrogen gas[12]. Animals were 6–12 h post-absorptive during all measurements and all measurements were made during the inactive phase of the day. We assumed a respiratory quotient of 0.8 in calculating $\dot{V}O_2$ (ref. 12). Because specific metabolism varies with body mass, we expressed the specific basal or resting metabolic rate as a proportion of that predicted by Kleiber[9] for a non-reproductive eutherian of the same body mass. This was intended only to simplify comparisons between individuals and species of different mass. Oxygen consumption was converted to kcal per day assuming 0.0048 kcal per cm^3 O_2 consumed. The energy content of the young was assumed to be 0.87 kcal per g wet body mass[13].

RMR increased throughout reproduction in all three species (Fig. 1). RMR_l of female opossums plus offspring peaked immediately before weaning (50–56 days; M. Roberts, unpublished data) at 189% of Kleiber's predicted rate, when mean maternal T_b increased from 35 to >36 °C. Between 35 days post-partum and weaning, female RMR_l of *Monodelphis* was within 15% of the predicted value, peaking during the last week of lactation, at 106% of Kleiber, before declining to near pre-reproductive BMR. Mean RMR_l of female *E. rufescens* was

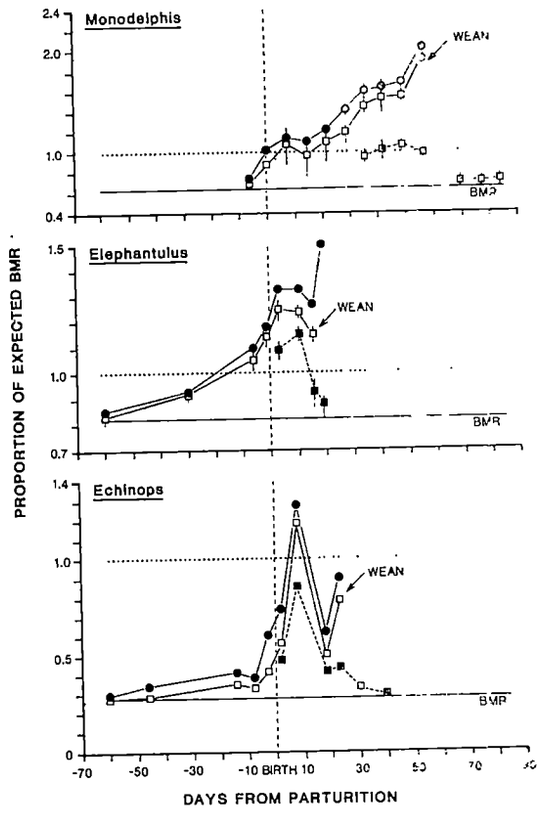

Fig. 1 Mass-independent rates of energy expenditure, expressed as a proportion of that expected from total body mass[9] of mother alone (solid squares), mother with young (open squares), and mother with young with rate of energy storage as growth of litter added to oxygen consumption (solid circles); symbols before birth reflect conception to birth, those after birth reflect birth to weaning. Dotted horizontal line identifies Kleiber's[9] predicted eutherian BMR. Solid horizontal line identifies mean BMR of non-reproductive females. Vertical bars denote ± 1 s.d. of the mean. Values calculated from $\dot{V}O_2$ h^{-1} times 0.0048 kcal per ml O_2 and assuming 0.87 kcal per g wet mass of growing offspring[13]. Values are per 24-h day.

Table 2 Proportion of incremental energy and total incremental energy expended during reproduction as a function of relative and absolute time from conception

CW, conception to weaning time. Incremental kcal = (RMR kcal per day of mother and young plus kcal stored as growth) − (BMR kcal per day of non-reproductive female). Cumulative effort = (incremental kcal per day/BMR of non-reproductive female) days from conception.

higher than predicted while that of *E. telfairi* was lower than predicted. These increases in specific metabolism were not due to separation anxiety; measurements made on the litters alone added to those for the mother alone were ±6.5% of values for mother and young measured together. Female plus offspring of both eutherians showed a similar increase in RMR over non-reproductive BMR, but peak RMR_l was lower than that of the opossum: 125% of Kleiber's predicted in *E. rufescens* and 118% in *E. telfairi*. Lowest tenrec RMR_l corresponded with maternal hypothermia, paralleling thermoregulatory patterns in resting non-reproductive tenrecs (S.D.T. and M.E.N., unpublished data) and involving a 3–5 °C reduction in T_b from 35–36 °C.

The proportion of total energy expended from conception to weaning, including that stored as growth of the young, which was allocated to pregnancy, reflected relative length of gestation and degree of neonatal development: 0.71 in the precocial *E. rufescens*, compared with 0.47 in *E. telfairi*, and 0.09 in *M. domestica*. Mean RMR_g of *M. domestica* was not significantly greater than the non-reproductive BMR in the same individuals ($U = 40$, d.f. = 16, $P > 0.05$), although $\dot{V}O_2$ rose as female mass increased (~5 g) during pregnancy (Fig. 1).

Comparison of *E. rufescens* and *M. domestica*, with their similar adult body mass and conception to weaning time, revealed that total energy expenditure (kcal) and incremental energy expenditures (exceeding that required for BMR of a non-reproductive female of the same mass) during reproduction were greater in the marsupial. Higher incremental costs in *M. domestica* were related to greater reproductive effort and a comparatively high RMR_l of the female plus offspring during late lactation. Although almost twice as large in size, total energy expenditure during reproduction by *E. telfairi* was lower than in *Monodelphis* (Table 1), reflecting maternal torpor and a slow increase in RMR from an extremely low BMR. Similarly, when *E. telfairi* is compared with a precocial rodent, *Sigmodon hispidus*, which has the same litter size and similar body mass[13], the difference in total energy expenditure during reproduction is surprisingly small given the divergence in duration of maternal care and BMR (Table 1). The similarity stems in part from the compensatory increase in tenrec maternal RMR towards Kleiber's predicted value, which the BMR of *S. hispidus* approximates with no increase in maternal RMR during reproduction[13].

Initial energy investment in reproduction, as defined by the incremental energy expended during the first 25% of parental care, was lower in the two eutherians than in *M. domestica*. Through the first 75% of the duration of parental care, all three species expended about 40–45% of their total energy allocation to reproduction and all deferred over 29% of their energy expenditure until the last 15% of maternal care (Table 2). Despite great differences in energetic effort, all species showed a gradual increase in energy expenditure regardless of allocation of time or energy to either gestation or lactation (Table 2).

Our data reveal no advantages to either marsupial or eutherian reproduction with respect to total, daily or temporal patterning of energy expenditure. Comparison of longitudinal energy expenditure during reproduction suggests a continuum based not on phylogeny but on relative BMR. Thus, our three low BMR species, of diverse phylogeny, show a large increase in mean maternal RMR during reproduction whereas for species with a BMR near that predicted, such as wild eutherians (Table 1), laboratory mice[14] and rats[15,16], mean maternal RMR is virtually the same as BMR. Our calculations from limited data for another marsupial, the North American opossum (*Didelphis virginiana*; Table 1), also show RMR_l values greater than BMR. Because species with high BMRs show little increase in reproductive RMR, we suggest that high RMRs are either advantageous or necessary for mammalian reproduction and that at least some mammals with low BMRs can compensate during reproduction. The increased mean maternal RMRs of our study are distinct from those reported for livestock[15–17], chiefly because most livestock have not been measured when post-absorptive; thus, these elevated maternal RMRs reflect the heat of feeding[17] associated with increased ingestion to support larger body mass during reproduction. Data from post-absorptive livestock agree with those in Table 1: fasted, lactating cows (BMR 87–120% predicted) have RMR_ls equal to BMR and fasted, lactating goats (with low BMRs, 70–75% predicted) have RMR_ls 12–15% above BMR[16]. Humans have BMRs near the predicted value and, whether fasted or fed, show little or no difference between average reproductive and non-reproductive rates of metabolism[15,16,18]. Interspecific variation in both BMR and the ability to elevate RMR during reproduction could be responsible for the wide variation in pre- and postnatal growth rates, and the interaction of reproductive RMR with duration of gestation and lactation could be associated with 'intermediates' along the continuum from altricial to precocial neonates[19,20]. If the latter proves correct, developmental stage (or relative mass) at birth will be more accurately predicted by the interaction of rate of metabolism and duration of gestation. Our study also supports recent suggestions that the predicted BMR reflects an advantageous or essential energetic regime for therian reproduction[21–24], from which deviations represent adaptation to small body size[24] or food habits[21].

R. D. Martin, P. Racey, M. Roberts and O. Oftedal made valuable comments on the manuscript. Dr B. K. McNab loaned the necessary equipment and the NZP's Departments of Zoological Research and Mammalogy provided financial support. DZR animal keepers and interns provided assistance in breeding and maintaining animals.

Enhanced detection in the aperture of focal attention during simple discrimination tasks

Dov Sagi

Department of Applied Mathematics, Weizmann Institute of Science, Rehovot 76100, Israel

Bela Julesz

AT&T Bell Laboratories, Murray Hill, New Jersey 07974, USA

There is increasing evidence that it is possible to shift an aperture of focal attention to a position in visual space independent of fixation and that this can be done much faster than the eyes are able to move[1-4]. Recently, we showed[4] that such serial scrutiny by the aperture of focal attention is required before an observer is able to tell what a target is (for example, to know whether the orientation of a line segment is horizontal or vertical). Here we considered whether attention directed towards a specific position in the visual field for an orientation discrimination task improves performance on a simple detection task in the area to which attention is directed. We found that a small test flash could be detected when it was positioned near a peripheral line target presented briefly, if the orientation of the target had to be identified. The test flash could not be detected when presented at some distance from the same target or when another target had to be identified. This enhancement implies that even simple identification tasks such as orientation discrimination are not performed passively by the visual system.

Against a dark field, we presented two bright targets each extending 0.7 degrees of arc in length (horizontal or vertical line segments; or the letter L or T), one in the position where the observer was fixating, the other at 4° eccentricity from the fixation marker, but in any random direction from this marker. Observers were asked to identify only one of the targets (either peripheral or central) in a given block of trials, and were told that the peripheral target would always be at the same eccentricity but in any random direction. Presentation time was short (10 ms) to avoid a second fixation on the target by eye movement, and a mask was applied at a specific time, termed stimulus onset asynchrony (SOA), after target onset, in order to limit processing time (see Fig. 1*a*). Simultaneously with this target identification task, we also presented a small test flash with a 4 arc min diameter lasting 10 ms, at various positions across the visual field, and asked observers to report the presence or absence of the test flash, by pressing one of four keys: two for presence or absence of the test flash when target A was identified and another when target B was identified. Detection errors were signalled by ringing of a bell on the computer that ran the experiments. The test flash and the targets were masked at different SOAs so that performance on the two tasks could be controlled independently. The test flash appeared on 66% of the trials, and was presented at positions along two cardinal directions from the peripheral target: on the perimeter of an imaginary circle of the same eccentricity as the peripheral target or on a line running from the central target to the peripheral target and beyond (see Fig. 1*b*). In each block of 50 trials the test flash could appear in any of the four directions and at any of three distances from the discrimination target. As observers had to identify only one of the targets in a given block of trials, we could compare detection rates for the test flash when the peripheral or the central target was identified, thus isolating changes in detection rate caused by the identification processes.

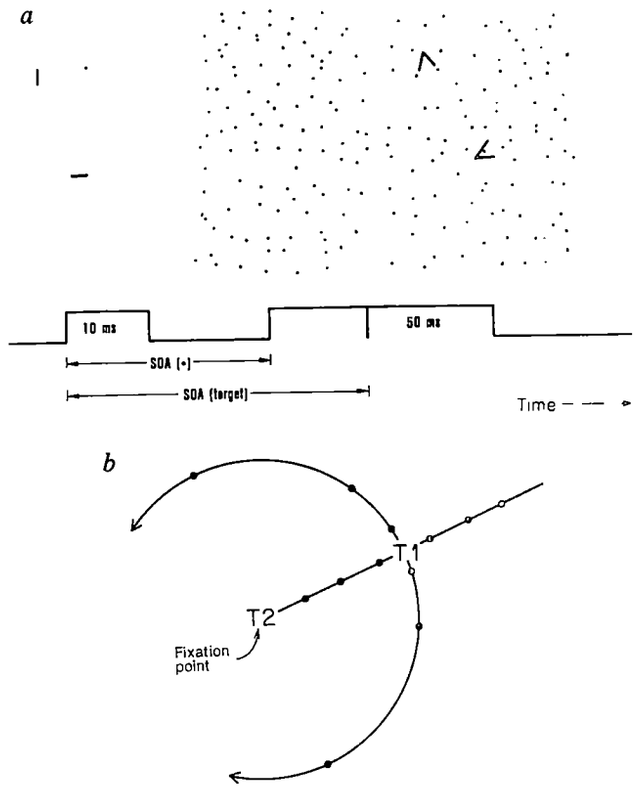

Fig. 1 *a*, The stimulus used in our experiments. The observers were presented first with a pair of targets, one at the fixation point (here a horizontal line) and another at 4° eccentricity. A small dot, the test flash, shown here near the vertical peripheral target, was presented on 66% of the trials. This pattern was presented for 10 ms then masked by random dots after a certain time, SOA(·), and after a longer time, SOA(target), a pair of randomly oriented 'V' symbols were presented at the locations of the targets for 50 ms. A fixation cross was presented at the position of the central target before each trial began, but was removed 50-100 ms (randomized between trials) before the stimulus onset. *b*, Possible locations of the test flash relative to the discrimination target T1. Fixation point is on T2, where the central target was presented. T1 represents the peripheral target; solid lines represent the two cardinal directions from T1 that were used for presenting the test flash. The test flash could be placed in one of 12 positions (indicated by the solid circles). These positions are relative to T1; when T1 appeared in another direction all the possible positions would rotate in this direction. We used the same configuration for experiments involving central and peripheral target discrimination.

The results of experiments in which observers had to identify the peripheral target are shown in Fig. 2*a*. The results are presented as the difference between the frequency of correct detection when the test flash was presented, P(detect), and the false alarm rate, P(FA), representing the frequency of observers falsely reporting the presence of the test flash. As the distances between the test flash and the discrimination target were varied in each block of trials, the same false alarm rate was measured for all distances, so an increase in $[P(\text{detect}) - P(\text{FA})]$ reflects

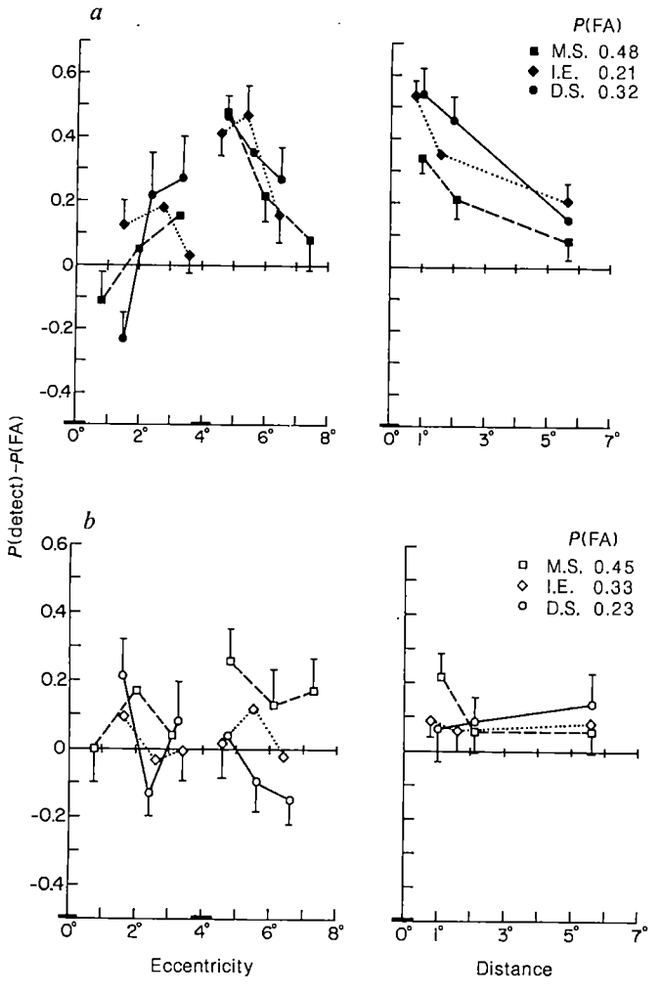

Fig. 2 *a*, Data from experiments in which observers had to identify the peripheral target. Plot on the left shows the dependence of $P(\text{detect}) - P(\text{FA})$ on the radial distance of the test flash from the fixation point, the peripheral target here being at 4° eccentricity. Plot on the right shows the dependence of $P(\text{detect}) - P(\text{FA})$ on the distance from the peripheral target along an equi-eccentricity circle; data for the clockwise and anticlockwise directions were combined. Data shown are for three observers: M.S. and D.S., who performed an orientation discrimination task with SOA(target) = 60 ms for M.S. and 70 ms for D.S. Observer I.E. discriminated between T and L with SOA(target) = 120 ms. For all observers SOA(·) was 60 ms. *b*, Same as *a*, but discrimination was performed on the central target. Target discrimination rates were 0.90 ± 0.01, 0.90 ± 0.02 and 0.89 ± 0.02 in *a* and 0.86 ± 0.02, 0.84 ± 0.02 and 0.83 ± 0.02 in *b* for observers I.E., D.S. and M.S., respectively.

an increase in correct detection for each observer. When examining detection rates for the test flash at different positions in the radial direction, at different eccentricities, a clear enhancement was seen at about 4° eccentricity, where the discrimination target was presented (Fig. 2*a*, left). The same increase in detection rate was seen along the constant eccentricity direction in the vicinity of the discrimination target (Fig. 2*a*, right). To prevent contamination, the test flash was never presented closer than 0.6° from the target centre. To ensure that the increase in detection rate did not originate from trials in which incorrect discriminations were made, we kept the error rate on the discrimination task low by adjusting the masking delay (SOA) for each observer, so that the performance on the discrimination task was ~90% correct (see Fig. 2 legend) for all observers (although one of us served as observer, the other two observers were unaware of the purpose of this study). Surprisingly, the detection rate was lower at positions between the central target (fixation point) and the

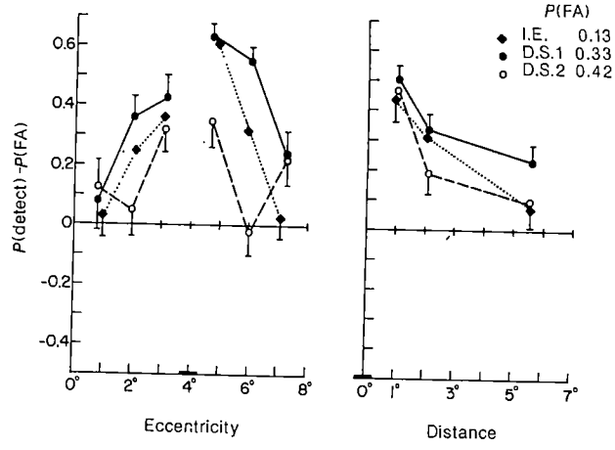

Fig. 3 The same as Fig. 2*a*, but without presentation of the central target. Note that detection at locations between the fixation point and the peripheral target is improved. Data shown are for observers I.E. (T/L discrimination) and D.S. (expt 1, T/L discrimination; expt 2, vertical/horizontal discrimination).

peripheral target than at more peripheral positions. Experiments in which the central target was absent yielded a more symmetrical enhancement around the peripheral target (see Fig. 3). Thus the area of highest detection rate is not around the fixation point, but is shifted to the location of the target being identified; this is demonstrated in a plot of $[P(\text{detect}) - P(\text{FA})]$ isocontours (Fig. 4). The two regions of enhancement were reconstructed from the data of two experiments, a new one with the peripheral target at 2° eccentricity and the one with the peripheral target at 4°, as in Figs 2, 3. The size of the enhancement area is larger at the larger eccentricity, having a diameter about twice that of the enhancement area at 2° eccentricity.

Next we attempted to confirm that this enhancement originated from the discrimination task that our observers were performing, rather than from the presence of the target itself. The presence of the target might cause luminance interaction between itself and the test flash or might bias the observers to detect the test flash when it is located near the target. We performed additional experiments using the same stimuli, but

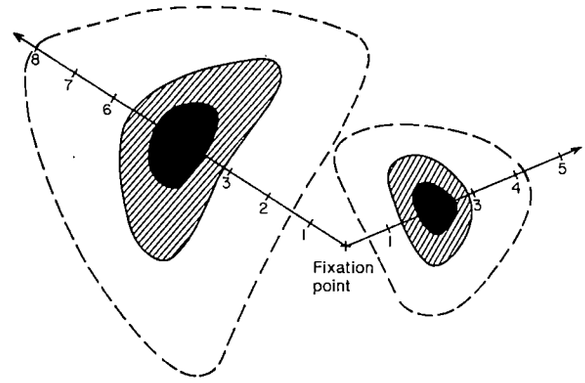

Fig. 4 Test flash detection isocontours plotted at two different eccentricities for observer D.S., in experiments such as those of Fig. 2*a*. The broken lines represent the borders of the enhancement areas where correct detection of the test flash is about the same as without enhancement (Fig. 2*b*), approaching the 'false alarm' rate; within the shaded area the detection rate is more than twice the false alarm rate, and in the solid area about three times the false alarm rate. Note that the linear size of the enhancement area scales linearly with eccentricity, being about twice the size at 4° than at 2°.

asked the observers to perform discrimination on the central target; the results of these experiments are shown in Fig. 2*b*. The enhancement around the peripheral target disappeared, and performance everywhere was close to chance level [P(detect) ~ P(FA)], with about the same false alarm rates as in the previous experiments). There was also no clear improvement at positions close to the central target. This lack of enhancement might be a result of the coarse sampling used, as the size of the enhancement area around the centre of gaze might be smaller than that at the peripheral positions. This decrease in size would be consistent with that seen with decreasing eccentricity (see Fig. 4).

When attention is focused on the discrimination task, does it cause a change of sensitivity or a change of criterion for detection of the test flash? The psychophysical method we used to investigate this question does not allow a direct answer as it was designed to maximize test-flash position uncertainty and to force attention shifts to the discrimination target. To obtain an answer, we would have to present the test flash at known locations on each block of trials, but that might have allowed the observers to shift their attention to the expected location of the test flash, a strategy we wanted to avoid. As a result, the false alarm responses from all locations were combined, thus it is unknown whether there was an increase in false alarm rate in the vicinity of the discrimination target resulting from the discrimination process. However, the false alarm rates measured using the peripheral target were not significantly larger than those for the central target (FA differences of 0.03 ± 0.06, -0.12 ± 0.06, 0.09 ± 0.08 for the three observers; ±s.e.m.).

We conclude, therefore, that visual discrimination involves a process that increases the probability of detecting a nearby test flash. This increase is not due to the presence of the target to be identified nor is it due to any expectation that the test flash will be found at a particular position, cued by the discrimination target, but results from discriminating the target. At present we cannot decide whether the observed visual enhancement is caused by some sensitivity or criterion change, but we find that this enhancement is involved in a task as simple as discriminating between vertical and horizontal lines. This result indicates that even a simple discrimination task cannot be performed passively by the visual discrimination system. The enhancement might be a property of the serial attentive process that is required for discrimination of orientation[4]. According to our finding, the size of the area processed by the attentive system is scaled with eccentricity, having an average diameter of ~3° at 4° eccentricity, and ~1.5° at 2° eccentricity. Interestingly, this area is the same for the two tasks that we used—orientation discrimination (vertical versus horizontal) and positional relationship discrimination (T versus L). It is possible that the area of visual enhancement that we have plotted here is the 'searchlight' of attention.

Phorbol esters block a voltage-sensitive chloride current in hippocampal pyramidal cells

Daniel V. Madison*, Robert C. Malenka & Roger A. Nicoll†

Departments of Pharmacology and Physiology, University of California, San Francisco, California 94143, USA

The importance of second-messenger systems in controlling the excitability of neurones and other cells, through modulation of voltage- and calcium-dependent ionic conductances, has become increasingly clear. Cyclic AMP[1-3], acting via protein kinase A[4-6], has been identified as the second messenger for several neurotransmitters, and recent studies have suggested that activation of protein kinase C may have similar modulatory actions on neurones[7-11]. Calcium and potassium currents have so far been shown to be the major ionic conductances modified by kinase activation[4-11]. We now report that hippocampal pyramidal cells contain a previously undescribed voltage-dependent chloride current which is active at resting potential and is turned off either by membrane depolarization or by activation of protein kinase C by phorbol esters. We propose that this current may reside predominantly in the cell's dendritic membrane and thereby may regulate dendritic excitability.

In 53 out of 55 rat hippocampal pyramidal cells in which K^+ currents were blocked (see Fig. 1 legend), voltage clamp recording with Cl^--containing microelectrodes revealed slow inward current relaxations, in response to hyperpolarizing steps from depolarized holding potentials. These current relaxations appeared to be caused by the turning on of an inward current, as the amplitude of the instantaneous current jump at the beginning of a hyperpolarizing step was smaller than that at the end, suggesting an increase in membrane conductance during the step (Fig. 1*a*). In addition, the amplitude of the instantaneous currents produced by short-duration hyperpolarizing voltage steps increased during the inward current relaxation produced by a long hyperpolarizing voltage step, and returned slowly to baseline amplitude when the membrane potential was stepped back to the holding potential (V_H) (Fig. 1*b*). This is in contrast to the M-current (I_M) recorded in conditions where K^+ currents are present, which turns off with similar voltage steps[12]. Also in contrast to I_M, this current was insensitive to muscarinic receptor activation. This slow inward current was voltage-sensitive over a wide range of membrane potentials (Fig. 1*c*). As determined by steady-state conductance measurements, the current was completely inactive at membrane potentials postive to approximately −10 mV, was largely active at the resting potential (−55 to −70 mV in these cells), and was fully activated at potentials negative to −90 mV (Fig. 1*c*). These voltage values could be overestimates of the actual voltage-sensitive range of the current if it was generated at a site electrotonically remote from the recording electrode in the soma (see below). Relaxations caused by this current could also be evoked by holding the cell at relatively hyperpolarized levels and turning it off with depolarizing commands (see Figs 1*e*, 2*b*).

We suspected that the ionic carrier of this current was chloride because currents carried by K^+, Ca^{2+} and Na^+ should be effectively blocked in the medium used in our experiments (see Fig. 1 legend). Indeed, when cells were impaled with electrodes containing the anion methyl sulphate ($MeSO_4^-$), hyperpolarizing steps produced an outward current (Fig. 1*d*(ii), $n = 11$), rather than an inward current as invariably seen in cells recorded with Cl^--filled electrodes (Fig. 1*d*(i), $n = 53$). The reversal potential of this current was determined with both Cl^- and $MeSO_4^-$-containing microelectrodes. With the former, when cells were held at hyperpolarized levels and depolarizing steps of increasing size were applied, a turning off of the current was observed, resulting in outward current relaxations which reversed to inward relaxations at a membrane potential of about +15 mV in the cell illustrated (Fig. 1*e*(i)). The average reversal potential of this current with Cl^- in the recording electrode was

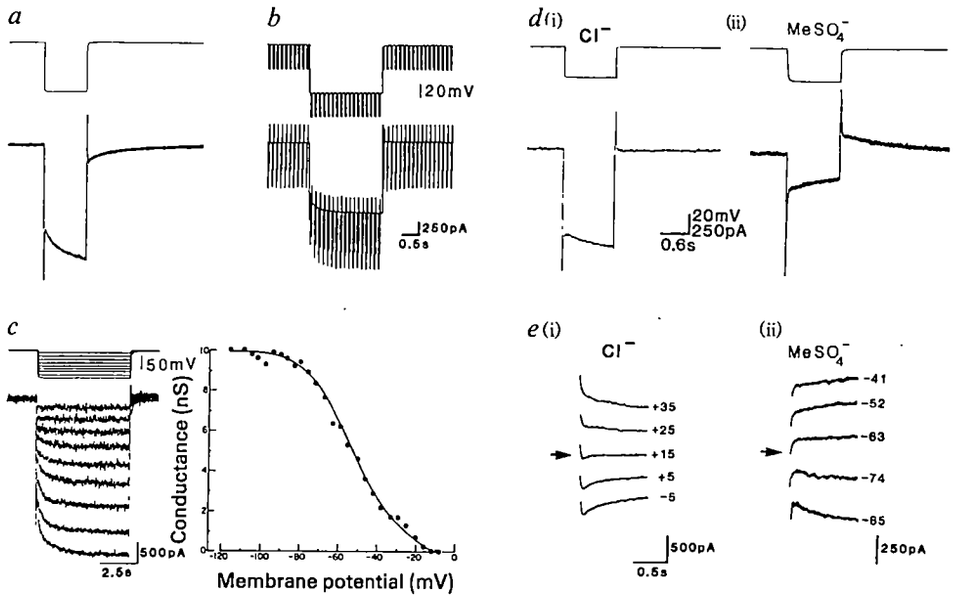

Fig. 1 A voltage-dependent chloride current ($I_{Cl(V)}$) in hippocampal pyramidal neurones. ***a***, A voltage- and time-dependent inward relaxation of membrane current in response to a 1-s hyperpolarizing voltage command from a holding potential (V_H) of −10 mV. An inward tail current follows the return to V_H. This cell was recorded with a CsCl (3 M)-filled microelectrode. ***b***, Short-duration hyperpolarizing pulses superimposed on a long-duration hyperpolarizing voltage step show an increase in membrane conductance during the developing inward current relaxation, and a slow return to resting conductance following return to V_H, although little tail current is visible due to the proximity of V_H to E_{Cl}. CsCl-filled microelectrode, $V_H = +5$ mV. ***c***, Membrane currents resulting from a family of long-duration hyperpolarizing commands from a V_H of −4 mV. A plot of the steady-state membrane conductance during the illustrated voltage commands (value plotted is the steady-state conductance during hyperpolarizing commands minus the steady-state conductance at V_H). CsCl-filled microelectrode. ***d*(i)**, Hyperpolarizing 1-s command from a holding potential of −20 mV in a cell impaled with a KCl-filled microelectrode produces an inward current. ***d*(ii)**, A similar voltage step in a cell impaled with a $KMeSO_4$-filled microelectrode produces an outward current; $V_H = -20$ mV. ***e*(i)**, Tracings of current relaxations produced by depolarizing voltage commands from a holding potential of −50 mV to the voltage indicated at the right of each trace (in mV) in a cell impaled with a KCl-filled microelectrode. ***e*(ii)**, Tracings of current relaxations produced by hyperpolarizing steps from a holding potential of −21 mV to the voltage (in mV) indicated at the right of each trace in a cell impaled with a $KMeSO_4$-filled microelectrode. The arrows indicate the approximate value of the reversal potential. Calibrations in *a* are the same as in *d*. Records in *a*, *b* and *d* were photographed from chart records; those in *c* were digitized on a Nicolet 4094 digital oscilloscope and plotted on a Hewlett-Packard 7470A digital plotter; those in *e* were traced by hand from chart records.

Methods. Rat hippocampal slices were prepared and maintained as described previously[19]. Intracellular recordings were made from the cell bodies of pyramidal neurones. Microelectrodes were made from thin-wall glass capillaries (Omega Dot; 1.2 mm o.d., 0.9 mm i.d.; Glass Company of America) and contained 3 M CsCl, 3 M KCl or 2 M potassium methyl sulphate ($KMeSO_4$). Membrane currents were recorded with an Axoclamp-2 single-electrode voltage clamp (Axon Instruments, Burlingame, California). Electrodes were coated to within ~50 μm of the tip with M-coat D (Measurements Group Inc., Raleigh, North Carolina) and the tips were dipped in mineral oil just before use to electrode capacitance. The voltage-clamp head-stage output was monitored continuously and the switching frequency adjusted to the maximum rate, which still allowed the electrode voltage to settle completely between oscillations, usually between 3 and 7 kHz. The superfusing medium used in most experiments was designed to block K^+, Ca^{2+} and Na^+ currents and consisted of (mM): NaCl, 70; KCl, 2.5; $MgSO_4$, 16; $NaHCO_3$, 26.2; glucose, 11; TEA as chloride, 30; CsCl, 10; and tetrodotoxin (TTX), 0.5 μM. Our standard medium consisted of (mM): NaCl, 119; KCl, 2.5; $CaCl_2$, 2.5; $MgSO_4$, 1.3; NaH_2PO_4, 1; $NaHCO_3$, 26.2; glucose, 11. Phorbol ester solutions were prepared and bath-applied as described previously[8].

+9.5 ± 6.6 mV (mean ± s.d., $n = 10$), which is in the range expected for Cl^--mediated events in Cl^--loaded pyramidal cells[13]. With $MeSO_4^-$ in the recording electrode, the outward current produced by hyperpolarizing steps reversed to an inward current at about −70 mV in the cell illustrated (Fig. 1*e*(ii)), and the average reversal potential was −71 ± 5.2 mV ($n = 8$). The large difference between the reversal potentials in cells recorded with Cl^-- and $MeSO_4^-$-containing electrodes indicates that Cl^- ions are the primary charge carrier for this current.

The evidence presented in Fig. 1 indicates that pyramidal cell membranes contain a voltage-sensitive Cl^- current that is turned off by depolarization. This current, which we will refer to as $I_{Cl(V)}$, resembles in many respects Cl^- currents described in peripheral and invertebrate systems[14–17]. However, $I_{Cl(V)}$ differs from a similar current found in *Aplysia* neurones[15,16] in that it does not require intracellular Cl^- loading for its detection. Like the similar voltage-sensitive Cl^- current found in rat superior cervical ganglion cells[17], $I_{Cl(V)}$ is blocked by cadmium (100 μM, $n = 3$), although it is clearly not dependent on Ca^{2+} influx because it is unaffected by medium containing 16 mM Mg^{2+} and no added Ca^{2+} (see Fig. 1).

The application of the phorbol esters 4β-phorbol-12,13-diacetate (PDAc) or 4β-phorbol-12,13-dibutyrate (PDBu), known to activate protein kinase C[18], caused a near-total abolition of $I_{Cl(V)}$ at all membrane potentials examined in all 11 cells tested (Fig. 2*a*). The blockade occurred regardless of the intracellular anionic composition, as the current relaxations seen with Cl^-- ($n = 7$; Fig. 2*b*(i)) or $MeSO_4^-$-filled microelectrodes ($n = 4$; Fig. 2*b*(ii)) were abolished by phorbol esters. When cells were held at −50 mV, a potential at which $I_{Cl(V)}$ is tonically active (see Fig. 1*c*), the application of phorbol esters to the bathing medium caused opposite shifts in the standing current depending on the anion contained in the microelectrode. When recording with Cl^--containing microelectrodes, phorbol esters caused a marked outward shift in standing membrane current which was associated with a decrease in membrane conductance (Fig. 2*c*(i)), whereas recording with a $MeSO_4^-$-containing electrode not only reversed the direction of the $I_{Cl(V)}$ relaxations (Fig. 2*b*(ii)), but also reversed the direction of the shift in standing current when phorbol ester was applied (Fig. 2*c*(ii)). This is to be expected because when the microelectrode contains the impermeant $MeSO_4^-$, the Cl^- current should be in the outward direction rather than inward as it was when Cl^- was in the electrode. The small size of the inward shift with $MeSO_4^-$ is due to the proximity of the holding potential to the reversal potential of $I_{Cl(V)}$. An analogue of phorbol, 4α-phorbol-12,13-didecanoate (10 μM), which has been shown in other systems not to activate protein kinase C[18], had no effect on $I_{Cl(V)}$ ($n = 5$), suggesting that the blockade of $I_{Cl(V)}$ by PDBu and PDAc results from the activation of protein kinase C. The effect of phorbol esters on $I_{Cl(V)}$ is not mediated synaptically, as these effects

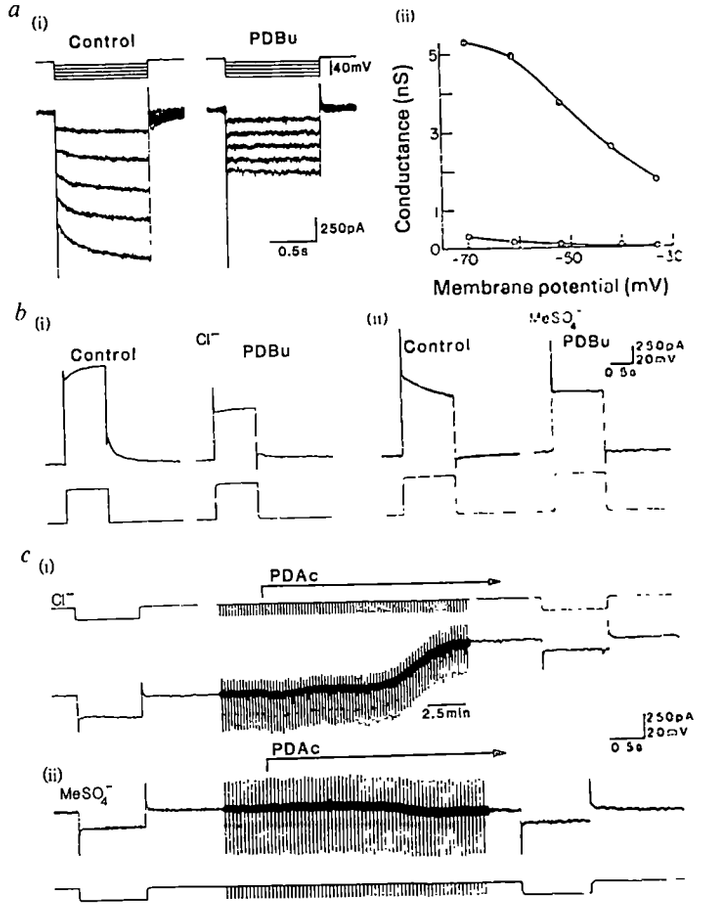

Fig. 2 $I_{Cl(V)}$ is blocked by phorbol esters. ***a*(i),** A family of currents resulting from hyperpolarizing voltage commands from a V_H of −35 mV in a control and 20 min after application of 10 μM 4β-phorbol-12,13-dibutyrate (PDBu). The substantial decrease in resting conductance caused by PDBu was presumably due to the fact that the holding potential of −35 mV was well within the range of $I_{Cl(V)}$ activation (see Fig. 1*c*); CsCl-filled microelectrode. ***a*(ii),** A plot of steady-state membrane conductance against membrane potential corresponding to the traces in *a*(i) (as in Fig. 1*c*) in control medium (closed circles) and in PDBu-containing medium (open circles). ***b*,** Depolarizing steps, which turn off $I_{Cl(V)}$, produce outward current relaxations and an outward tail current in cells impaled with CsCl-filled microelectrodes (i) and inward relaxations and tail currents in cells impaled with $KMeSO_4$-filled microelectrodes (ii) (V_H in both cases −50 mV). These current relaxations and tail currents were abolished by 10 μM PDBu regardless of the recording anion used. ***c*(i),** Effects of 4β-phorbol-12,13-diacetate (PDAc) (10 μM) on the resting membrane conductance and current at a holding potential of −50 mV in a cell impaled with a KCl-filled microelectrode. In this condition, PDAc caused an outward shift in resting membrane current and a decrease in membrane conductance, as measured by the instantaneous current produced by 10-mV hyperpolarizing steps. ***c*(ii),** Same as *c*(i) except in a cell impaled with a $KMeSO_4$-filled microelectrode. In this case PDAc (10 μM) caused an inward shift in resting current and a decrease in membrane conductance. The bathing medium for all experiments was the same as for Fig. 1. Records in *a* were digitized on a Nicolet 4094 oscilloscope; *b* and *c* were photographed from chart records.

occur in medium containing no added Ca^{2+} and high (16 mM) Mg^{2+}.

Although we found no direct evidence for the membrane localization of this current, we were unable to detect $I_{Cl(V)}$ in our somatic voltage-clamp recordings in the absence of K^+-channel blockade. One of several explanations might account for this finding. First, the use of intracellular Cs^+ ions and/or extracellular tetraethylammonium (TEA) or Cs^+ could themselves enhance the size of this current. This seems unlikely as $I_{Cl(V)}$ could be seen clearly after blockade of the M-current and Ca^{2+}-activated K^+ current using bath-applied carbachol (40 μM) in otherwise standard medium ($n = 4$; not shown). Second, prior blockade of K^+ currents may be necessary for the detection of $I_{Cl(V)}$ because K^+ currents with voltage sensitivities and kinetics similar to $I_{Cl(V)}$ may mask the Cl^- current present in the somatic membrane. $I_{Cl(V)}$ present in the somatic membrane should contribute substantially to somatic resting input resistance because this current is active at membrane potentials near the resting potential. However, $I_{Cl(V)}$ does not seem to contribute significantly to the resting conductance measured at the soma, as phorbol esters do not increase somatic input resistance in standard medium and in fact usually cause a small decrease (ref. 8, but see ref. 7). We favour a third possibility, that a substantial portion of this current is generated at a site electrotonically remote from the soma, perhaps in the dendritic membrane. In this case, blockade of resting K^+ currents would lengthen the space constant of the cell and allow voltage steps imposed at a somatic site to be more effective in eliciting changes in $I_{Cl(V)}$ in the dendrites and would also enhance passive propagation of this current back to the recording site at the soma.

Although a physiological role for $I_{Cl(V)}$ remains to be demonstrated, it is active at the resting membrane potential, and therefore should contribute substantially to the resting conductance of the membrane at which it is located. If this current is present in dendritic membranes, its blockade by activation of protein kinase C could, by increasing dendritic membrane resistance, increase the transmission of dendritic excitatory events, such as excitatory postsynaptic potentials, to the spike trigger zone in the soma/initial segment.

Phorbol ester facilitates ^{45}Ca accumulation and catecholamine secretion by nicotine and excess K^+ but not by muscarine in rat adrenal medulla

Arun R. Wakade, Ravindra K. Malhotra & Taruna D. Wakade

Department of Pharmacology, State University of New York, Downstate Medical Center, 450 Clarkson Avenue, Brooklyn, New York 11203, USA

Several investigators have shown that tumour promoter phorbol esters mimic the effects of endogenous diacylglycerol to activate a second messenger, protein kinase C (refs 1–3). These phorbol esters have proved to be valuable tools for exploring the role of protein kinase C in many cellular functions[3–8]. We demonstrate here that secretion of catecholamines evoked from the rat adrenal gland[9,10] by stimulation of splanchnic nerves, excess potassium (K^+) and nicotine is facilitated by phorbol 12,13-dibutyrate. An inhibitor of protein kinase C, polymixin B, produced concentration-dependent inhibition of the evoked secretion, and the effect was reversed by the phorbol ester. Furthermore, we show that an increase in the accumulation of radioactively labelled calcium (^{45}Ca) obtained in the adrenal medulla after stimulation with nicotinic agonists and excess K^+ is further enhanced by phorbol ester. Muscarine-evoked secretion of catecholamines, which depends on mobilization of intracellularly bound Ca^{2+}, was not associated with an increase in $^{45}Ca^{2+}$ uptake, and phorbol ester did not facilitate either catecholamine secretion or $^{45}Ca^{2+}$ accumulation. We suggest that protein kinase C is involved in the exocytotic secretion of catecholamines by regulating the influx of Ca^{2+} through voltage-sensitive and nicotine receptor-linked Ca^{2+} channels of rat chromaffin cells.

Figure 1 shows that increasing concentrations of phorbol 12,13-dibutyrate (phorbol ester) produce a concentration-dependent increase in catecholamine secretion evoked by stimulation of splanchnic nerves. Secretion increased significantly at 1 nM, more than trebled at 10 nM and was maximal at 30 nM. At 1–30 nM, phorbol ester had no effect on the spontaneous secretion of catecholamines, but 100 nM produced a modest increase in the secretion (16±2 compared with 4±3 ng per 6 min, $n=12$). The inset of Fig. 1*a* shows that phorbol ester facilitated the secretion evoked at 1 Hz and 10 Hz; however, the degree of facilitation was significantly ($P<0.001$) greater at 1 Hz. The most commonly used activator of protein kinase C, 12-*O*-tetradecanoylphorbol 13-acetate (TPA), also enhanced catecholamine secretion evoked at 1 Hz by about fivefold (58±7 compared with 276±31 ng per 6 min, $n=7$). On the other hand, a non-tumour promoter, phorbol 13-acetate, even in high concentrations (up to 1,000 nM), did not modify catecholamine secretion at rest or after stimulation. The enhancing effect of phorbol ester was reversed within 15 min after the washout, whereas that of TPA lasted for at least 2 h after its washout (not shown).

Several compounds inhibit the activity of protein kinase C isolated from pig heart and rat brain[12,13]. As shown in Fig. 1*b*, polymixin B caused concentration-dependent (10–100 μg ml^{-1}) inhibition of the secretion. The inhibitory effect was fully reversible 30 min after washout of the drug (not shown). Furthermore, prior treatment of the adrenal medulla with 50 nM phorbol ester partially reversed the inhibitory effects of 100 μg ml^{-1} polymixin B, almost prevented the inhibitory effects of 30 μg ml^{-1} polymixin B, and produced a significant enhancement in the presence of 10 μg ml^{-1} polymixin B (Fig. 1*b*).

The increased catecholamine secretion described in Fig. 1*a* could be a result of the action of phorbol ester either on splanchnic nerves to release more acetylcholine or on postsynaptic

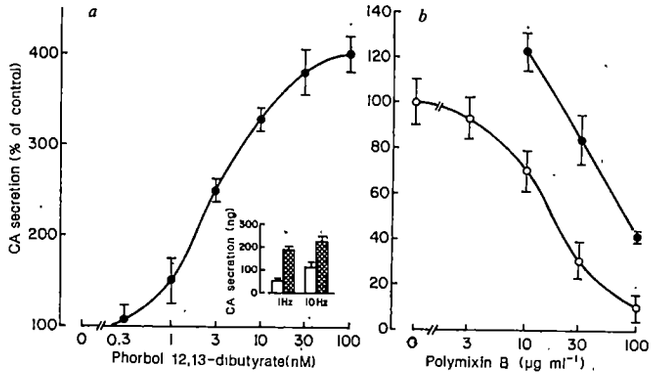

Fig. 1 *a*, Facilitation by phorbol 12,13-dibutyrate of the secretion of catecholamines (CA) evoked by stimulation of splanchnic nerves. *b*, Polymixin B-induced inhibition of catecholamine secretion evoked by nerve stimulation, and its reversal by phorbol ester. In *a*, the left adrenal glands of male rats (300–350 g) were prepared for *in vitro* perfusion as described previously[9]. The perfusion medium was Krebs–bicarbonate solution and the rate of perfusion was 0.35 ml min^{-1} at 37 °C. Ag/AgCl electrodes were used for transmural stimulation of the gland, and the parameters were set to stimulate selectively presynaptic splanchnic nerve terminals[9,10]. Splanchnic nerves were stimulated at 1 Hz (300 pulses), first without phorbol ester and then in increasing concentrations of phorbol ester (●). Each concentration remained in contact with the adrenal medulla for 15 min before collection of samples. Perfusate was collected for 6 min to determine catecholamine secretion in the absence of stimulation, and then for another 6 min, during which the gland was stimulated for 300 s. Amounts of catecholamines secreted during the immediately non-stimulation period have been subtracted from those secreted during stimulation period to obtain net catecholamine secretion, which is expressed either in per cent or in absolute values. In *a* all values are expressed as per cent of the control, which was 64±6 ng, $n=16$. The inset shows the effect of 30 nM phorbol ester on catecholamine secretion evoked by delivering 300 pulses at 1 and 10 Hz. Open columns, control; cross-hatched columns, phorbol ester–Krebs solution. Catecholamine content of the perfusate was measured directly by the fluorometric method as described elsewhere[9,11]. Adrenaline (base) was used as a standard; all values are presented as means with standard errors, and differences were compared using Student's paired *t*-test. Phorbol ester (LC Services, Woburn, Massachusetts) was dissolved in dimethyl sulphoxide and added to Krebs solution. The final dilution of the solvent in the Krebs solution was 500–100-fold. At these dilutions, the solvent alone had no effect on catecholamine secretion when added to Krebs solution. Each dot and column is a mean of four experiments. Vertical lines show s.e.m. In *b*, catecholamine secretion was evoked by stimulation of splanchnic nerves at 10 Hz (300 pulses), first in Krebs solution and then in increasing concentrations of polymixin B (○). The adrenal medulla was pretreated with each concentration for 15 min, and then nerves were stimulated in the presence of the agent. After testing the highest concentration, the adrenal gland was perfused with Krebs solution for 30 min to determine whether the inhibitory effect was reversible. In all the glands tested ($n=5$), secretion was restored to 110±14% of the initial control value. The perfusion medium was then changed over to 50 nM phorbol ester–Krebs solution for 10 min, and in its presence various concentrations of polymixin B were added (●) for 15 min and then samples (spontaneous and stimulated) collected. All values are expressed as per cent of control, which was 103±9 ng ($n=7$). The entire protocol was carried out in the same adrenal gland. Each point, except the control, represents a mean of four experiments. Vertical lines show s.e.m.

chromaffin cells to release more catecholamine from acetylcholine-induced activation of the nicotinic and muscarinic receptors[9,10]. To distinguish between these possibilities, we investigated the effect of phorbol ester on catecholamine secretion evoked by direct stimulation of chromaffin cells with cholinergic agonists as well as excess K^+ (Fig. 2).

Secretion of catecholamines evoked by nicotine, carbamylcholine and excess K^+ was approximately doubled by 30 nM phorbol ester. However, secretion evoked by muscarine, which was of the same order of magnitude as that evoked by nicotine, remained unaffected by phorbol ester. Because of these differential effects of phorbol ester, it was essential to know the role of Ca^{2+} in the secretion evoked by nicotine and muscarine. Perfusion of the adrenal gland with Ca-free and 1 mM EGTA–Krebs solution for 15 min completely blocked the secretion evoked by nicotine and muscarine (Fig. 3), and addition of phorbol ester to this medium had no effect on secretion evoked by either agent. If the same adrenal gland was perfused with 0.1 mM

Table 1 Effects of different stimulatory agents on $^{45}Ca^{2+}$ accumulation and secretion of catecholamine in absence and presence of phorbol ester

Stimulating agent	Catecholamine secretion (ng mg^{-1})		$^{45}Ca^{2+}$ accumulation (pg mg^{-1})	
	Krebs	Phorbol ester* (30 nM)	Krebs	Phorbol ester* (30 nM)
None (control)	2±0.4	2±0.4 (NS)	110±20	123±25 (NS)
Muscarine (30 μg ml^{-1})	38±4.5	41±5.1 (NS)	126±11	124±28 (NS)
Carbamylcholine (4 μg ml^{-1})	39±6.3	68±7.4 ($P<0.001$)	303±34	489±32 ($P<0.001$)
Nicotine (3 μg ml^{-1})	29±0.2	67±8.2 ($P<0.001$)	343±21	463±26 ($P<0.001$)
Excess K^+ (1.5 mg ml^{-1})	48±6.5	91±17.4 ($P<0.001$)	303±25	507±48 ($P<0.001$)

Thirty minutes after perfusion of the adrenal gland with Krebs solution, the medium was changed to Krebs solution containing 0.5 μg ml^{-1} $^{45}Ca^{2+}$ (as $^{45}CaCl_2$, specific activity 23.69 mCi mg^{-1}; NEN) for 10 min. The gland was perfused for a further 30 min with Krebs solution to wash out most of the extracellular $^{45}Ca^{2+}$. Within this time period the radioactivity in the wash fluid approaches a very low and steady-state level (~2% of that in the first 5-min period). An identical protocol was then carried out in further series of adrenal glands, except that the 10-min perfusion with $^{45}Ca^{2+}$-Krebs solution contained various secretagogues. Perfusates collected for 10 min during $^{45}Ca^{2+}$ exposure and stimulatory agents were assayed for catecholamine to ensure the expected effects of these agents on catecholamine secretion. NS, statistically non-significant; other P values show comparison between the data obtained in Krebs solution and in phorbol ester–Krebs solution.

* In another series, the above protocol was carried out, except that before exposure to $^{45}Ca^{2+}$ medium the adrenal gland was perfused with Krebs solution containing 30 nM phorbol ester for 15 min. Phorbol ester was also present during 10 min perfusion with $^{45}Ca^{2+}$ medium alone, or that containing stimulatory agent. After the 30-min wash period, the adrenal gland was removed, and the adrenal medulla separated, weighed, homogenized in 1 ml of 0.05 M perchloric acid; the homogenate was centrifuged and the supernatant (0.5 ml) was counted in a liquid scintillation counter (Beckman, model LS7000). Total counts after correction for dilution and quenching were converted to pg and expressed as pg per mg of the wet weight of the adrenal medulla. Each value represents a mean of four or five experiments.

Ca–Krebs solution and the secretion was evoked by both agents, nicotine-evoked secretion was <20% of that in 2.5 mM Ca medium, but that evoked by muscarine was ~65% of the control value. Phorbol ester increased nicotine-evoked secretion by more than 300% in 0.1 mM Ca medium, but muscarine-evoked secretion was enhanced only 15% in the same medium (statistically not significant, $P>0.5$).

The effect of phorbol ester on $^{45}Ca^{2+}$ accumulation in the adrenal medulla was investigated at rest and after stimulation with different agonists (Table 1). Although muscarine increased catecholamine secretion from a basal level of 2 ng to 38 ng, it was not accompanied by a significant increase in the accumulation of $^{45}Ca^{2+}$ over the control value. More importantly, phorbol ester did not enhance the effect of muscarine on catecholamine secretion and $^{45}Ca^{2+}$ accumulation. Catecholamine secretion evoked by carbamylcholine and nicotine, which was almost identical to that evoked by muscarine, was associated with a marked increase (275%) in $^{45}Ca^{2+}$ accumulation. In the presence of phorbol ester, the secretion was even further enhanced, and that too was associated with an additional increase (400%) in $^{45}Ca^{2+}$ uptake. K^+-evoked secretion was also accompanied by a large increase in the accumulation of $^{45}Ca^{2+}$ and was further enhanced by the phorbol ester. Catecholamine secretion and $^{45}Ca^{2+}$ accumulation under resting conditions were not affected by the phorbol ester.

Phorbol 12,13-dibutyrate significantly enhanced catecholamine secretion evoked by several procedures that activate chromaffin cells, either directly or indirectly, through the splanchnic nerves. We believe this to be the first report in which phorbol ester has produced a clear-cut facilitation of catecholamine secretion after activation of nicotinic receptors and depolarization of chromaffin cells. Furthermore, we show that an inhibitor of protein kinase C, polymixin B (ref. 13), almost completely inhibits catecholamine secretion, and the effect is reversed by the phorbol ester. This is the first example in which phorbol ester was able to overcome the inhibitory effects of an inactivator of protein kinase C to restore the secretory process. Assuming that the major target of action of phorbol ester and polymixin B in the rat chromaffin cells is the protein kinase C, it is tempting to postulate that this second messenger is involved in the exocytotic secretion of adrenal medullary hormones. Knight and Baker first studied the effects of phorbol ester on catecholamine secretion in bovine adrenal medullary cells, and found that Ca^{2+} sensitivity of the secretory process was enhanced by TPA. They therefore concluded that protein kinase C is involved in exocytosis[4]. Other investigators have reached a similar conclusion by studying the effects of phorbol ester in cultured bovine chromaffin cells and phaeochromocytoma (PC12) cells[14–16]. However, in none of these experiments was it possible to show facilitation by phorbol ester of catecholamine secretion evoked by a nicotinic agonist or excess K^+.

The next question is at which step protein kinase C participates in the process of exocytosis. We have found that the net increase in $^{45}Ca^{2+}$ accumulation obtained after stimulation of chromaffin cells with nicotinic agents and excess K^+ was further enhanced by phorbol ester. We therefore propose that protein kinase C may actually control the transport of Ca^{2+} entering through nicotinic receptor-operated and voltage-sensitive Ca^{2+} channels of the chromaffin cells. Recently, it has been reported that

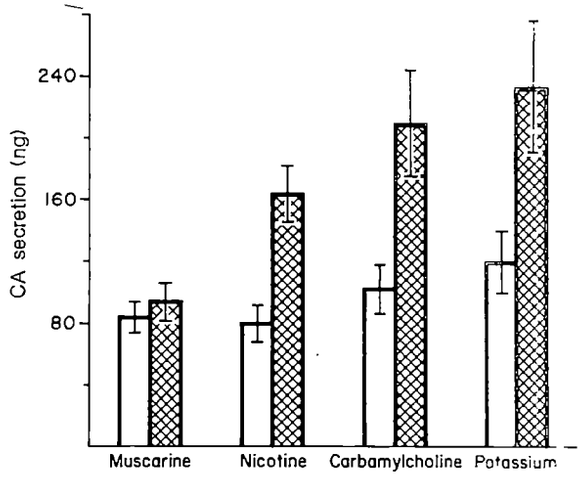

Fig. 2 Effects of phorbol ester on catecholamine secretion evoked by nicotinic agonists, muscarine and excess K^+. Adrenal gland was perfused with Krebs solution and secretion was then evoked by injecting muscarine (30 μg) and nicotine (0.3 μg) (open columns) within 20 min of each other. The perfusion medium was then changed to Krebs solution containing 30 nM phorbol ester for 15 min and in its presence muscarine and nicotine were injected (cross-hatched columns), as described above. The same protocol was carried out in another series of adrenal glands, except that nicotine was replaced with either carbamylcholine (4 μg) or KCl (40 μg) before (open columns) and after (cross-hatched columns) 30 nM phorbol ester. All agents were injected in a total volume of 100 μl saline. Each column is a mean of 5 experiments, except the column for muscarine, which is a mean of 10 experiments. Vertical lines represent s.e.m.

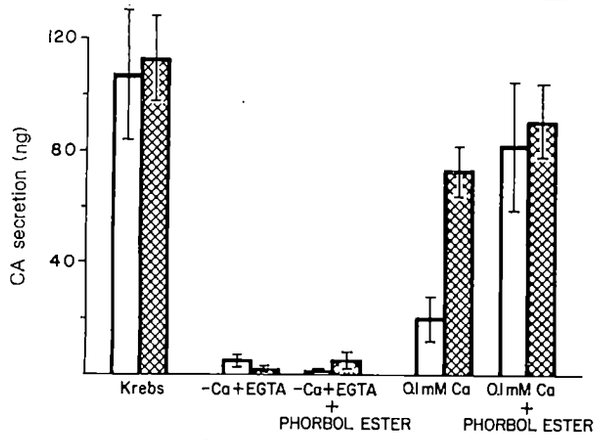

Fig. 3 Role of Ca^{2+} in the enhancement of catecholamine secretion evoked by nicotine and muscarine. Secretion was evoked by nicotine (open column) and muscarine (cross-hatched column), as described in Fig. 2 legend, in Krebs solution, Ca^{2+}-free plus 1 mM EGTA-Krebs solution and 0.1 mM Ca^{2+}-Krebs solution, before and after addition of 30 nM phorbol ester to various solutions. The adrenal gland was perfused with each solution for 15–30 min before sample collection. The entire protocol was carried out in the same adrenal gland. Each column represents a mean of four experiments. Vertical lines represent s.e.m.

injection of purified protein kinase C into *Aplysia* neurones or treatment with phorbol ester enhances the potential-sensitive membrane Ca^{2+} current[17]. It is likely that protein kinase C regulates the activity of Ca^{2+} channels by phosphorylating membrane proteins involved in opening and closing these channels. Protein kinase C-induced phosphorylation of different types of proteins associated with cytosol, cytoskeleton and other unidentified cell organelles of neuronal tissues has been documented[18–22]. Our present work shows that phorbol ester alone does not increase catecholamine secretion and has no effect on $^{45}Ca^{2+}$ accumulation. This means that active protein kinase C itself cannot affect the kinetics of Ca^{2+} channel opening and that their opening depends on other intracellular messengers generated by nicotinic receptor activation and membrane depolarization.

Another important finding leading to our proposal that protein kinase C regulates Ca^{2+} channels was the inability of phorbol ester to increase muscarine-evoked catacholamine secretion and of muscarine to increase $^{45}Ca^{2+}$ accumulation in either the absence or presence of phorbol ester. Note that Ca^{2+} is essential for muscarine-evoked secretion. These results clearly demonstrate the differential modes of Ca^{2+} mobilization by nicotinic and muscarinic agonists in the rat chromaffin cells; nicotine enhances the influx of extracellular Ca^{2+}, whereas muscarine mobilizes intracellularly bound Ca^{2+}. In bovine adrenal medullary cells, muscarine produces a modest rise in intracellular Ca^{2+} that is independent of external Ca^{2+} (ref. 23), however this increase in Ca^{2+} concentration does not lead to catecholamine secretion[24]. In the rat chromaffin cell, muscarine must mobilize large amounts of intracellular Ca^{2+} to raise its levels sufficiently high to initiate secretion. Because muscarine-evoked secretion is unaffected by phorbol ester, it is likely that the role of protein kinase C is restricted to the events regulating the influx of extracellular Ca^{2+} rather than those affecting the steps involved in the utilization of Ca^{2+} in exocytosis.

Natural cell-mediated cytotoxic activity in the mouse has been associated with two types of effector cells, the natural killer (NK) cell and the natural cytotoxic (NC) cell, which seem to differ with regard to their patterns of target selectivity, cell surface characteristics and susceptibility to regulatory factors[1]. During studies on the mechanism of action of cytotoxic molecules, it became evident that WEHI-164, the prototype NC target cell, was highly susceptible to direct lysis by both human and mouse recombinant tumour necrosis factor (TNF). Here we show that NC, but not NK activity mediated by normal splenocytes, is abrogated by rabbit antibodies to recombinant and natural TNF, respectively. Thus, the cell-mediated activity defined as NC is due to release of TNF by normal spleen cells and does not represent a unique natural effector mechanism.

The prototype target for detection of mouse NK activity is the YAC-1 lymphoma cell line[2], whereas WEHI-164 cells are the main targets used to selectively measure NC activity[1,3]. Mouse NK cells have been shown to express asialo-GM_1, and the alloantigens of Ly5, Qa5, NK1 and NK2, on the cell surface[2,4,5]. Some mouse NK cells also express Thy-1 antigen. In contrast, treatment of cells bearing any of these markers with antibody plus complement has little effect on NC activity[1,3,6]. NK activity is quite rapid, with close to maximum levels achieved within 4 h, whereas NC activity usually requires incubation periods of 18 h or longer[1,5]. NK activity has been shown to be strongly augmented by pretreatment of the effector cells with interferon or interleukin-2 (refs 5, 7, 8), whereas NC activity has been shown to be enhanced primarily by interleukin-3 (refs 7, 9). Mouse NK activity, analogous to previous findings with human and rat NK cells[5], has been closely associated with a morphological counterpart, the large granular lymphocyte[5]. In contrast, it has proved difficult to directly associate NC activity with any specific cell type[5,9], raising the possibility that this activity is not a direct cell-mediated event. In addition to the

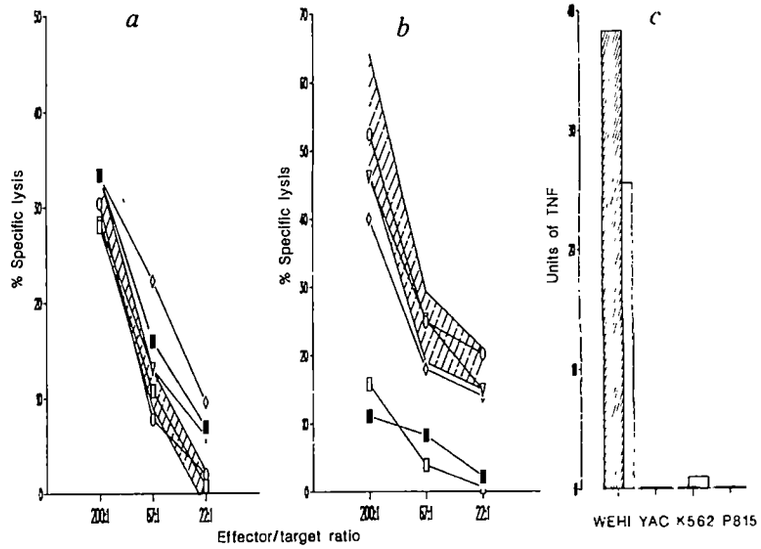

Fig. 1 *a, b,* Effect of antisera or monoclonal antibodies on cell-mediated lysis of YAC-1 (NK) and WEHI-164 (NC) cells, respectively. *c,* TNF stimulation by various target cells. The per cent specific lysis of ^{51}Cr-labelled WEHI-164 and YAC-1 targets in an 18-h or 4-h assay[8,9] is shown in *a* and *b*, respectively. Effector cells from 7-week-old C57BL/6 mice were tested at various effector/target cell ratios (200:1, 67:1 and 22:1, with 5,000 targets per well) in a standard microcytotoxicity assay[8]. The specific lysis above that obtained in control medium is shown. The shaded area represents the control level of cytotoxicity (mean ± s.d.) mediated by untreated spleen cells. A final 1:40 dilution of each antibody was added to the assay. Similar results were seen with a 1:200 final dilution, with approximately 50% inhibition of cytotoxicity seen with antisera to mouse TNF (data not shown). ■, Rabbit anti-TNF-1 antiserum (300 TNF neutralizing units); □, rabbit anti-TNF-2 antiserum (300 TNF neutralizing units); ○, monoclonal anti-human TNF antibody (1,000 TNF neutralizing units); ▽, monoclonal anti-human LT antibody (1,000 LT neutralizing units); ◇, normal rabbit serum (obtained from a pre-bleed for anti-TNF-1 antiserum). Similar results to those for NRS were seen with two other normal rabbit sera (data not shown). *c,* Plot of units per ml of TNF produced during co-culture of nylon-passed C57BL/6 spleen cells (2×10^6) with various targets: NK (K562-human NK; YAC-mouse NK), NC (WEHI) or NK/NC-insusceptible (P815). Supernatants from reactions with effector splenocytes/target cell ratios of 200:1 (▨) or 50:1 (□) were collected after 18 h, filtered and units of mouse TNF determined relative to a recombinant mouse TNF standard curve. Controls consisting of cells alone and targets alone yielded no detectable TNF production (data not shown).

incomplete characterization of the NC effector cells, there is also little information available concerning the mechanism of cytotoxicity of NC cells. In contrast, recent studies have indicated that a highly cytolytic protein in the granules of large granular lymphocytes has a key role in the cytotoxic activity of NK cells[10]. Also, NK cells have been shown to release a soluble cytotoxic factor (NKCF) on interaction with NK-susceptible target cells[11]. Thus, it was of considerable interest to determine whether a similar mechanism of cytotoxicity was used by NC cells.

During re-examination of the spectrum of cytotoxic activity reported for human tumour necrosis factor (TNF)[12], we found that WEHI-164 cells were highly susceptible to the effects of this cytotoxic factor, which raised questions regarding the possible role of TNF in the mechanism of cytotoxicity of NC cells. We have found that WEHI-164 cells are highly susceptible to both recombinant mouse TNF and recombinant human TNF. In addition, NC activity by mouse spleen cells was strongly inhibited by two independently produced rabbit antisera raised against mouse TNF. Thus, the cell-mediated cytotoxicity defined as NC activity appears to be attributable to release of TNF *in vitro* by normal mouse spleen cells. These data also indicate that this cytokine may be produced spontaneously by certain normal cells and thereby contribute to natural cell-mediated cytotoxicity.

Table 1 shows the susceptibility of WEHI-164 cells to lysis by purified recombinant mouse TNF (Biogen SA) and by recombinant human TNF[13] (provided by Dr M. Shepard, Genentech, Inc., South San Francisco). Both recombinant TNFs had cytolytic activity against WEHI-164 cells but had little effect on YAC-1, the classical mouse target cells for NK activity. To confirm that the activities observed were indeed due to TNF,

Table 1 Effect of anti-TNF and anti-LT antibodies on lysis of WEHI-16 cells by recombinant mouse or human TNF

	% Specific lysis in TNF in the presence of various antibodies						
		WEHI-164					
Agent (U ml^{-1})	YAC-1	None	Anti-TNF-1	Anti-TNF-2	Monoclonal anti-TNF	Monoclonal anti-LT	NRS
MuTNF (500)	2.2	68.8	13.3	36.8	78.5	80.4	76.8
MuTNF (50)	2.1	54.6	11.6	33.7	62.5	57.5	52.5
MuTNF (5)	0.5	41.4	NT	NT	NT	NT	NT
HuTNF (500)	3.2	65.3	NT	NT	10.2	68.7	NT
HuTNF (50)	−1.1	56.7	NT	NT	5.4	54.3	NT
HuTNF (5)	0.1	44.3	NT	NT	1.3	40.3	NT

The per cent specific lysis of ^{51}Cr-labelled WEHI-164 target cells in an 18-h release assay is shown[8,9]. The results presented indicate the per cent release of ^{51}Cr above the background of spontaneous release in medium alone. The table shows the effects of rabbit anti-mouse TNF-1 (300 TNF neutralizing units), rabbit anti-mouse TNF-2 (300 TNF neutralizing units), monoclonal anti-human TNF antibody (1,000 TNF neutralizing units), monoclonal anti-human LT antibody (1,000 LT neutralizing units), and normal rabbit serum (NRS) obtained from a preimmunization bleeding of the rabbit used for production of anti-TNF-1. The assay was performed as described previously[8,9]. Recombinant human (Hu) and mouse (Mu) TNF were purified from *Escherichia coli* cells containing HuTNF and MuTNF gene-encoded plasmids. The cells were broken using a Manton-Gaulin press. The TNF in the supernatant was then purified using DEAE-Sepharose CL6B, phenyl-Sepharose CL4B and Sephacryl S-200. The proteins were purified to greater than 97% purity with a specific activity of 3×10^7 U mg^{-1} for MuTNF and 1.5×10^7 U mg^{-1} for HuTNF. One unit of TNF, as defined previously[12], is the amount resulting in 50% inhibition of growth of the L929 cell line. Anti-MuTNF antiserum was produced in a New Zealand White female rabbit by intradermal immunization at multiple sites with a suspension of purified mouse TNF (200 μg ml^{-1} in phosphate-buffered saline, 1 ml) in Freund's complete adjuvant (1 ml); this was followed by a booster injection at 1 month. Serum was obtained 10–14 days after the boost. The rabbit produced satisfactory titres of antibody (<3,000) as determined by enzyme-linked immunosorbent assay. Various concentrations of recombinant mouse or human TNF preparations were added to labelled target cells in the presence of various concentrations of antisera or monoclonal antibodies. A final 1:40 dilution of each antibody was added to the assay. NT, not tested.

we determined the effects of specific anti-TNF antibodies. The cytotoxicity of recombinant mouse TNF for WEHI-164 target cells was inhibited strongly by two different rabbit antisera, raised independently against either the purified natural mouse cytokine (anti-TNF-1) or recombinant mouse TNF (anti-TNF-2). In contrast, monoclonal antibody to human TNF or lymphotoxin (LT), or normal rabbit serum (NRS), had no significant effect on the cytotoxicity of recombinant mouse TNF. However, monoclonal antibody to human TNF blocked human TNF-mediated lysis of WEHI-164 cells (Table 1). The species specificity of this monoclonal antibody suggests that the blocking effect is not dependent on the NC target, but rather on the source of TNF. It is noteworthy that YAC-1 cells were highly resistant to lysis by either human or mouse TNF. Addition of antisera against target cells had no toxic effect on NK or NC targets (data not shown).

To study more directly the possible involvement of TNF in NC activity, the antibodies to mouse TNF were added to a standard NC assay (Fig. 1). Each of these antibodies to murine TNF strongly inhibited the lysis of WEHI-164 cells by normal mouse spleen cells. Based on calculations of the lytic units, derived from the cytotoxicity data at several effector to target cell ratios, greater than 90% of the lytic activity was neutralized by each of the rabbit anti-mouse TNF antibodies. In contrast, no significant inhibition was seen with the NRS controls including sera from preimmunization bleeds, or with monoclonal antibody to human TNF or LT. Parallel experiments were performed to evaluate the possible effects of the antibodies on mouse NK activity against YAC-1 target cells. No significant inhibition of NK lysis was seen with any of the antibodies (Fig. 1). The increase in NK lysis seen at low effector/target cell ratio with selected antisera was not observed in all experiments or at higher dilutions of antisera. Thus, two antisera to mouse TNF (one raised against recombinant and the other against highly purified natural mouse TNF) selectively inhibited cell-mediated cytotoxicity against the NC target cells but had no effect on NK activity. This result further demonstrates a major distinction between these two forms of natural cytotoxicity.

We have demonstrated that NC activity against WEHI-164 target cells appears to be a cytokine-mediated phenomenon, apparently mediated by the spontaneous release of TNF during the cytotoxicity assay. The mediation of NC activity by the release of TNF may explain the prolonged incubation periods required to demonstrate this activity, in contrast to the rapid kinetics of NK activity. This notion is supported by the results in Fig. 1*c*, which demonstrate high levels of TNF production only in co-cultures with WEHI-164, but not in co-cultures with NK or other potential targets. Presumably the extended period of incubation is required for sufficient release, if not also production, of the cytokine. The association of TNF with NC activity also provides new clues as to the nature of the NC cell. TNF has been found to be produced predominantly by macrophages[12,15]. The possible derivation of NC cells from the myelomonocytic lineage would be consistent with previous evidence for adherence properties of NC cells[1,5,9], the resistance of NC activity to treatments which strongly inhibit lymphocyte numbers and functions (for example, a high dose of cyclophosphamide and anti-lymphocyte antibodies plus complement), and the ability of interleukin-3, a cytokine with multipotential colony-stimulating factor effects on monocytic cells as well as other haematopoietic cells, to promote both the growth and cytolytic activity of NC cells[5,7,9].

Our observation that TNF has a key role in NC, but not NK, activity raises the possibility of a new approach to discriminating between NC and NK activities. Although it was initially thought that most solid tumour cells were selectively sensitive to NC cells and that lymphoma cells were preferentially lysed by NK cells[9], it has recently been found that many target cells of both types are susceptible, to a certain extent, to lysis by each category of effector cells[5]. Monoclonal antibody to TNF may help to determine the contribution of NC cells to the natural cell-mediated lysis of various target cells. Also, in analogy to the present results with mouse NC cells, it will be of considerable interest to study the effects of antibodies to human TNF on the recently reported human counterpart to NC activity[14].

A block to elongation is largely responsible for decreased transcription of c-*myc* in differentiated HL60 cells

David L. Bentley & Mark Groudine*

Fred Hutchinson Cancer Research Center, 1124 Columbia Street, Seattle, Washington 98104, USA and *Department of Radiation Oncology, University of Washington School of Medicine, Seattle, Washington 98195, USA

The c-*myc* gene product is a nuclear protein[1,2] expressed in a wide variety of cell types[3]. It has been implicated in the control of normal cell growth as well as transformation[4–7], but its exact function is unknown. When the human promyelocytic leukaemia cell line HL60 is treated with retinoic acid, the cells differentiate into granulocytes, and there is a reduction in steady state c-*myc* RNA of more than 10-fold[8]. Nuclear runoff assays show that this reduction is caused by a corresponding decrease in the transcription of exon 2. However, only a minor decrease in exon 1 transcription is observed upon differentiation. In undifferentiated HL60 cells there is an approximately 3-fold molar excess of exon 1 transcription over exon 2, and this excess increases to about 15-fold in differentiated cells. This observation suggests that a major component of c-*myc* transcriptional down-regulation in HL60 cells is at the level of elongation rather than at the level of initiation. The position of the elongation block was mapped to the region of the boundary between exon 1 and intron 1. During HL60 differentiation, a DNase I hypersensitive site in the chromatin about 300 bases downstream of the 5′ end of of intron 1 increases in intensity relative to other sites, possibly reflecting events associated with the termination of transcription. Our runoff analysis also revealed transcription of both strands immediately upstream of exon 1 in HL60 cells. The sense strand transcription of this region produces a novel c-*myc* RNA which initiates several hundred bases upstream of the previously defined promoters and is found in a variety of cell types.

Large changes in c-*myc* RNA levels occur during terminal differentiation[8,9] and mitogenic stimulation of quiescent cells[5]. Both transcriptional[10] and post-transcriptional mechanisms[11] have been reported to control the transient increase of c-*myc* expression which follows mitogenic stimulation. In contrast, post-transcriptional destabilization alone has been reported to account for the reduction in c-*myc* RNA level of differentiating

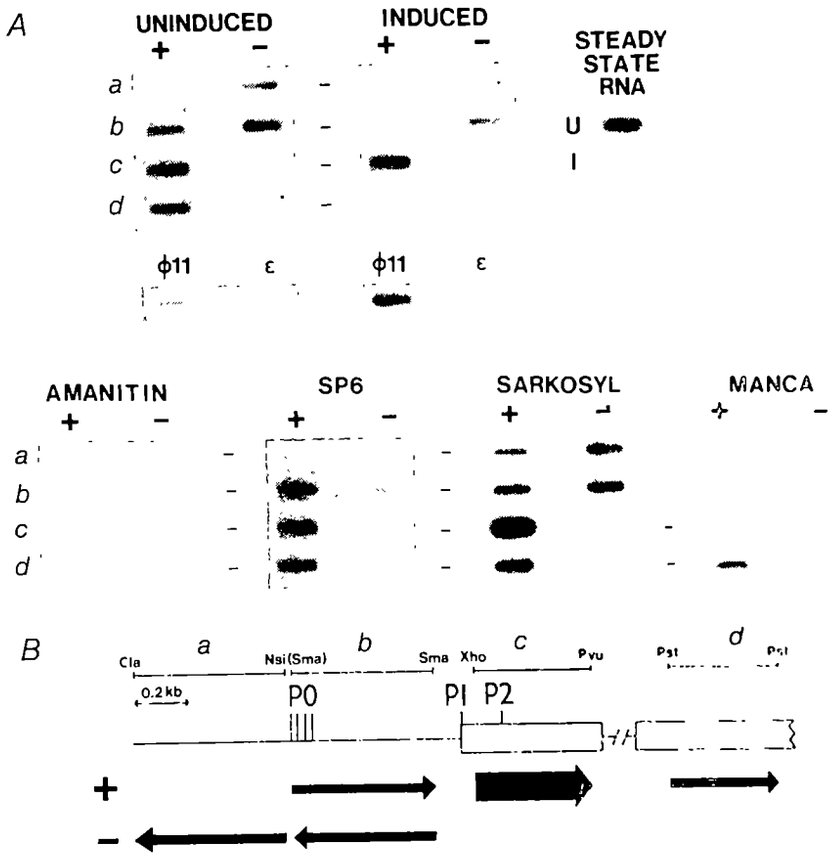

Fig. 1 Runoff transcription of c-*myc* in HL60. *Steady state RNA*: Slot blotted total RNA (4 μg) from the same cell prep used for the run-off assays shown to the left was hybridized to a ^{32}P-RNA exon 3 probe. By Northern analysis, this probe detects only genuine c-*myc* transcripts. *A*, Hybridization of RNA (15×10^6 c.p.m.) from HL60 uninduced or induced for 2.5 days in retinoic acid (1 μM). Probes marked +, detect sense transcripts and − detect anti-sense transcripts. As controls equimolar amounts of the pε 0.7 ε-globin plasmid[18] and the granulocyte specific Φ11 cDNA clone (1.4 kb) were used. *α-amanitin*: Hybridization of RNA from uninduced HL60 synthesized in the presence of 2 μg ml^{-1} α-amanitin. The number of cells used was 33% more than in untreated samples. Under these conditions the amount of rRNA synthesized is as great as in untreated samples (not shown). *SP6*: Hybridization of SP6 RNA from a full length P0 cDNA clone[19]. Transcripts were eluted from a gel and degraded in NaOH prior to hybridization. *Sarkosyl*: Hybridization of RNA from uninduced HL60 synthesized in the presence of 0.5% sarkosyl. *Manca*: Run-off transcripts from the Manca, B-cell lymphoma. *B*, Map of the restriction fragment probes, *a–d*, cloned in M13 vectors and summary of c-*myc* transcription pattern in HL60. The mapping of the P0 promoter will be published elsewhere[19]. The lengths of the probes are: *a*, 586, *b*, 535, *c*, 443, *d*, 414 bases. They were subcloned from the genomic clone pMC41-HE[20] (*a*) or the P0 cDNA clone (*b–d*).

Methods. Preparation of nuclei was as described (15) and equivalent results were obtained from fresh and frozen nuclei. The results shown except for Manca were from nuclei pretreated with 10 μg ml^{-1} RNase A for 30 min on ice[16] but identical results were also obtained with untreated nuclei. (In the latter case ^{32}P-RNA was hydrolysed with 0.3 M NaOH for 10 min on ice.) RNase was inactivated with RNasin (200 U ml^{-1}) and washing once in 500 μl nuclear freezing buffer (NFB; ref. 15) plus RNasin. The nuclei ($\simeq3\times10^7$) were then resuspended in 210 μl of NFB and the runoff reaction performed as in ref. 17. The ^{32}P-RNA was on average 100 bases long. Hybridizations to 0.5 μg of single-stranded M13 DNA slot blotted in 20×SSC were carried out at 0.3 M NaCl and 65 °C for 36–40 h followed by washing in 0.1×SSC, 0.1% SDS at 65 °C (ref. 17). Washing the filters at 72 °C did not alter the signal ratio of the c-*myc* probes. Autoradiographs were exposed for 2 days.

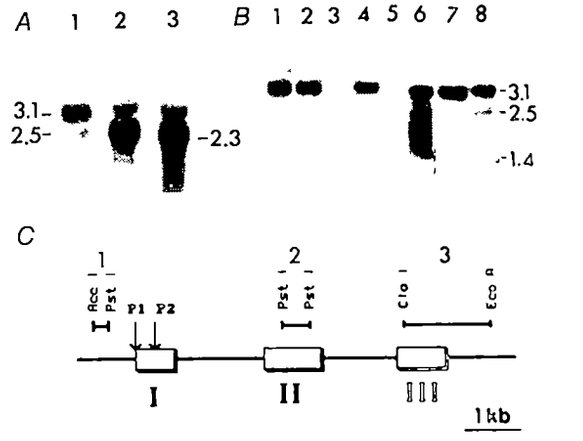

Fig. 2 *A*, Northern blot of c-*myc* RNAs in HL60 cells. Lanes 1–3: Poly (A)$^+$ RNA (10 μg) was analysed by hybridization to the corresponding nick-translated restriction fragments in Fig. 1*c*. Autoradiography was for 20 h, 1 h, and 1 h for lanes 1, 2 and 3 respectively. *B*, P0 transcripts in different cell types. Northern filters containing poly(A)$^+$ RNA (1–5 μg) were hybridized to an antisense strand ^{32}P-RNA of fragment 1 (Fig. 1*c*). as in ref. 24. Autoradiography was for 1–5 days. Lane 1, KG1; 2, KC122; 3, EBV transformed B lymphoblasts; 4, EM3; 5, K562; 6, foreskin fibroblasts, passage 5; 7, COLO-320 neuroendocrine carcinoma; 8, 293 embryo kidney cells. Lanes 1,2 4 and 5 contain RNA from myeloid leukaemia cell lines. *C*, Map of the human c-*myc* gene. The three exons, the P1 and P2 promoters and fragments 1–3 which were used as hybridization probes, are marked.

F9 embryonal carcinoma and mouse erythroleukaemia cells[9]. We have investigated transcription of the amplified c-*myc* genes in HL60 using a nuclear runoff assay. In this assay, short labelled RNAs (approximately 100 bases) are synthesized by polymerases *in situ* and hybridized to an excess of a cloned probe. Assuming a constant elongation rate, the hybridization signals from different probes reflect the number of RNA polymerase molecules present in corresponding regions of the gene. We initially examined transcription in four regions of the c-*myc* gene, labelled *a–d* in Fig. 1, using single-stranded M13 probes for both strands. The cloned restriction fragments were of similar length so as to be approximately equally efficient hybridization targets.

As shown in Fig. 1, transcription of exons 1 and 2 is highly strand-specific, and the amount of exon 1 transcription is greater than that of exon 2 by an average of 3-fold (range 2–5) in uninduced cells and 15-fold (range 9–24) in induced cells. Each of these values is the average of four independent determinations made by densitometry of autoradiograms. Background signal was not subtracted, so the average value of 15 for the ratio of exon 1 to exon 2 transcription in differentiated cells is a minimum estimate. To ensure that the high exon 1 signal is not due to

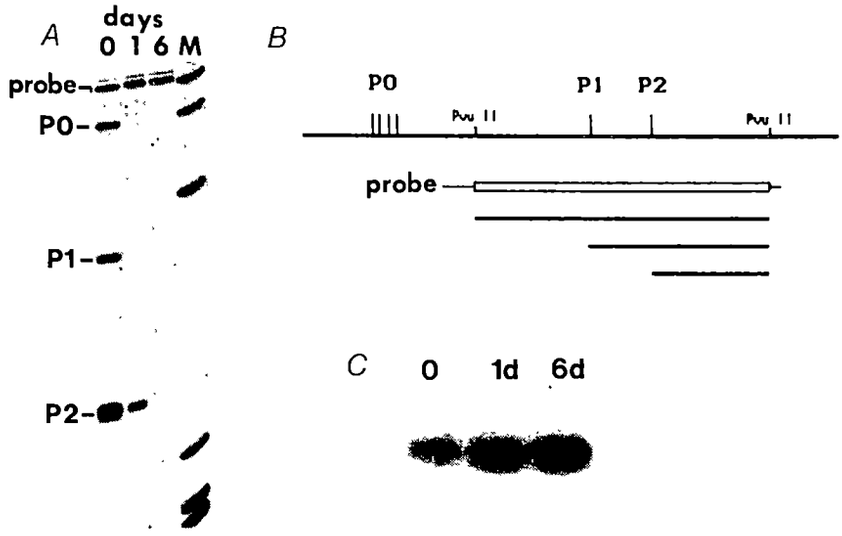

Fig. 3 *A*, S_1 analysis of c-*myc* RNA during retinoic acid induced differentiation of HL60 cells. Markers (*M*) are 1,078; 872; 603; 310; 278 and 271 bases. *B*, Strategy for S_1 mapping. The probe is depicted with thin lines for M13 vector sequence and an open bar for c-*myc* sequence. The solid lines below represent S_1 resistant fragments characteristic of P0, P1 and P2 RNAs. *C*, Northern blot of actin RNA. Samples of 1 μg of the same RNA samples as in Fig. 3*A* were analysed by hybridization to a ^{32}P-RNA probe from the chicken β-actin gene[26] (3 h exposure).

Methods. The probe in *A* was a uniformly labelled single-stranded fragment (prepared as in ref. 25) including 862 bases between two *Pvu*II sites and about 200 bases of M13 vector sequences. Samples of 1 μg poly $(A)^+$ RNA from uninduced cells labelled 0, and from cells treated with retinoic acid for 1 day (21 h) and 6 days were analysed. 0.5 ng of probe (25,000 c.p.m.) was hybridized to RNA in 10 μl of 0.5 M NaCl, 20 mM PIPES, *p*H 6.4, 1 mM EDTA at 65 °C for 3 h, then digested in 100 μl containing 350 mM NaCl, 30 mM Na-acetate, *p*H 4.5, 1 mM $ZnSO_4$, 1,200 U ml^{-1} S_1 nuclease (BRL) for 40 min at 37 °C followed by ethanol precipitation and electrophoresis on a 4.5% acrylamide 7 M urea gel. (2.5 day expsoure).

cross-hybridization with other transcribed sequences in the genome, we analysed runoff transcripts in another human cell line which was expected to have little or no exon 1 transcription. This line was the B-cell lymphoma Manca which has a single active c-*myc* allele that is disrupted in the first intron such that exons 2 and 3 are transcribed from cryptic promoters under the influence of the immunoglobulin heavy chain enhancer[12]. In contrast to HL60, Manca, showed an excess of exon 2 transcription over exon 1 (Fig. 1). This result rules out the possibility of a highly transcribed sequence in the human genome which spuriously hybridizes to our exon 1 probe. In addition, ^{32}P-RNA corresponding to the anti-sense strand of probe C (Fig. 1) hybridizes to a unique band in Southern blots of HL60 and placental DNA (data not shown), thereby eliminating the possibility that the molar excess of exon 1 signal over exon 2 is due to the presence of amplified truncated c-*myc* genes containing exon 1 but not exon 2 sequences in HL60. The unequal signals obtained with exon 1 and exon 2 probes are not the result of differential hybridization efficiency since these two probes hybridized equally well to SP6 RNA from a cDNA clone (Fig. 1). The excess exon 1 transcription also does not represent artifactual initiation resulting from the nuclear isolation and runoff procedures, since the pattern of transcription in both uninduced (Fig. 1) and induced cells (data not shown) is unaffected by concentrations of sarkosyl (0.5%) which block Pol II initiation but not elongation[13]. The slight differences between the 'uninduced' and 'sarkosyl' runoff experiments shown in Fig. 1 are within the normal range of variation between experiments. Transcription of all parts of the gene assayed was sensitive to 2 μg ml^{-1} α-amanitin, demonstrating that these transcripts are synthesized by RNA polymerase II[14] (Fig. 1). The high level of exon 1 transcription is apparently due to a high polymerase density throughout this exon and not a pile up of polymerases at its 5′ end, since an equally high signal relative to probe length was obtained when the 5′ 150 bases of probe C were deleted (data not shown).

Transcription of exon 2 sequences was down-regulated by over 90% when the cells were induced to differentiate for 2.5 days. This transcriptional regulation (Fig. 1) fully explains the reduction in steady state c-*myc* RNA in this cell preparation (see Fig. 1) without the need to invoke post-transcriptional control. Our result confirms a previous report[21] in which a v-*myc* probe homologous to exons 2 and 3 was used to monitor transcription. As a positive control for the transcriptional activity of differentiated cells, we monitored the induction of a gene called Φ11, which was selected from an HL60 cDNA library by a differential screening procedure (D.B., unpublished).

In contrast to exon 2, there was only a 10–20% down regulation of exon 1 transcription during HL60 differentiation in four experiments. At least part of the modest transcriptional down regulation of exon 1 is due to reduced transcription from upstream of the gene (see below). These results suggest that the major c-*myc* promoter, P2, is not turned off during HL60 differentiation. We cannot eliminate the possibility that the P1 promoter is turned off, since it seems to be a minor transcriptional start site based on steady state RNA measurements (see Fig. 3 below). The maintenance of a high transcription rate of exon 1 in differentiated cells while exon 2 transcription declines to background levels suggests that inhibition of elongation between exons 1 and 2 is an important component of the c-*myc* down-regulation in HL-60.

An unexpected result of the runoff assay was the detection of transcription upstream of exon 1 on both strands, at a level almost as great as that of exon 2. The observed hybridization is not due to homology with another part of the genome since nick-translated fragment *b* (Fig. 1) hybridized to a unique sequence in a Southern blot of genomic DNA (data not shown). In addition, the bidirectional transcription signal does not result from a lack of strand specificity of the probes, as demonstrated by asymmetric hybridization of SP6 RNA synthesized from a cDNA clone (Fig. 1). The origin of anti-sense transcripts was mapped to a *Sma*I-*Nae*I fragment that extends from 101 bases upstream of P1 to 49 bases downstream of P2 (data not shown). This fragment contains two TATA box homologies which might promote transcription: a GATAAA at 2,483–2,488 and a TATAAA at 2,298–2,303 of the sequence in ref. 22 as well as the distal element consensus, CCGCCC at 2,531–2,536. Divergent transcription from the area of the major promoter of the mouse dihydrofolate reductase (DHFR) gene has also been observed[23]. Perhaps these two cases of divergent transcription are indicative of a more widespread lack of absolute polarity in promoter function. Anti-sense transcription originating about

100 bases upstream of the major mouse DHFR promoter produces a cytoplasmic, spliced polyadenylated RNA with an open reading frame. We have been unable to detect such a stable anti-sense RNA from the c-*myc* gene in HL60 or human fibroblasts; therefore, we presume that the anti-sense transcripts are very unstable.

In contrast, we did detect sense strand transcripts of the region upstream of P1 in steady-state RNA. Northern blots of HL60 RNA revealed a 3.1-kilobase (kb) c-*myc* RNA which hybridizes to a probe (Fragment 1, Fig. 2*C*) spanning 409–608 bases upstream of the P1 promoter (Fig. 2*A*, lane 1). A minor 2.5-kb RNA is also detected by this upstream probe. The 3.1-kb species also hybridized to exon 2 and exon 3 specific probes (Fig. 2*A*, lanes 2 and 3). Full length cDNAs of both these RNA species have been isolated and characterized, and the 5′ ends of these RNAs were mapped to a promoter called P0 located 550–650 bases upstream of P1[19]. Several human cultured cell lines as well as primary fibroblasts were surveyed by Northern blot hybridization with the upstream probe, and all of them contain the 3.1-kb transcript (Fig. 2*B*), although usually as a lower proportion of c-*myc* RNA than observed in HL60. Thus, transcripts initiating upstream of the first exon appear to be found wherever the c-*myc* gene is expressed.

The regulation of P0, P1, and P2 RNAs during differentiation of HL60 into granulocytes was examined using an S1 protection assay (Fig. 3*B*). The results (Fig. 3*A*) show that steady-state levels of P0, P1 and P2 RNA are coordinately reduced when the cells differentiate. RNA levels declined to less than 10% of their original amounts after 21 hours when there is no overt morphological differentiation, and to undetectable levels after 6 days when differentiation is complete. As a control for the integrity of these RNA samples, a Northern blot was hybridized to an actin probe, and a slight increase in the amount of actin RNA was observed in the differentiated HL60 cells (Fig. 3*C*).

The relative amounts of RNA from the three c-*myc* promoters in HL60 were measured by cutting out the gel bands in Fig. 3*A*, lane 0 and counting them. After compensating for the number of labelled nucleotides in each fragment, it was calculated that P0, P1, and P2 contributed 7%, 12% and 81% of c-*myc* RNA respectively. The small amount of steady-state P0 RNA contrasts with the relatively high transcription rate from this promoter as judged by the nuclear runoff assay. This result implies that the majority of P0 transcripts are less stable than P1/P2 transcripts.

We next examined whether HL60 differentiation was accompanied by a change in the chromatin fine structure of the c-*myc* gene. DNase I hypersensitive sites in the c-*myc* gene of undifferentiated and differentiated HL60 cells were mapped using the indirect end-labelling strategy in Fig. 4*A*. The result demonstrates two major differences in chromatin structure on treatment with retinoic acid for 3 days. Hypersensitive site 2 (II_2 in ref. 28) which is located about 100 bases upstream of the P0 promoter disappears, as previously reported[29], whereas site 4 located in the first intron is enhanced relative to the other sites upon differentiation. Note also that the relative intensities of site 1 (1.85 kb upstream of P1) and site 3 (between P1 and P2) are unchanged after retinoic acid treatment. The disappearance of site 2 correlates with turn-off of the P0 promoter (Figs 1 and 3) which appears to be regulated independently of the major promoters P1 and P2. The persistence of site 3 (III_2 in ref. 28) correlates with maintenance of a high exon 1 transcription rate in differentiated cells (Fig. 1).

The position of hypersensitive site 4 about 300 bases into the first intron, and its induction during differentiation suggest that it may be associated with the block to elongation of transcription between exons 1 and 2. We therefore analysed transcription of the intron 1 sequences around this hypersensitive site in differentiated HL60 cells (Fig. 4*b*). The results show a sharp drop in the transcription downstream of probe A (Fig. 4*b*) which extends to the *Pvu*II site 40 bases upstream of the exon 1 splice donor. The apparent site of the transcriptional block

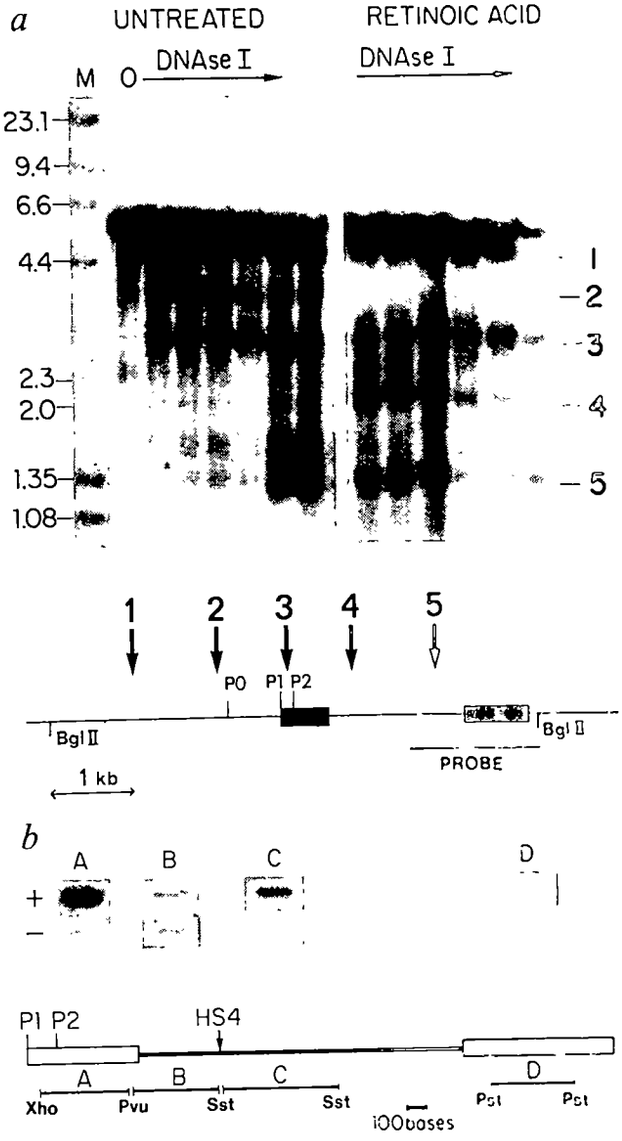

Fig. 4 *a*, DNase I hypersensitive sites in differentiating HL60. *b*, Run-off transcription of HL60 cells induced with retinoic acid for 2.5 days.

Methods. *a*, DNA from DNase I digested nuclei was restricted with *Bgl*II, blotted and hybridized[27] to the nick translated 1.5 kb *Sac*I fragment spanning exon 2. The map shows the 5′ portion of the gene including the first two exons and marks the five hypersensitive sites. (The minor sites II_1 and III_1[28] were not clearly resolved.) Lane M, marker; Lane 0, no DNase I. Arrows indicate increasing extents of DNase I digestion. HL60 was induced with 1 μM retinoic acid for 3 days. Methods for *b* were as in Fig. 1. + and − refer to probes which detect sense and anti-sense transcripts, respectively. Lengths of probes: A, 443; B, 430; C, 606; D, 414 bases.

therefore maps to the 3′ end of exon 1 or the 5′ end of intron 1 several hundred bases upstream of hypersensitive site 4. One testable hypothesis is that sequences near this hypsersenstive site function at a distance to influence the process of termination which occurs upstream. It is of interest that several stretches of T residues occur in the region of the elongation block defined in Fig. 4*b*: T_7, T_4 and T_7 occur 17, 64 and 74 bases downstream of the *Pvu*II site near the end of exon 1. Such sequences have previously been implicated in the termination of transcription. Pol III terminates at the 3′ end of *Xenopus* 5S RNA genes within clusters of four or more T residues[30]. Furthermore, in two cases of termination by Pol II the phage λ 4S gene[31] *in vitro* and the human gastrin gene *in vivo*[32], the 3′ termini map to clusters of

five or more T residues. Similarly, premature termination downstream of the adenovirus 2 major late promoter *in vivo* occurs near a cluster of 5 T residues[33,34]. Further analysis is required to establish whether the T-rich sequence near the exon 1-intron 1 border of the c-*myc* gene also functions as a terminator.

Our nuclear runoff analysis of c-*myc* transcription in HL60 led to the discovery of a novel c-myc RNA initiating several hundred bases upstream of the major promoters. In addition, perhaps the most striking feature of the transcription pattern revealed here is the molar excess of exon 1 over exon 2 transcription observed in HL60 (Fig. 1) and also in HeLa and COLO 320 cells (data not shown). In this respect, our results differ from those of Blanchard *et al.*[11] who concluded that there was equimolar transcription throughout the c-*myc* gene in Chinese hamster lung fibroblasts. The explanation for this discrepancy could be the different cell types used. However, it is possible that the results of Blanchard *et al.* were biased against exon 1 by using non-homologous human probes. Exon 1 sequences have diverged considerably more between human and mouse than have the protein coding sequences of exons 2 and 3[35]. The excess of exon 1 over exon 2 transcription which is accentuated from approximately 3- to 15-fold when HL60 cells differentiate, suggests a block to transcriptional elongation which can be modulated to control synthesis of full-length c-*myc* RNA. We have mapped the site of this block to the region of the boundary between exon 1 and intron 1. Although premature termination at this site seems likely, we cannot rule out the alternative of transcriptional pausing. In either case an elongation block, rather than decreased initiation, seems to account for the reduced exon 2 transcription in differentiated HL60 cells, and hence the reduced steady-state c-*myc* RNA level. Control of gene expression by blocking elongation is a flexible mechanism that allows modulation of transcription without requiring assembly an disassembly of the transcriptional apparatus. It will be of interest to determine whether this mechanism operates in other eukaryotic genes whose transcription is rapidly regulated.

Idealization of the hydrophobic segment of the alkaline phosphatase signal peptide

Debra A. Kendall, Susan Clark Bock & Emil Thomas Kaiser

Laboratory of Bioorganic Chemistry and Biochemistry, The Rockefeller University, New York, New York 10021, USA

Proteins secreted by prokaryotic cells are synthesized as precursors containing an amino-terminal extension sequence or signal peptide[1]. Although these signal peptides share little primary sequence homology, recent studies suggest that they function via common pathways during the transport process[2] and that a common element may reside in their secondary structural characteristics[3–7]. We are investigating the role of an idealized hydrophobic sequence with high potential for α-helix formation in the *Escherichia coli* alkaline phosphatase signal peptide. Here, amino-acid substitutions were made using site-directed mutagenesis to produce a mutant signal sequence containing nine consecutive leucine residues in the hydrophobic core segment. Transport studies with this mutant precursor indicate that mature alkaline phosphatase is correctly targeted to the *E. coli* periplasm and that processing of the precursor to the mature form of the enzyme is extremely rapid. In contrast, processing is slowed when the mutant signal sequence is lengthened by the insertion of five additional leucine residues and one serine.

The alkaline phosphatase signal peptide, like other signal sequences, is characterized by a positively charged amino-terminus, a central hydrophobic core and a cleavage site recognized by the signal peptidase[1]. Previous studies suggest that the hydrophobicity[8] and helix-forming potential[5,6,9] of the residues in the core region are important to signal peptide function. The unambiguous evaluation of the importance of these features has been complicated, however, as these studies often involve peptides of varied amino-acid composition. To optimize the potential to form an α-helical, hydrophobic domain and minimize problems in interpretation due to heterogeneity in amino-acid content, we have designed a mutant alkaline phosphatase signal sequence having a core region consisting of nine leucine residues. Leucine is an ideal amino acid for this approach as it is hydrophobic, has a substantial propensity to adopt an α-helical conformation[10,11] and, fortuitously, already occurs five times in the alkaline phosphatase signal peptide. A similar approach has been used successfully to determine the requirements for amphiphilic secondary structures in peptide hormones, using chemically synthesized analogues[12].

The mutant signal peptide, denoted 13A (see Fig. 1), was constructed by making single amino-acid substitutions during each of four successive rounds of site-directed mutagenesis. In each round, a synthetic oligonucleotide primer containing the DNA sequence for the desired amino-acid substitution was annealed to single-stranded phage DNA from M13mp19 into which the structural gene[13] for alkaline phosphatase (*phoA*) had been cloned. After elongation of the mutagenic primer and a second 'universal' primer[14] located 5′ to it, followed by ligation, the double-stranded phage DNA was used to transform *E. coli* strain AW1043F′ Amp (Δ*lac galU galK* Δ(*leu-ara*) *phoA-E15 proC* : : Tn*5* F′Amp). Mutant phage were identified by screen-

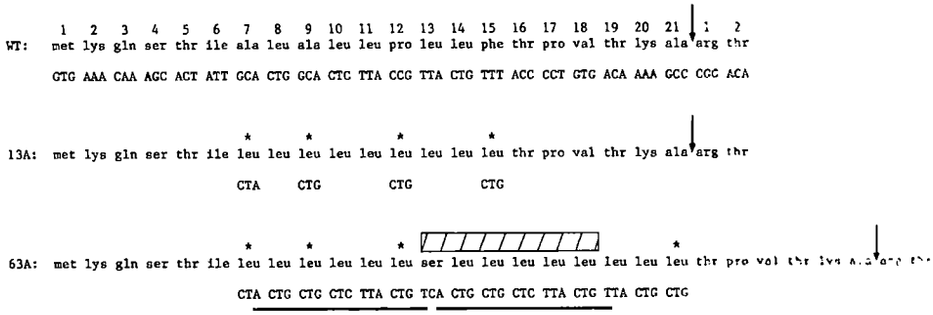

Fig. 1 Amino-acid and DNA sequences of wild-type (WT) and mutant alkaline phosphatase signal peptides. The amino-terminal 23 codons of the precursor DNA are shown in sense-strand polarity, together with the corresponding amino-acid residues and the signal processing site (arrow). Amino-acid substitutions used to construct mutants 13A and 63A are indicated by asterisks. Residues inserted into the hydrophobic core of the mutant 63A sequence are indicated by a hatched bar, and the DNA sequence repeated in this mutant is underlined. The DNA sequences of mutants 13A and 63A are identical to wild type except for the nucleotides shown.

ing plaque lifts with the ^{32}P-labelled oligomer used for mutagenesis, and subsequently verified by direct DNA sequencing[15]. Single-stranded template containing this mutant sequence was then used during the next round of mutagenesis.

During mutagenesis, an additional mutant containing an insertion of six amino-acid residues was isolated. This insertion resulted in a sequence of 14 leucine residues with a serine at the centre of this hydrophobic core (denoted 63A; see Fig. 1). The 63A mutant contains a 17-base-pair direct repeat, and probably arose from DNA replication or repair errors.

For transport studies, 2.5-kilobase DNA fragments containing the mutant *phoA* genes were subcloned into pBR322 between the *Bam*HI and *Hin*dIII sites and the resultant plasmids were used to transform *E. coli* strain AW1043 (Δ*lac galU galK* Δ(*leu-ara*) *phoA-E15 proC* : : Tn*5*). This strain contains a partially deleted alkaline phosphatase gene and a wild-type *phoR* regulatory gene[13,16].

Since a secretion-competent signal peptide directs export of alkaline phosphatase to the *E. coli* periplasm, we analysed the contents of this cellular compartment for the presence of the mature enzyme. Cells that harboured wild-type or mutant plasmids were labelled with ^{35}S-methionine for 1.5 min, washed, then treated with lysozyme to release the contents of the periplasm. Protein from the periplasmic fraction and an aliquot of whole cells were immunoprecipitated with rabbit anti-alkaline phosphatase antiserum, then analysed by SDS-polyacrylamide gel electrophoresis and autoradiography. Analysis of the periplasmic fraction for mutant 13A (Fig. 2) demonstrated that mature alkaline phosphatase was transported efficiently and correctly and localized within the periplasmic space. The protein from this fraction co-migrated with purified bacterial alkaline phosphatase (data not shown). No acccumulation of precursor was observed in the whole-cell sample from this mutant.

Analysis of mutant 63A (Fig. 2) also showed release of mature alkaline phosphatase into the periplasm but, in contrast to 13A, some accumulation of precursor in immunoprecipitates of whole cells was observed. We have found that the precursor form of the 63A mutant has a slightly greater electrophoretic mobility than the wild-type precursor; this may reflect changes in SDS binding caused by the introduction of extra hydrophobic residues rather than aberrant processing. Similar changes of electrophoretic mobility for mutant precursors have been noted in other systems[17].

To assess the effect of the signal mutations on alkaline phosphatase processing, the rate of conversion of the precursor to the mature form was determined in pulse-chase experiments. Cells were radiolabelled with ^{35}S-methionine for 40 s, then chased with cold methionine for the times indicated in Fig. 3. The chase was stopped by adding trichloroacetic acid (TCA), then the cells were extracted with acetone. After extract solubilization, alkaline-phosphatase-immunoreactive material was isolated and analysed by SDS-PAGE and autoradiography. Analysis of the ratio of the precursor to the mature form of alkaline phosphatase in the pulse-chase experiment shown in Fig. 3 indicates that cleavage of the mutant 13A signal peptide was rapid. Within the detection limits of our experiment, there was

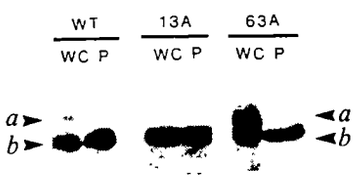

Fig. 2 Localization of alkaline phosphatase in *E. coli* transformed with wild-type, mutant 13A or mutant 63A plasmids. Arrows indicate the positions of the precursor (*a*) and mature forms (*b*) of alkaline phosphatase. WC, whole cell; P, periplasm.
Methods. Cultures of *E. coli* were washed and resuspended in MOPS (morpholinopropanesulphonate) medium[21] supplemented with amino acids at 20 μg ml^{-1}, minus methionine. The cells were labelled with 100 μCi ^{35}S-methionine for 1.5 min. Labelling was stopped by adding ice-cold 200 mM sodium azide, 10 mM dinitrophenol and 200 μg ml^{-1} chloramphenicol as described previously[2]. Half the culture was pelleted and washed with cold acetone. Protein was solubilized with 10 mM Tris *p*H 8.0, 1% SDS, 1 mM EDTA by boiling for 3 min. Following dilution by the addition of 50 mM Tris *p*H 8.0, 150 mM NaCl, 0.1 mM EDTA, 2% Triton X-100, the clarified supernatant was immunoprecipitated essentially as described by Ito *et al.*[22]; this constituted the whole-cell fraction. The remaining portion of the culture was washed with 33 mM Tris *p*H 7.5, 30 mM NaCl, then resuspended in 20% sucrose, 30 mM Tris *p*H 7.5, 1.0 mM EDTA containing 50 μg ml^{-1} lysozyme for 20 min on ice[23]. After centrifugation, the supernatant which constituted the periplasmic fraction was immunoprecipitated[22]. The immune precipitates from whole cells and the periplasm were then analysed by SDS-PAGE under reducing conditions[24].

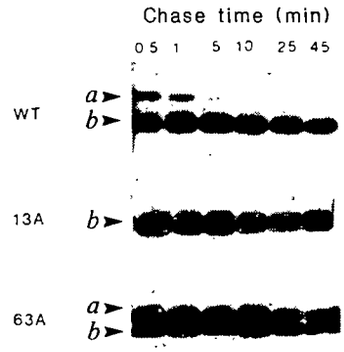

Fig. 3 Kinetics of alkaline phosphatase maturation in *E. coli* strains carrying the wild-type, mutant 13A or mutant 63A plasmids. Arrows indicate the positions of the precursor (*a*) and mature forms (*b*) of alkaline phophatase.
Methods. Cultures were washed and resuspended in MOPS medium[21] supplemented with amino acids at 20 μg ml^{-1}, minus methionine. The cells were labelled with 100 μCi ^{35}S-methionine for 40 s, and the chase was initiated by adding cold methionine to a final concentration of 4 mg ml^{-1}. At the times indicated, an aliquot of cells was precipitated in 5% TCA, then washed with cold acetone. Protein was solubilized, immunoprecipitated[22] with anti-alkaline phosphatase antiserum, and analysed as described in Fig. 2 legend.

no accumulation of the 13A precursor. The accelerated rate of maturation of alkaline phosphatase encoded by the mutant 13A gene relative to that of alkaline phosphtase encoded by the corresponding wild-type gene may reflect optimization of an important recognition element or stabilization of an active conformation. In contrast, the kinetics of maturation of the 63A alkaline phosphatase gene product were slower than those for the wild-type gene and some mutant precursor was observed throughout the experiment. Inclusion of a serine in the hydrophobic core sequence and/or lengthening of this region thus seem to decrease the efficiency of processing and transport of the enzyme.

The above experiments were carried out using bacteria carrying a multi-copy plasmid bearing the wild-type or mutant alkaline phosphatase gene. Cellular transport factors may become limiting in a multi-copy situation where large amounts of a specific, secreted protein are being produced and the extent to which the cellular transport system is overburdened may contribute to the observed differences in processing rates. The wild-type, 13A and 63A plasmids are identical except in the regions encoding the signal peptide hydrophobic core. However, it is possible that, because of their location in the 5′ end of the gene, these signal mutations could have nucleotide sequence-mediated effects on the degree of translation. The predicted minimum-energy structures[18] for the 5′ ends of the wild-type and mutant messenger RNAs were found to differ somewhat. It is possible, therefore, that translation initiation occurs at different rates in the mutants[19,20]. Parallel experiments in single-copy systems will allow definitive examintion of this issue.

The present results demonstrate that a signal peptide containing a polyleucine core region efficiently supports export of alkaline phosphatase to the *E. coli* periplasm. The signal sequence of this mutant (13A) differs from the wild type by four amino-acid substitutions. The complete retention of biological activity despite multiple residue changes in the mutant enzyme underlines the importance of overall structural features as opposed to primary sequence. Furthermore, the interpretation of the effects of individual substitutions can be misleading: for example, we have found that the individual substitution of phenylalanine for leucine (residue 15; see Fig. 1) in the alkaline phosphatase signal sequence retards precursor processing although export does occur (data not shown). The detrimental perturbation produced by this single mutation appears to be eliminated by the complete idealization of the region.

Extending the total length of the signal sequence by six residues may impair the orientation of the cleavage site, leading to the diminished rate of processing of the mutant 63A precursor. In addition, the inclusion of an extra serine, with its polar hydroxyl group, may decrease the effective length of the hydrophobic, potentially helical segment between this residue and the polar amino-terminus. Characterization of several export-defective mutants of maltose-binding protein indicates that the length of an uninterrupted hydrophobic domain is critical to function[5].

In previous studies, correlations have been observed between the predicted secondary structure of signal peptides, transport activity, and the conformation of synthetic peptides corresponding to these sequences[5,6,9]. We have now used a new approach to delineate the relationship between macromolecular structure and the function of signal peptides—that is, we have idealized the core segment to maximize the potential for formation of a hydrophobic α-helix. The results demonstrate that optimization of this structural unit is sufficient for transport and processing, and that specific residues are not required in the hydrophobic domain of the alkaline phosphatase signal peptide. This modelling approach can now be extended to other regions of the signal peptide and the mature protein.

We thank Drs H. Inouye and J. Beckwith for providing the original alkaline phosphatase plasmid and *E. coli* strains used in this work; Dr D. Osterman for suggestions regarding the approach to these studies; Drs S. Ghosh, S. Rokita, K. Strauch, P. Model and M. Russel for helpful discussions; and D. Levitan, J. Marrinan, J. Harris and E. Radziejewska for technical assistance. Support of D.A.K. by NIH postdoctoral fellowship HD06570 is gratefully acknowledged.

Stringent control of initiation of chromosomal replication in *Bacillus subtilis*

Simone J. Séror, Francoise Vannier, Alain Levine & Gilles Henckes

Institut de Microbiologie, Bâtiment 409, University Paris XI, 91405 Orsay, Cedex 05, France

Interconnecting regulatory networks are characteristic of probably all cellular systems. Such 'regulons' allow the cell to respond in a coordinated manner to changes in its environment, including a rapid return to balanced growth after stress[1,2]. A regulon is usually composed of diverse metabolic pathways whose activities are amplified or inhibited by regulatory proteins, through the action of a small molecule, an alarmone[3]. Thus, for example, when the level of any aminoacyl transfer RNA becomes limiting in the bacterial cell, the stringent response is initiated; this is mediated through the nucleotide ppGpp and leads to the inhibition of synthesis of several major macromolecules, including stable RNA[4,5]. Surprisingly, the key control point in the cell cycle, initiation of DNA replication, has not previously been implicated in the stringent response. Using a *Bacillus subtilis* mutant in which the transcriptional step of initiation can be studied independently of any requirement for protein synthesis[6], we now show that initiation of chromosomal replication is indeed subject to stringent control.

The synthesis of a specific RNA–DNA co-polymer containing RNA and DNA sequences has been correlated with the transcriptional step required for initiation in *B. subtilis*[7,8]. Moreover, a ribosomal RNA operon, *rrnO*, has been identified within the origin region of the chromosome[9]. These observations suggested to us that initiation of DNA replication, which may involve the synthesis of a stable RNA, was also likely to be subject to stringent control.

To induce the stringent response, we used *O*-methylthreonine (*O*-MeT), an inhibitor of isoleucyl tRNA synthetase, or an aminoacyl hydroxamate. These drugs promote the accumulation of large amounts of ppGpp and inhibit synthesis of stable RNA in a *relA*$^+$ strain[10,11]. In contrast, in a *relA*$^-$ strain, the rate of RNA synthesis continues relatively undisturbed under these conditions. Figure 1 shows the results obtained with strains OMM242(*dna37, thy*$^-$, *trp*$^-$, *relA*$^+$) and OMM243(*dna37, thy*$^-$, *trp*$^-$, *relA*$^-$).

We tested the effect of the drugs on initiation of chromosomal replication and, for that purpose, replication rounds were synchronized in the temperature-sensitive *dna37* mutant of *B. subtilis*. As described previously[12], after return to the permissive temperature, DNA synthesis is synchronized for at least two rounds of replication. Under these conditions, initiation of the first round proceeds even in the absence of protein synthesis. However, the first round of DNA replication is blocked in the presence of inhibitors of transcription, for example, rifampicin and streptolydigin. Thus, we were able to test the effect of *O*-MeT on the transcriptional step quite independently of any requirement for protein synthesis. When added at the time of initiation, *O*-MeT, completely abolished DNA synthesis in the *relA*$^+$ strain (Fig. 2*a*). To exclude the possibility that the drug was inhibiting elongation of DNA replication or the uptake of the labelled precursor, rather than inhibiting initiation, control experiments were done using exponentially growing cultures in which either the rate of incorporation of ^{3}H-adenine into DNA or the amount of residual DNA synthesis in uniformly labelled cells was measured after the addition of *O*-MeT or chloramphenicol, which also blocks chromosomal initiation. In both cases, the effects of *O*-MeT and chloramphenicol were identical, indicating no major effect of *O*-MeT on uptake or DNA replication *per se*. Moreover, in synchronized cells, when *O*-MeT was added after initiation, substantial levels of DNA synthesis were detected (Fig. 2*a*).

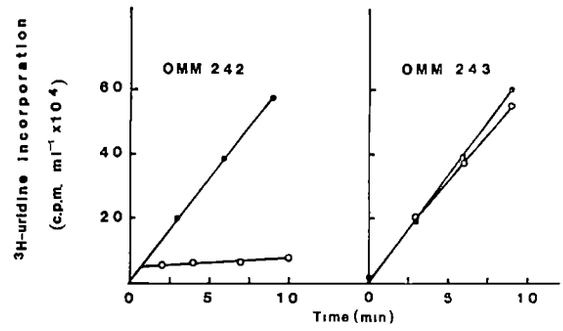

Fig. 1 Effect of *O*-MeT on RNA synthesis in *B. subtilis* OMM242 (*dna37 thy*$^-$*trp*$^-$*relA*$^+$) and OMM243 (*dna37 thy*$^-$*trp*$^-$*relA*$^-$). A derivative of OMM242 carrying the *relA*$^-$ locus was constructed by transformation from strain BR17 (ref. 23). Strains OMM242 and OMM243 were grown at 30 °C in Spizizen medium[24] containing glucose (0.5%), casein hydrolysate (0.02%) and the required supplements. At t_0, cells were labelled with ^{3}H-uridine (24 Ci mmol^{-1}; 10 μCi ml^{-1}) and *O*-MeT (1 mg ml^{-1}) (Sigma) was added to induce the stringent response. At intervals samples were removed and radioactivity in the RNA was determined after precipitation with trichloroacetic acid (TCA). ●, Without *O*-MeT; ○, plus *O*-MeT.

The effect of *O*-MeT was then tested in a *relA*$^-$ derivative of *dna37*. As shown in Fig. 2*b*, initiation of DNA synthesis was in this case largely resistant to the presence of *O*-MeT. Using another inhibitor of tRNA synthetase, arginine hydroxamate, which also induces the stringent response in OMM242, we found that initiation of DNA replication was again blocked in the *relA*$^+$ strain but not in the *relA*$^-$ derivative.

It was important to establish whether DNA synthesis occurring in the *relA*$^-$ strain in the presence of such drugs involved initiation from the normal origin of the chromosome. Therefore, we compared the first fragments to bed replicated after initiation of DNA synthesis in the untreated *relA*$^-$ strain and in the same strain exposed to the drug. Figure 3 shows that the earliest fragments to be replicated were in fact identical in both cases. Moreover, these fragments corresponded exactly to the origin region of the chromosome (ref. 13 and A.L., G.H. and S.J.S., in preparation).

All these results indicate that initiation is subject to stringent control and therefore imply that high levels of ppGpp inhibit chromosomal initiation. One way to test that possibility is to increase the concentration of ppGpp without inducing amino-acid starvation; this can be achieved by adding a drug which inhibits the normal degradation of ppGpp. We used levallorphan[14], which completely inhibited initiation of DNA replication in OMM242 without affecting DNA synthesis. This result is consistent with our hypothesis. However, as the full effects of levallorphan might be quite complex, further work is needed to verify this conclusion.

Here, we have presented evidence that chromosomal initiation is subject to stringent control in *B. subtilis*. Our results also indicate that ppGpp might be involved in this process. Future work will be concerned with identifying the precise step of the initiation process that is regulated by the stringent response.

In a previous study, Orr *et al.*[15] examined the factors required for the expression of initiation potential that accumulated in non-synchronized cultures of the *Escherichia coli dnaA46* initiation mutant. Those workers observed that, although initiation proteins could be expressed during amino-acid starvation in a *relA*$^-$ strain, this was not the case in a *relA*$^+$ strain. These results indicated that normal initiation in *E. coli* might also be subject

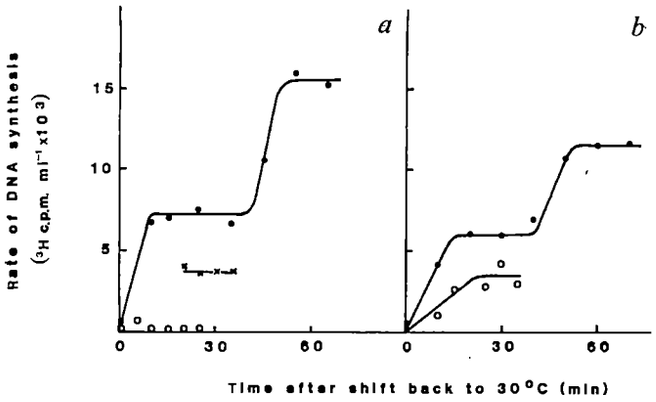

Fig. 2 Effect of *O*-MeT on initiation of DNA synthesis in cultures of *B. subtilis* OMM242 (*a*) and OMM243 (*b*) synchronized for DNA replication. An exponential culture of strain OMM242 and its derivative OMM243 ($A_{570}=0.175$) was shifted to 45 °C for 30 min, diluted three times and shifted back to 30 °C. Under these conditions, DNA replication is synchronized. At intervals, 2.5-ml samples were removed and ^{3}H-adenine (19 Ci mmol^{-1}; 2 μCi ml^{-1} was added. After 10 s, 2 min and 4 min, 0.5-ml samples were withdrawn and incorporation was stopped by adding 0.1 vol. of 1 mM NaN_3. Samples were incubated at 80 °C for 30 min in the presence of 0.4 M NaOH, neutralized by addition of 0.5 ml of 0.5 M HCl and precipitated with TCA. The rate of DNA synthesis is expressed as ^{3}H-adenine counts incorporated per ml of culture. ●, Control cultures; ○, plus *O*-MeT (1 mg ml^{-1}). The drug was added at 45 °C 3 min before the return to 30 °C. X, Addition of *O*-MeT (1 mg ml^{-1}) 15 min after the return to 30 °C.

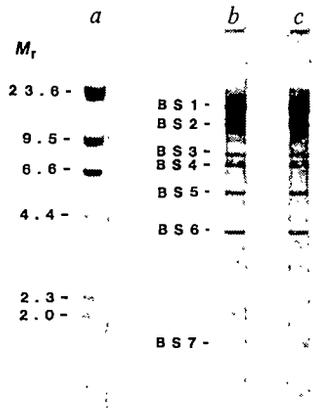

Fig. 3 Identification of the first DNA fragments to be replicated in *B. subtilis* OMM243 in the presence of arginine hydroxamate. A culture of strain OMM243 was shifted back from 45 °C to 30 °C as described in Fig. 2 legend, then pulse-labelled for 3 min with ^{3}H-thymidine (40 Ci mmol^{-1}; 20 μCi ml^{-1}) in either the absence (*b*) or presence (*c*) of arginine hydroxamate (50 μg ml^{-1}); (sigma). The labelled DNA was purified and digested with *Bam*HI and *Sal*I. ^{3}H-labelled first replicating DNA fragments were separated by electrophoresis on a 0.8% agarose gel and detected by fluorography as described elsewhere[25]. BS1–BS7 are fragments numbers from the replication origin of the chromosome. *Hin*dIII-digested λ fragments, indicated in *a*, are relative molecular mass (M_r) markers.

to stringent control, although the authors did not draw this conclusion. In the light of the results with *B. subtilis*, we re-investigated this possibility using an initiation mutant of *E. coli*, under similar conditions to those described in the present paper. Our preliminary results indicate that initiation of chromosomal replication in *E. coli* is also subject to stringent control Interestingly, Hecker *et al.*[16] have reported that the replication of the multi-copy plasmid pBR322 is also negatively controlled by the stringent response in *E. coli*.

In the present work, the effect of the *rel* system on initiation was observed under stress conditions mimicking amino-acid starvation. The question remains as to whether the stringent control system has any part in regulation of initiation under steady-state conditions. Bremer and colleagues[17] have provided evidence that the levels of ppGpp are strictly correlated with ribosomal RNA synthesis in *E. coli* under steady-state growth conditions. Moreover, Van Verseveld *et al.*[18] reported that ppGpp also negatively regulated cell division in *E. coli*, at least at extremely slow growth rates. It is therefore possible that the *rel* system, perhaps mediated through the effect of ppGpp, also has a role in the regulation of initiation during steady-state growth of bacteria.

As the initiation of chromosomal replication must be coordinated with the overall growth of a cell, it seems logical to suppose that this process also forms part of the stringent control system which includes the coordinated control of, for example, stable RNA, nucleotides, carbohydrates, fatty acids and peptidoglycan[19]. In eukaryotes there is evidence that the alarmone Ap4A, rather than ppGpp, is involved in some way in the regulation of DNA replication[20,21] and in cellular proliferation[22]. It would be interesting to determine whether this particular phosphorylated nucleotide is also involved in the coordination of other macromolecular processes in a regulon analogous to the *rel* system, in higher organisms.

We thank Drs I. Barry Holland, Paul Boquet, A. Danchin and Mathias Springer for helpful discussions during this work. These studies were supported by grants from CNRS, ATP 'Biotechnologie', no. 040136.

NEW EDITION

INFORMATION SOURCES IN BIOTECHNOLOGY, *2nd Edition*

Anita Crafts-Lighty

"This book is a model. As such it should be in the hands of every librarian and information officer..." *Process Biochemistry*

"...very useful. No comparable work is available." *Choice*

First Edition—*Choice* Outstanding Academic book 1984-5

Revised and updated throughout, this new edition provides even more practical, incisive evaluations of both the traditional and more elusive sources of information in biotechnology. It will bring you right up to date by systematically and critically reviewing the many different sources available in:

• Trade and research literature • Market surveys • Company directories • Conference Reports • Secondary sources—abstracts, title lists, indexes, bibliographies

PLUS—*Greatly expanded sections on* • Conference proceedings • Reading lists of introductory books • *New information on* • international organizations • Books out of print • How to set up and run information services • What is available for those seeking state-of-the-art coverage

A full index of publishers and addresses is included.

NEW

INTELLECTUAL PROPERTY RIGHTS IN BIOTECHNOLOGY WORLDWIDE

R. Schwaab, D. Conlin, D. Jeffery, S. Bent

The first comprehensive guide to the law governing the protection of new developments in biotechnology

This up-to-date resource will provide valuable guidance on protecting applied biological inventions in a broad range of countries. Covering patent laws, plant breeders' rights, trade secret laws, and relevant international treaties, *it gives you the latest tools with which to develop appropriate protection strategies.*

The book's practical "how-to" approach emphasizes how legal principles differ from country to country, and helps you answer such questions as: What laws can and should I turn to? Does a specific action in one country harm my position in another? What are the implications for research and development, investment and product planning?

Intellectual Property Rights in Biotechnology will prove essential to biotechnologists, business people, attorneys and libraries.

Order your copy now on FREE APPROVAL by mail or phone.

Principles of Optical Disc Systems. By G. BOUWHUIS *et al. Adam Hilger:1985. Pp.277. ISBN 0-85274-785-3. £30, $47.50.*

Rayleigh-Wave Theory and Application. E.A. ASH and E.G.S. PAIGE (eds). *Springer-Verlag: 1985. Pp. 360, Hbk ISBN 3-540-15933-9. DM 89.*

Spectroscopy of Molecular Excitons. By V.L. BROUDE, E.I. RASHBA and E.F. SHEKA. *Springer-Verlag:1985. Pp.271. Hbk ISBN 3-540-12409-8. DM 148.*

Techniques and Concepts of High-Energy Physics III. THOMAS FERBEL (ed.). *Plenum:1985. Pp.436. Hbk ISBN 0-306-42106-2. Np.*

The Thermodynamics of Fluid Systems. By L.C. WOODS. *Oxford University Press: 1985. Pp. 359. Pbk ISBN 0-19-856180-6. £12.50.*

Thermodynamics and an Introduction to Thermostatistics, 2nd Edn. By HERBERT B. CALLEN. *Wiley:1985. Pp.493. ISBN 0-471-86256-8. £34.75.*

Viscoelasticity and Rheology. ARTHUR S. LODGE, MICHAEL RENARDY and JOHN A. NOHEL (eds). *Academic:1985. Pp.445. ISBN 0-12-454940-3. $35, £31.50.*

Biological Sciences

Adenosine: Receptors and Modulation of Cell Function. V. STEFANOVICH, K. RUDOLPHI and P. SCHUBERT (eds). *IRL Press, P.O. Box 1, Eynsham, Oxford, UK: 1985. Pp.520. Pbk ISBN 0-947946-49-7. £36, $65.*

Advances in Animal Conservation. J.P. HEARN and J.K. HODGES (eds). *Oxford University Press: 1985. Pp.282. ISBN 0-19-854002-7. $35.*

Amino Acids. ALAN A. BOULTON, GLEN B. BAKER and JAMES D. WOOD (eds). *Humana: 1985. Pp.281. ISBN 0-85603-077-6. $45.*

Aquatic Microbiology, 3rd Edn. By G. RHEINHEIMER. *Wiley: 1985. Pp.257. Hbk ISBN 0-471-90657-3. £17.95.*

Assessment of Ventricular Function ANGELO RAINERI, ROBERT D. LEACHMAN and JAN J. KELLERMANN (eds). *Plenum: 1985. Pp. 347. Hbk ISBN 0-306-42092-9. Np.*

The BALB/c Mouse: Genetics and Immunology. M. POTTER (ed.). *Springer-Verlag: 1985. Pp.253. Hbk ISBN 3-540-15834-0. DM 126.*

Biochemistry of Macrophages. Ciba Foundation Symposium 118. *Pitman: 1986. Pp.256. Hbk ISBN 0-272-79822-3. $35.*

Biochimie Illustrée. By PETER N. CAMPBELL and ANTHONY D. SMITH. *Masson, Paris: 1985. Pp.240. Pbk ISBN 2-225-80456-7. F 120.*

The Biology of Echinococcus and Hydatid Disease. R.C.A. THOMPSON (ed.). *George Allen & Unwin: 1986. Pp.290. Hbk ISBN 0-04-591020-0. £35, $50.*

Brain Plasticity, Learning, and Memory. B.E. WILL, P. SCHMITT and J.C. DALRYMPLE-ALFORD (eds). *Plenum: 1985. Pp.599. Hbk ISBN 0-306-42063-5. Np.*

Cancer: An Enigma in Biology and Society. By R. NERY. *Croom Helm, London & Sydney: 1985. Pp.436. Hbk ISBN 0-7099-1825-9. £29.50.*

Cell Membranes and Cancer. T. GALEOTTI *et al.* (eds). *Elsevier: 1985. Pp.446. ISBN 0-444-80723-3. Np.*

Ctenostome Bryoans. By P.J. HAYWARD. *E.J. Brill: 1985. Pp.169. ISBN 90-04-07471-6. Pbk Dfl. 56.*

Current Topics in Microbiology and Immunology. Iridoviridae. DAWN B. WILLIS (ed.). *Springer-Verlag: 1985. Pp.173. Hbk ISBN 3-540-15172-9. DM 118.*

Darwin's Metaphor. By ROBERT M. YOUNG. *Cambridge University Press: 1985. Pp.341. Hbk ISBN 0-521-30083-5; pbk ISBN 0-521-31742-8. Hbk £27.50, $44.50; pbk £9.95, $15.95.*

The Flowers Around Us. By MARY PARKER BUCKLES. *Harper & Row: 1986. Pp.118. ISBN 0-8262-0480-5. £23.50.*

Fundamentals of Insect Physiology. MURRAY S. BLUM (ed.). *Wiley: 1985. Pp.598. ISBN 0-471-05468-2. £40.90.*

Handbook of European Sphagna. By R.E. DANIELS and A. EDDY. *Natural Environment Research Council: 1985. Pp.262. Pbk ISBN 0-904282-82-1. £10.50.*

Heavy Metals in Water Organisms. J. SALANKI (ed.). *Akademiai Kiado, P.O.B. 24, H-1363 Budapest: 1985. Pp. 440. Hbk ISBN 963-05-3614-5. £32.50.*

Immune Regulation. MARC FELDMANN and N.A. MITCHISON (eds). *Humana: 1985. Pp.391. ISBN 0-89603-083-0. $55.*

The Insect World. By KEITH PORTER. *Macmillian: 1986. Pp.48. ISBN 0-333-40933-7. £4.95.*

International Review of Neurobiology, Vol. 27. JOHN R. SMYTHIES and RONALD J. BRADLEY (eds). *Academic: 1985. Pp.398. Hbk ISBN 0-12-366827-1. £68.00, $78.50.*

Introductory Microbiology, 2nd Edn. By FREDERICK C. ROSS. *Merrill: 1986. Pp.551. Hbk ISBN 20460-7. Np.*

The Leafhoppers and Planthoppers. L.R. NAULT and J.G. RODRIGUEZ (eds). *Wiley: 1985. Pp.500. Hbk ISBN 0-471-80611-0. £61.35.*

Membranes and Muscle. MERVYN C BERMAN, WIELAND GEVERS and LIONEL H. OPIE (eds). *IRL Press: 1985. Pp.392. Pbk ISBN 0-947946-40-3 £27.00, $50.00.*

Methods in Enzymology. Vol. 18: Glutamate, Glutamine, Glutathione and Related Compounds. ALTON MEISTER (ed.). *Academic: 1985. Pp 723. ISBN 0-12-182013-0. $75, £65.*

Molecular Mechanisms of Transmembrane Signalling. P. COHEN and M.D. HOUSLAY (eds) *Elsevier: 1985. Pp.487. ISBN 0-444-80689-X. Dfl. 315.*

Neurobiology of Arachnids. FREDRICH G BARTH (ed.). *Springer-Verlag: 1985 Pp 385. Hbk ISBN 3-540-15303-9. DM 198.*

Photosynthetic Mechanisms and the Environment. J. BARBER and N.R. BAKER (eds). *Elsevier: 1985. Pp.565. ISBN 0-444-80674-1. Dfl. 375*

Plasma Fibronectin: Structure and Function. JAN MCDONAGH (ed.). *Dekker: 1985 Pp.288. Hbk ISBN 0-8247-7384-5. $59.75 (US and Canada), $71.50 (other countries).*

Recent Advances in Biological Membrane Studies. Structure and Biogenesis, Oxidation and Energetics. LESTER PACKER (ed.). *Plenum: 1985. Pp.554. Hbk ISBN 0-306-42017-1. Np.*

Regulation of Vertebrate Limb Regeneration. RAYMOND E. SICARD (ed.). *Oxford University Press. 1985. Pp.185. ISBN 0-19-503604-2. £40.*

Space, Time and Life: The Probabilistic Pathways of Evolution. By V.V. NALIMOV. *ISI Press: 1985. Pp.110. ISBN 0-89495-048-7. Np.*

Surgical Anatomy of the Orbit. By BARRY M. ZIDE and GLENN W. JELKS. *Raven: 1985. Pp.87. ISBN 0-88167-054-5. $71.50.*

Synopsis of Invertebrate Pathology Exclusive of Insects. By ALBERT K. SPARKS. *Elsevier: 1985. Pp.423. ISBN 0-444-80678-4. Dfl. 325*

Termitologia, Tome III: Comportement, Socialite, Ecologie, Evolution, Systematiques. By PIERRE P. GRASSE. *Masson: 1986. Pp.715. Hbk ISBN 2-225-80368-4. F 465.*

Tratado de Entomologia. By JUAN MANUEL NIETO NAFRIA and MILAGROS PILAR MIER DURANTE. *Ediciones Omega, Plato 26, 08006 Barcelona, Spain: 1985. Pp.599. Pbk ISBN 84-282-0748-8. Np.*

Trichothecenes and Other Mycotoxins. Proceedings of the International Mycotoxin Symposium, Sydney, Australia (1984). JOHN LACEY (ed.). *Wiley: 1985 Pp.571. Hbk ISBN 0-471-90751-0. £55.*

World Perspectives in Apiculture. By EVA CRANE. *International Bee Research Association, Hill House, Gerrards Cross, Bucks SL9 0NR, UK: 1985 Pp.184. Pbk ISBN 0-86098-142-8. Pbk £11.60, $14.*

Applied Biological Sciences

Adenosine Deaminase in Disorders of Purine Metabolism and in Immune Deficiency. Annals of the New York Academy of Sciences, Vol. 451. GEORGE L. TRITSCH (ed.). *The New York Academy of Sciences: 1985. Pp.345. Pbk ISBN 0-89766-297-0 Np.*

Advances in Gene Technology: Molecular Biology of the Immune System. J. WAYNE STREILEIN *et al.* (eds). *Cambridge University Press:1985. Pp.366. ISBN 0-521-30486-5. £30, $59.50.*

Advances in Inflammation Research, Vol. 10. FRANCOISE RUSSO-MARIE, JEAN MICHEL MENCIA-HUERTA and MICHEL CHIGNARD (eds). *Raven Press:1985. Pp.461. Hbk ISBN 0-88167-123-1. $60.50.*

Advances in Microscopy. RONALD R. COWDEN and FREDERICK W. HARRISON (eds). *Alan R. Liss:1985. Pp.362. ISBN 0-8451-5046-4. £38.*

Advances in Nutritional Research, Vol. 7. HAROLD H. DRAPER (ed.). *Plenum 1985 Pp. 273. ISBN 0-306-42213-1. Np.*

Alpha-Fetoprotein and Congenital Disorders. GERALD J. MIZEJEWSKI and IAN H. PORTER (eds). *Academic:1985. Pp.363. ISBN 0-12-501630-1 $35, £31.*

Ataxia-Telangiectasia Genetics, Neuropathology, and Immunology of a Degenerative Disease of Childhood. Kroc Foundation Series, Vol. 19. RICHARD A. GATTI and MICHAEL SWIFT (eds). *Alan R. Liss: 1985. Pp.430. Hbk ISBN 0-8451-0309-1. $79.*

Behavioural Epidemiology and Disease Prevention. R.M. KAPLAN and M.H. CRIQUI (eds). *Plenum: 1985. Pp.450. Hbk ISBN 0-306-41929-7. Np.*

Biochemical Basis of Medicine. By ERIC D. WILLIS. *Wright, Techno House, Redcliffe Way, Bristol, UK:1985. Pp.631. ISBN 0-7236-0722-2. £14.95.*

Biological Responses to Cancer, Vol. 4. ENRICO MIHICH (ed.). *Plenum:1985. Pp.256. Hbk ISBN 0-306-42044-9. Np.*

Burn and Scald Accidents to Children. Report of a Working Party of the Child Accident Prevention Trust. *Bedford Square Press:1985. Pp.65. Pbk ISBN 0-7199-1160-5. £3.95.*

Cancer: A Biological and Clinical Introduction. 2nd Edn. By STEVEN B. OPPENHEIMER. *Jones and Bartlett Publishers Inc., Boston:1985. Pp.262. Hbk ISBN 0-86720-062-6. Np.*

Carbon Nitrogen Sulfur. Human Interference in Grand Biospheric Cycles. By VACLAV SMIL. *Plenum:1985. Pp.459. Hbk ISBN 0-306-42026-0. Np.*

Causation of Cardiovascular Risk Factors in Children: Perspectives on Cardiovascular Risk in Early Life. GERALD S. BERENSON (ed.). *Raven:1985. Pp. 408. ISBN 0-88167-138-X. $76.50.*

21st Century Medicine: A Layman's Guide to the Medicine of the Future. By J. N. KENYON. *Thorsons: 1986. Pp.160. Pbk ISBN 0-7225-1198-1. Pbk £4.99.*

Current Studies in Nephrology, Dialysis and Transplantation. G. D'AMICO and G. COLASANTI (eds). *Karger:1986. Pp.206. Hbk ISBN 3-8055-4141-4. SwFr. 138, DM 165, $58.75.*

Diabetes Mellitus. Recent Knowledge on Aetiology, Complications and Treatment. SHIGEAKI BABA, MICHAEL K. GOULD and PAUL ZIMMET (eds). *Academic:1985. Pp.256. Hbk ISBN 0-12-069450-6. £37.50, $49.50.*

Dietary Fiber: Basic and Clinical Aspects. G. V. VAHOUNY and D. KRITCHESVSKY (eds). *Plenum: 1985. Pp.566. ISBN 0-306-42028-7. Np.*

Diseases of Complex Etiology in Small Populations: Ethnic Differences and Research Approaches. Progress in Clinical and Biological Research, Vol. 194. RANAJIT CHAKRABORTY and EMOKE J.E. SZATHMARY (eds). *Alan R. Liss:1985. Pp.436. Hbk ISBN 0-8451-5044-8. £38.*

Drug Level Monitoring. Analytical Techniques, Metabolism and Pharmacokinetics, Vol. 2. EMIL T. LIN and WOLFGANG SADEE (eds). *Wiley:1986. Pp.364. Hbk ISBN 0-471-80613-7. £61.35.*

Dyslipoproteinaemias and Diabetes. R.W. JAMES and D. POMETTA (ed.). *Karger: 1985. Pp.180. ISBN 3-8055-4139-2. DM 178, £46.60.*

Endocoids. Progress in Clinical and Biological Research, Vol. 192. HARBANS LAL, FRANK LABELLA and JOHN LANE (eds). *Alan R. Liss: 1985. Pp.566. Hbk ISBN 0-8451-5042-1. £60.*

The Endocrine Physiology of Pregnancy and the Peripartal Period. Serono Symposia Publications, Vol. 21. R.B. JAFFE and S. DELL'ACQUA (eds). *Raven Press:1985. Pp. 290. Hbk ISBN 0-88167-096-0. $43.*

The Enzymology of Post-translational Modification of Proteins, Vol. 2. ROBERT B. FREEDMAN and HILARY C. HAWKINS (eds). *Academic:1985. Pp. 374. Hbk ISBN 0-12-266502-3. £81, $95.*

Fetal Liver Transplantation. ROBERT PETER GALE, JEAN-LOUIS TOURAINE and GUIDO LACARELLI (eds). *Alan R. Liss:1985. Pp.373. Hbk ISBN 0-8451-5043-X. £44.*

Gastrointestinal Disorders in Diabetes Mellitus. By S. FORGACS. *Akademiai Kiado, Budapest, Hungary:1985. Pp.104. Hbk ISBN 963-05-3948-9. £8.50.*

Genetic Control of Host Resistance to Infection and Malignancy. Progress in Leukocyte Biology, Vol. 3. EMIL SKAMENE (ed.). *Alan R. Liss:1985. Pp.860. Hbk ISBN 0-8451-4102-3. £75.*

Have Healthy Teeth and Gums. By MERVYN PICHEL and NEIL CURTIS. *Javelin Books, Dorset, UK:1986. Pp.128. Pbk ISBN 0-7137-1431-X. £2.95.*

Homeostasis and Thermal Stress: Experimental and Therapeutic Advances. K. COOPER, P. LOMAX, E. SCHÖNBAUM and W.L. VEALE (eds). *Karger: 1986. Pp.210. Hbk ISBN 3-8055-4228-3. SwFr. 116, DM 139, £36.30, $49.50.*

Hybrid Models of Tropical Infections. Lecture Notes in Biomathematics, 59. By INGEMAR NASELL. *Springer-Verlag:1985. Pp.206. Pbk ISBN 3-540-15978-9. DM 36.*

Immunobiology of Proteins and Peptides-III. Viral and Bacterial Antigens. Advances in Experimental Medicine and Biology, Vol. 185. M. ZOUHAIR ATASSI and HOWARD L. BACHRACH (eds). *Plenum:1985. Pp.280. Hbk ISBN 0-306-42014-7. Np.*

Immunology of Rheumatic Diseases. SUDHIR GUPTA and NORMAN TALAL (eds). *Plenum: 1985. Pp.818. Hbk ISBN 0-306-41987-4. Np.*

Immunopharmacology. Serono Symposia Publications from Raven Press, Vol. 23. P.A. MIESCHER, L. BOLIS and M. GHIONE (eds). *Raven Press:1985. Pp.261. Hbk ISBN 0-88167-093-6. $43.*

Introduction to Drug Metabolism. By G. GORDON GIBSON and PAUL SKETT. *Chapman and Hall:1986. Pp.293. Pbk ISBN 0-412-26400-5. Pbk £12.95.*

An Introduction to Medical Genetics, 8th Edn. By J.A. FRASER ROBERTS and MARCUS E. PEMBREY. *Oxford University Press: 1985. Pp.394. Pbk ISBN 0-19-261409-6. £11.95.*

Ion Measurements in Physiology and Medicine. M. KESSLER, D.K. HARRISON and J. HÖPER. *Springer-Verlag:1985. Pp.336. Pbk ISBN 0-387-15468-X. Pbk DM 120.*

Leukemia: Recent Advances in Biology and Treatment. ROBERT PETER GALE and DAVID W. GOLDE (eds). *Alan R. Liss:1985. Pp.741. ISBN 0-8451-2627-X. £69.*

Logic of Discovery and Diagnosis in Medicine. K.F. SCHAFFNER (ed.). *University of California Press: 1985. Pp. 248. ISBN 0-520-05305-2. Np.*

Macromolecules as Drugs and as Carriers for Biological Active Materials. D.A. TIRRELL *et al.* (eds). *New York Academy of Sciences: 1985. Pp.458. Hbk ISBN 0-89766-286-5; pbk ISBN 0-89766-287-3. Np.*

The Management of AIDS Patients. DAVID MILLER, JONATHAN WEBER and JOHN GREEN (eds). *Macmillan Press:1986. Pp.202. Pbk ISBN 0-333-40466-1. £10.50.*

Mechanisms and Toxicity of Chemical Carcinogens and Mutagens. W.G. FLAMM and R.J. LORENTZEN (eds). *Princeton Scientific Publishing: 1985. Pp.264. Hbk ISBN 0-911131124. £53.35.*

Metabolic and Endocrine Disturbances in Renal Diseases. A. AMERIO, P. CORATELLI, V.M. CAMPESE and S.G. MASSRY (eds). *Karger:1985. Pp.224. Hbk ISBN 3-8055-4143-0. SwFr. 93, DM 111, $39.75.*

Myocardial Revascularization in Acute Conditions: Medico-Surgical Aspects. S.G. DEGRE (ed.). *Karger:1985. Pp.146. Hbk ISBN 3-8055-4142-2. SwFr. 115, DM 138, £36, $49.*

Non-Hodgkin's Lymphomas: New Techniques and Treatments. J.J. SOTTO, C. VROUSOS, M.F. SOTTO and F. VINCENT (eds). *Karger: 1985. Pp. 232. Hbk ISBN 3-8055-4064-7. SwFr. 162, DM 194, £50.70, $69.*

Non-Mammalian Models for Research on Aging. F.A. LINTS (ed.). *Karger:1985. Pp.288. Hbk ISBN 3-8055-4019-1. SwFr. 198, DM 237, $84.25.*

Occlusive Arterial Diseases of the Lower Limbs in Young Patients. P. FIORANI, G.R. PISTOLESE and C. SPARTERA (eds). *Raven:1985. Pp.312. ISBN 0-88167-090-1. $47.*

Patients and Practitioners: Lay Perceptions of Medicine in Pre-Industrial Society. ROY PORTER (ed.). *Cambridge University Press: 1986. Pp.356. Hbk ISBN 0-521-30915-8. £27.50, $49.50.*

Pocket Atlas of Normal Ultrasound Anatomy. By M.D. RIFKIN and L. WALDROUP. *Raven Press: 1985. Pp.70. Pbk ISBN 0-88167-163-0. $14.*

Polymeric Materials in Medication. C.G. GEBELEIN and C.E. CARRAHER Jr. (eds). *Plenum:1985. Pp.302. ISBN 0-306-42115-1. Np.*

The Posterior Pituitary: Hormone Secretion in Health and Disease. PETER H. BAYLIS and PAUL L. PADFIELD (eds). *Marcel Dekker: 1985. Pp.416. Hbk ISBN 0-8247-7359-4. $75 (US & Canada), $90 (other countries).*

Prostaglandins, Leukotrienes and Lipoxins: Biochemistry, Mechanism of Action and Clinical Applications. J. MARTYN BAILEY (ed.). *Plenum:1985. Pp. 705. Hbk ISBN 0-306-41980-7. Np.*

Rabies: the Facts (new edn.). By COLIN KAPLAN, G.S. TURNER and D.A. WARRELL. *Oxford University Press:1986. Pp. 126. Hbk ISBN 0-19-261441-X. £7.50.*

Rapid Detection and Identification of Infectious Agents. DAVID T. KINGSBURY and STANLEY FALKOW (eds). *Academic:1985. Pp.296. Hbk ISBN 0-12-408550-4. £26.50, $29.50.*

Rapid Methods and Automation in Microbiology and Immunology. K-O. HABERMEHL (ed.). *Springer-Verlag:1985. Pp.730. Hbk ISBN 3-540-13695-9. DM 248.*

Recent Developments in Parkinson's Disease. STANLEY FAHN, C. DAVID MARSDEN, PETER JENNER and PAUL TEYCHENNE (eds). *Raven Press:1986. Pp.397. Hbk ISBN 0-88167-132-0. $82.50.*

Renal Tubular Disorders: Pathophysiology, Diagnosis and Management. HARVEY C. GONICK and VARDAMAN M. BUCKALEW (eds). *Marcel Dekker:1985. Pp.640. Hbk ISBN 0-8247-7371-3. $95 (US & Canada), $114 (all other countries).*

Surgery and Support of the Premature Infant. P. PURI (ed.). *Karger:1985. Pp.210. Hbk ISBN 3-8055-4073-6. SwFr. 163, DM 195, £51, $69.50.*

Therapeutic Photomedicine. H.HONIGSMANN and G. STINGL (eds). *Karger:1986. Pp.308. Hbk ISBN 3-8055-4151-1. SwFr 230, DM 276, £71.90, $98.*

Tumor Markers in Cancer Control. HERBERT E. NIEBURGS, J.H. HOLZNER and VICTOR E. VALLI (eds). *Alan R. Liss: 1985. Pp.346. ISBN 0-8451-4201-1. £52.*

Veterinary Viral Diseases: Their Significance in South-East Asia and the Western Pacific. ANTONY J. DELLA-PORTA (ed.). *Academic:1985. Pp.616. Hbk ISBN 0-12-208870-0. Np.*

Virology in Medicine. HENRY ROTHSCHILD and J. CRAIG COHEN (eds). *Oxford University Press:1986. Pp.334. Hbk ISBN 0-19-503559-3. £39.95.*

Vitamin B-6: Its Role in Health and Disease. Current Topics in Nutrition and Disease, Vol. 13. R. D. REYNOLDS and J. E. LEKLEM (eds). *Alan R. Liss: 1985. Pp.526. Hbk ISBN 0-8451-1612-6. £60.*

X-Ray Microanalysis in Electron Microscopy for Biologists. By A.J. MORGAN. *Oxford University Press:1985. Pp.79. Pbk ISBN 0-19-856409-0. £5.95.*

General

Advances in Meat Research. Vol.1 Electrical Stimulation. By A.M. PEARSON and T.R. DUTSON. *AVI:1985. Pp.327. ISBN 0-87055-457-3. Np.*

Applied and Computational Complex Analysis, Vol.3. By PETER HENRICI. *Wiley:1986. Pp.637. Hbk ISBN 0-471-08703-3. £61.35.*

Architecture in Living Structures. G.A. ZWEERS and P. DULLEMEIJER (eds). *Nijhoff:1985. Pp.290. ISBN 90-247-3240-9. £33.25.*

Artificial Seawaters: Formulas and Methods. By JOSEPH P. BIDWELL and STEPHEN SPOTTE. *Jones and Bartlett Publishers Inc., Boston:1985. Pp.349. Hbk ISBN 0-86720-057-X. Np.*

Children Within Environments: Towards a Psychology of Accident Prevention. TOMMY GARLING and JAAN VALSINER (eds). *Plenum:1985. Pp.249. ISBN 0-306-42116-X. Np.*

Countryside Conversation. Resource Management Series 3. 2nd Edn. By B. GREEN. *George Allen & Unwin: 1985. Pp.253. Hbk ISBN 0-04-719005-1; pbk ISBN 0-04-719006-X. Hbk £25, $30; pbk £8.95, $19.95.*

Day of the Bomb. Countdown to Hiroshima. By DAN KURZMAN. *McGraw-Hill:1986. Pp.546. Hbk ISBN 0-07-035683-1. $19.95.*

Deception: Perspectives on Human and Nonhuman Deceit. ROBERT W. MITCHELL and NICHOLAS S. THOMPSON (eds). *State University of New York Press:1986. Pp.388. Hbk ISBN 0-88706-107-9. $44.50.*

nature

Where next with the greenhouse?

The US Congress seems to have taken the threat of catastrophic greenhouse warming under its wing politically. But there is a long way to go before it can decide what to do about it.

Now that the seasonal summer has at last arrived in the Northern Hemisphere, it is natural enough that the US Congress should be in turmoil (see p.714) about the greenhouse effect, a phenomenon that comes to the surface every few years. But it is hard to believe that either of the two representative houses that sit on Capitol Hill in Washington can seriously think they have the means to legislate about this complicated matter when, to tell by recent experience, they cannot bring themselves to do the decent thing by the government of which they are a part, and avoid spoiling the administration's posture on free trade if the result is that they must abandon protection for US printing.

Here are a few homilies on the greenhouse effect that may (but that is unlikely) give Congress pause. They are offered, so to speak, in a spirit of moderation: Congress is indeed worrying about an issue on which the expenditure of anxiety is appropriate and even potentially constructive, but there is a danger that it may pace its anxiety by the timetable laid down for general elections, every two years for mere representatives and six years for grander senators. The time-span of the greenhouse effect is longer than either. And it is incalculable.

Recent past experience shows that well enough. Carbon dioxide absorbs radiation more efficiently in the infrared than in the visible part of the spectrum, so that if it should accumulate in the atmosphere, the result should be that solar energy will the relatively more easily reach the surface of the Earth than escape from it, increasing the surface temperature. This primitive scenario has been current for the best part of half a century. Moreover, it is now plain that carbon dioxide has indeed accumulated in the Earth's atmosphere, by roughly 30 per cent in the past century. So the temperature at the surface of the Earth should be steadily increasing, should it not?

Events have unfortunately taken a more tortuous course. The increase in the concentration of atmospheric carbon dioxide has been substantial and dramatic, but is roughly only a half of what it would have been if all the fossil fuel burned in the past century had produced combustion gases that had stayed in the atmosphere. Where has the rest gone? A general flourishing of vegetation is one possibility, solution in the oceans is another. There is also the curious but surprising conundrum that, the concentration of carbon dioxide having increased, the temperature has not followed by the amount predicted. The difficulty here is that the soothsayers (many of them professional scientists) have made more of their first-approximation models than is proper; they may not, for example, have disclosed that they cannot cope with real clouds in their climatic models or that ocean-atmosphere interactions are accounted for only in the most rudimentary way, but are likely when properly counted to be stabilizing. Even so, the long-term outlook cannot but be gloomy. One day, in the next few decades or so, the greenhouse effect will become reality. That, with its occasional introspections on the subject, is the issue for which Congress is preparing itself.

It might do worse than read the two articles on the remarkable disappearance of ozone from the Antarctic which appear on pp.755 and 759 of this issue. Ozone is an important component of the lower stratosphere because it absorbs solar ultraviolet, heating that layer and protecting the people who live beneath from ultraviolet radiation that might cause skin cancer. What the data show is a quick destruction of atmospheric ozone when the Sun appears above the horizon at the end of the Antarctic night; the assumption that most damage to the stratispheric ozone layer is done by chlorine is on this occasion complemented by the damage done by bromine, another halogen used for the general good in the putting out of fires, whose use is generally applauded by Congress. These phenomena also have an influence on what the greenhouse will do, but in ways that cannot yet be determined. The importance of these components of the upper atmosphere is that their presence has been recognized only recently, that they may in various chemical guises be greenhouse gases like carbon dioxide, but that their influence may also tend in the other direction.

What should Congress do? First it must recognize that the problem is essentially international. Everybody puts carbon dioxide into the air, for reasons that are usually good — keeping warm, cooking food, getting from one place to another. So when the temperature of the Earth's surface begins significantly to increase, some mechanism will have to be invented whereby something that might provisionally be called the World, or the World Community, is empowered to tell smaller parts of itself that they cannot continue doing what they have always done.

While the general principle is generally acceptable, its implementation is beyond the present ken of those who generate carbon dioxide. A host of academic conferences in the past decade has amply illustrated what the difficulties would be. Should carbon dioxide (or other greenhouse gas) quotas be proportional to present GNP? Or to potential GNP? Or to some other index of a country's ambition, such as the size of its population? By what means could such an agreement be enforced? By fines proportional to the disadvantage done to the peoples of countries other than the transgressor's? And should the disadvantaging multiplier be so great that people would find it more profitable to turn to nuclear power than to pay the fines? The enthusiasts for the greenhouse problem now raising the roof in Congress had better take a close look at what lies down the pike before they pin their electoral futures on this scary prospect.

What is to happen to the rest of us? In a world in which legislative bodies, including Congress, are notoriously unwilling to sign binding international agreements, there are two rational attitudes to strike. One is to concentrate on the uncertainties in present calculations, and on the features of most respectable calculations which show that there will be winners as well as losers in the global greenhouse, and to say that the problem is of no significance. The other is to take the line that there will be a greenhouse problem one day, perhaps next decade, perhaps a century from now; in that case, the rational course is now to seek to strengthen international institutions, and the trust that ordinary people put in them, against the time that a durable agreement is needed. Sadly, there is no obvious correlation between the opinions on contemporary international issues among those who have lately rediscovered the greenhouse effect and the small membership that would, for example, do something about arms control. □

Atmospheric greenhouse

US Congress says climate is part of politics

Washington

POLITICAL efforts are under way in Washington to bring into the policy arena the depletion of the atmospheric ozone layer warming due to the greenhouse effect. Declaring that the topics "can no longer be treated solely as important scientific questions", Senator John Chafee (Republican, Rhode Island), chairman of the Senate subcommittee on environmental pollution, last week announced that he would ask the Environmental Protection Agency (EPA) and Congress's Office of Technology Assessment to conduct studies of policy options to stabilize world levels of atmospheric gases.

Chafee's statement was made at the start of two days of hearings at which administration officials and prominent scientists were called to give evidence on the problem and their views of appropriate responses. Chafee also said he would ask the National Academy of Sciences to review gaps in scientific knowledge on the topic, and that he would ask the State Department to bring the issue to international attention.

Although administration officials at the hearings generally stuck to the line that more research is needed before policy options can be considered, EPA administrator Lee Thomas said a working group has been established within the agency to estimate trends in greenhouse gas emissions and to determine possible control options. The working group will also conduct long-term research.

EPA is already considering further controls on the use of chlorofluorocarbons (CFCs), which catalyse the breakdown of the ozone layer; a decision will be made by November 1987. Several witnesses referred to recent measurements showing a 40 per cent reduction in the ozone layer over Antarctica, the causes of which remain unknown but which may be related to human activities.

Concern over the effects of CFCs on the ozone layer led the United States in 1978 to ban their use in non-essential aerosol sprays, but EPA has failed to persuade other nations to follow suit. Thomas said EPA had "stepped back" from those efforts, but it is considering regulations further to limit domestic uses of CFCs, used mainly as refrigerants.

Several witnesses at last week's hearings referred to the need for international cooperation on research, including Thomas and Alvin Trivelpiece, director of the office of energy research at the Department of Energy (DoE). DoE is concluding an agreement on joint climate research with China, to be conducted through the Chinese Academy of Sciences. Other countries are participating in DoE's carbon dioxide research programme.

A scientific view of the problems was provided by James Hansen of the National Aeronautics and Space Administration (NASA)'s Goddard Space Flight Center. Hansen has used a global climatic model to simulate the climatic effect of the transient growth of atmospheric carbon dioxide and other trace gases now thought collectively to be as important.

Among Hansen's results is the conclusion that a large part of the equilibrium warming due to the well-documented carbon dioxide increase since 1850 has probably not yet occurred; the same is true for the other gases. The effect of warming will start to emerge from statistical background noise in the 1990s.

In response to submitted questions, Hansen also prepared estimates of the increased number of days per year over 90 degrees Fahrenheit in Washington DC that would result from a doubling of carbon dioxide. Conclusion: from 35 days (at present) to 85, with 12 of them over 100 degrees. Temperature across much of the United States might rise by an average of 3 degrees Fahrenheit or more by 2020. Local press, sweltering in 90-degree-plus weather, were duly impressed.

Hansen said later in an interview that he was surprised at Chafee's call for immediate studies of policy options; he would prefer to emphasize the need for integrated and long-term studies of climate systems as he thought policy options would not meet political approval in the absence of clearer evidence. Recommendations along these lines have been made in a report to be published by the NASA Earth System Sciences Committee chaired by Francis Bretherton of the National Center for Atmospheric Research. But, while also stressing the need for more research, Bretherton said he approved of Chafee's call for an assessment of policy options.

Although the greenhouse effect is not at present under specific consideration in the White House, a consensus is emerging in the scientific community on the need for coordinated and long-term measurements of climate. An international initiative has been proposed by the International Council of Scientific Unions, and the roles of US federal agencies in a long-term climate study are being considered in the administration by the Senior Inter-agency Group on Space, called SIG-Space. A major international conference on the subject sponsored by the United Nations Environment Programme and EPA takes place this week in Arlington, Virginia.

Tim Beardsley

French universities

One reform too many?

FRENCH university presidents walked out of a meeting with the new research and higher education minister, Alain Devaquet, last week, after hearing that France is to abandon its newly-created PhD degree, much welcomed by natural scientists for its similarities to the research degrees of Britain and the United States. The plan is to return to the old idiosyncratic system of "troisième cycle" and "thése d'Etat" degrees.

This is just one of the reforms promised last week by Devaquet, a physicist, in a new law for the universities to be put before the National Assembly before the summer. Another reform will allow universities to select their own students, the first such selection system allowed in France since the European university revolution of 1968. But the selection will be only nominal: Devaquet, no doubt fearful of the political consequences of avowing selection, has also reaffirmed the right of every school-leaver who passes the coveted "baccalaureate" to gain a university place, just as each of them can do at present. It will be up to local education authorities to square this selective circle.

Other promised reforms include a lightening of the system of the three elective councils by which universities and their departments are managed, in order to give more power to professors ("and less to cleaning staff", according to one supporter), but the present national system for awarding degrees will be retained.

The law thus does not go so far as the promise of Prime Minister Jacques Chirac to return autonomy to the universities both in the selection of students and the awarding of degrees. But it went far enough for the university presidents to walk out of their meeting with Devaquet, which was held just a couple of hours before the minister's previously arranged press conference on the new law. The presidents were protesting at an almost total lack of consultation in the brief preparation of the law since the general elections in March, and at the prospect of yet another long hot summer of discontent as the French university system is yet again lifted up by the roots to see how the fragile plant is growing.

Robert Walgate

US copyright

Will Congress blot US copybook?

Washington

WHILE the US administration bangs the drum of free trade, Congress is busily preparing to muffle its beat. Now, a coalition of 54 major corporations and association is lobbying hard to persuade Congress not to extend legislation requiring non-dramatic works by US authors to be printed in the United States.

The so-called "manufacturing clause" has been declared illegal by the General Agreement on Tariffs and Trade (GATT), and the European Economic Community (EEC) has threatened economic sanctions against the United States if the clause is not allowed to expire at the end of this month. But influential members of Congress want the clause made permanent, and the Senate Finance Committee has approved a bill to do so.

The current manufacturing clause prohibits importing into the United States copyrighted non-dramatic literary material in English unless it is printed and bound there. The effect is to ensure that US copyright material is printed in the United States. The price of books in the United States is consequently estimated to be 12 per cent higher than it would otherwise be. Newspapers are also affected.

Among those most affected by the bill are manufacturers of computers and business equipment; the legislation prevents them from printing instruction manuals and the like abroad, where many of their manufacturing plants are situated. Burroughs, IBM and Xerox are among the corporations that have joined the Coalition to Oppose the Manufacturing Clause. EEC estimates the clause costs it between $300 and $500 million per year and has threatened retaliatory sanctions.

The clause is also opposed by the US Department of Commerce: commerce secretary Malcolm Baldrige told the Senate Finance Committee last week that the clause is "an embarrassment" that undermines the United States' position as it tries to negotiate fair trade practices and strong protection for intellectual property rights overseas. Baldrige said he would advise President Reagan to veto any legislation Congress might pass to extend the clause.

The clause was formerly set to expire in 1982, but Congress voted then to extend it and overturned a presidential veto. It had not by then been declared illegal by GATT, however, and opponents are using the GATT ruling as a major plank for their case. The clause also makes it impossible for the United States to adhere to the Berne copyright convention, which provides international protection for intellectual property rights.

The controversial clause dates back to 1891, when it was enacted to protect the US printing industry. Although it has since been progressively weakened, the printing industry would still like to see the clause extended, and some members of Congress are unwilling to be seen to be increasing foreign competition for the industry. Critics contend, however, that the number of US printing jobs that would be saved if the clause is extended is trivial compared with the number of jobs lost in other export industries. Singapore, thought to be one of several countries that turn a blind eye to piracy of US-copyright trade materials, has tied improvements to its copyright laws to an exemption from the US manufacturing clause, and other countries may follow suit.

Some computer manufacturers have already chosen to forgo US copyright protection on their manuals printed overseas rather than print them in the United States, according to the coalition. Vico Henriques, president of the Computer and Business Equipment Manufacturers' Association, said it was recognized good business practice to print documentation for a product at the point of manufacture so that local alterations and conditions could be included easily.

The legislation approved by the Senate finance committee to extend the clause (S. 1822) would remove the existing exemption for Canada. The exemption allows Canada to export to the United States US-copyright works not printed in the United States. Retaliatory action from Canada would therefore also be on the cards if the legislation were passed.

To placate the opposition, the Senate bill, introducted by Republican Senator Strom Thurmond, includes some compromise provisions. The chief one is that after two years, waivers could be issued allowing imports from countries which the Secretary of Commerce certifies as fair trading partners that respect US copyright laws (among other things). But the US Trade Representative, Clayton Yeutter, told the finance committee that he had "strong doubts that Canada, the European Economic Community or Japan could obtain a waiver" under the "cumbersome" waiver provisions. Yeutter said the ostensible purpose of the clause, protection of US printers' jobs, was unnecessary: total employment in the US printing and publishing sector is projected to grow by 2.2 per cent a year to 1995, creating more than 30,000 jobs each year.

The House of Representatives' Judiciary Committee is soon to consider a bill identical to Thurmond's. Senate floor action on Thurmond's bill is scheduled for next week; the coalition is only cautiously optistic that it will have rallied sufficient votes to defeat it. **Tim Beardsley**

British software

Looking over the shoulder

THE common British conceit that Britain may not be much good at hardware, but has the edge in software, takes a tumble this week with the publication of a report by a committee of the Advisory Council for Applied Research and Development (ACARD) that cries for urgent action from everybody in sight (*Software. A vital key to UK competitiveness*. HMSO. £6.00). It is not true, says ACARD, that British software houses run on an inside track; after the United States, France is next, while even in Europe, West Germany is number two.

Both perceptively and courageously, ACARD sees the British software problem as part of the general decline of British industrial competiveness. While the "man in the street" may still expect that software houses would be among the most rapidly growing and most profitable parts of British industry, the real prospect is quite different.

The committee says that evidence from overseas confirms its own view that the rate of growth of the British software industry will lag behind that of the world leaders, that market shares will decline and that the British market for software will be dominated by overseas suppliers in the 1990s.

The ACARD committee gives several reasons for this gloomy outlook, including the chronic shortage of skilled people in information technology, the failure of companies in the field to spend enough on selling the products they have developed and, latterly, their unwillingness or incapacity to invest in research and development. According to the ACARD report, the chief objective among software houses now is to make software development less labour-intensive, which means investment in the techniques of automation.

The diagnosis is more persuasive than the remedy. Above all, ACARD wants Britain to know there is a problem. Beyond that it has a miscellany of remedies, such as the proposal that government departments should give thought to generic needs when commissioning new developments, that the Science and Engineering Research Council should elevate the information engineering committee of its engineering board to the status of a full board and that the programming language BASIC should be outlawed as soon as it can be replaced by something better.

The committee's theme is that designing a piece of software is like making anything else — a task in engineering in the widest sense. Many British software-users will say amen to that.

Cancer research

Boom in new laboratories

FUNDAMENTAL cancer research in Europe is about to be strengthened by several new privately financed laboratories. One will be in Vienna and is jointly owned by Genentech, the Californian biotechnology company, and the West German chemical and pharmaceutical company Boehringer Ingelheim. The other four, and probably five, laboratories are new branches of the Ludwig Institute of Cancer Research, administered from Zurich.

Despite its commercial backing, the Vienna institute will be concerned only with basic research in the general area of molecular pathology, with a particular focus on oncogenes. First rights on any discovery of commercial interest stemming from the research are shared by Genentech and Boehringer Ingelheim. The German partner will foot the bill for the institute for its first five years, after which costs will be shared equally.

During the initial five-year period, Genentech's contribution is know-how, in terms of both the recruitment of suitable staff and the structure of the research programme. Just over half the cost of building the institute (in Vienna's third district) and 80 per cent of the running costs for the first five years will be met by Boehringer Ingelheim, with the balance coming from the city of Vienna and the Austrian government, eager to counter a Freudian past with a double-helical future. Various relevant university institutes, at present scattered around the city, are likely to be re-sited alongside the new institute.

Building work on what is likely to be called the Institute of Molecular Pathology will begin this summer. Shortly thereafter its director, Dr Max Birnstiel, will leave the University of Zurich for Vienna. Negotiations are already well advanced with some potential group leaders for the institute and enthusiasm for heading east is said to run high.

Those who prefer to head west or north may find positions in four new branches of the Ludwig Institute of Cancer Research. Two of these have begun operation in Sweden (in Stockholm, under Dr Ulf Pettersson and in Uppsala, under Dr Carl-Henrik Heldin) and two will start soon in London (at Middlesex Hospital Medical School, under Dr Michael Waterfield, and at St Mary's Hospital Medical School, under Dr Paul Farrell). Negotiations are under way for another London branch and Dr Webster Cavenee has just begun to direct a new Ludwig in Montreal's McGill University.

As a result, there are now 14 Ludwig branches consuming US$33 million last year. There will now be a period of consolidation with no new branches, according to Mr Hugo Frei, chairman of the board of directors, which is responsible for managing the assets provided by Mr Daniel K. Ludwig in 1974 in such a way as to produce sufficient income to finance the research programme. Each branch, of 20–80 people, is set up in cooperation with a hospital for an initial six-year period and is subject to review every three years. So far, the only branch to be closed was the previous London laboratory at Sutton (see *Nature* **318**, 400; 1985) for reasons that included its location, lack of patients and scientific shortcomings, according to Frei.

To judge by the new branches, Ludwig has little difficulty in attracting good directors despite the lack of guaranteed long-term support and a policy that sets salaries at local levels.

There is, however, some generosity in terms of capital expenditure. A recent board decision means that the US Research Corporation will handle the transfer to commerce of any potentially profitable discovery in a Ludwig laboratory.

Peter Newmark

Soviet education

University shake-up canvassed

A RADICAL reorganization of Soviet higher education is on the cards. In what is called a draft proposal, published last week, the Central Committee of the Soviet Communist Party says the time has come for curricula to be "retuned" and for the administration of higher education to be simplified. There should be more money for equipment and better salaries for professors. If implemented, the proposals will give universities a more prominent place in the pattern of Soviet research, at present dominated by academy and ministry institutes.

The theme of the proposals is familiar outside the Soviet Union, to arrange matters so that higher education contributes more fully to the national economy. But the breadth of what is proposed represents radical reform of many established practices and institutions.

The scale of Soviet higher education, with a total of 894 universities and other institutions of higher education, is huge. But, according to the Central Committee, the system is bedevilled by bureaucracy. Part of the trouble is the division of responsibility between the All-Union and republic governments, but ministries and departments also run their own institutions for training people with special skills, as in agriculture and medicine. Altogether, 74 ministries and departments are in some way involved, but 30 of these run only one or two institutions (called VUZy when they are not universities).

To meet the complaint that many production ministries and departments fail to provide suitable teaching staff and facilities for their institutions, the Central Committee proposes that the Ministry of Higher Education should have more control of VUZy run by other ministries. There would be regular checks of teaching standards and, because sectional interests have often led to the duplication of specialist courses and, sometimes, whole new VUZy, the system would be rationalized so that redundant courses and establishments would be gradually phased out.

Teaching is also to be overhauled. The Central Committee says that the present pay structure discourages the best scholars and scientists from making an academic career. It says that too much emphasis is placed on formal lectures and textbook knowledge, with the result that students are overworked, while the ratio of students to staff is far too high.

What the Central Committee wants to see is more teaching in small seminar groups (not more than 15 people), with more practical and laboratory work. The notion that each student should have an individual timetable and more choice of lecture courses is encouraged, and there is even a tentative suggestion that intending university teachers should spend a probationary period of two years in some part of the national economy in which their students may later work.

Recruitment into graduate programmes will centre on people seconded from industry or with work experience in their chosen field. Research for the degree of Candidate (PhD) will concentrate on "priority fields of science and technology" and efforts will be made to raise the ideological as well as scientific standard of research students. The possibility is canvassed that some universities and VUZy might offer courses leading to the degree of Doctor of Science, at present awarded on the basis of a second dissertation in the course of a professional career.

Apart from the threat of more direct control, the Central Committee's prospectus should be welcomed by Soviet universities and VUZy. More is to be spent on laboratories, libraries and computers. Students are to have better living conditions, and academics better pay. There is even talk of higher aesthetic standards for university buildings. In return, the universities and VUZy have to produce graduates of the type required by the "scientific and technical revolution" and also play a part in the intended "unified state retraining scheme for older generations of scientists".

Vera Rich

Chemical weapons

Binary weapons in trouble

Washington

A GENERAL Accounting Office (GAO) report has given a black eye to Bigeye, the binary chemical weapon the US Department of Defense (DoD) says will give the chemical weapons arsenal a deep-strike capability now said to be lacking. But in spite of the doubts raised by the GAO report, DoD is proceeding with operational tests of Bigeye, and hopes soon to begin initial production at a low rate.

The GAO report focuses on DoD's tests of Bigeye performed since 1982. The Bigeye bomb consists of two non-lethal chemicals carried separately. When mixed, these agents form the persistent lethal nerve agent VX. Originally, DoD planned that high-flying aircraft would drop the bomb after the two chemicals had combined. But lessons learned during the 1976 Yom Kippur War in the Middle East convinced DoD that this approach made planes too vulnerable to anti-aircraft missiles, so that DoD decided that the bomb would have to be carried by aircraft flying at high speed and low altitude.

This plan also has problems. The extra temperature caused by increased air friction at low altitudes raised pressure inside the bomb, causing one to explode during testing. This is why, since 1982, DoD's plans for delivering Bigeye have required mixing the two chemicals only after the bomb has left the plane, and "lofting" the bomb — tossing it upwards from the aircraft — so that the chemicals have time to mix before the bomb's contents are released. The GAO report concludes that this delivery scheme places a heavy burden on pilots and systems software.

Eleanor Chelimsky, one of the report's principal authors, said at a press conference last week that the Bigeye bomb has satisfied neither chemical purity requirements nor system reliability, and is "therefore not ready for production". Pressure build-up inside the bomb after mixing could still result in a premature release of its contents. DoD solved the pressure problem in laboratory tests with a pressure relief valve, but the valve will not be included in working models of the bomb.

Another concern is the potential of the bomb's chemical components to catch fire or "flash", destroying the nerve agent's effectiveness. Also troubling Chelimsky is the way DoD performed tests on the bomb. "DoD seems to be confused about what in fact has been tested and what the results have been", she says. According to the GAO report, DoD changed performance criteria during testing to make Bigeye look better.

DoD is quick to defend Bigeye. John E. Krings, director of DoD's office of Operational Test and Evaluation, agreed that GAO had identified some of Bigeye's initial problems, but said the report was "not totally accurate". Krings denied that the criteria that the weapon had to meet had in any sense been eased, pointing out that all new weapons systems experience modifications in design criteria during testing. The bottom line, says Deputy Assistant to the Secretary of Defense for Chemical Matters Thomas J. Welch, is whether the bomb represents an improvement in combat effectiveness. Welch believes it does. "We understand the shortcomings of Bigeye", says Welch. "We have a handle on fixing them, and the fixes are under way." The logic of binary weapons is that they are safer to store and transport than unitary weapons. But even here Bigeye has problems. VX is formed by mixing QL (ethyl 2-(diisopropylamino) ethyl methyl-phosphonite) with rhombic sulphur. But according to sources at GAO, DoD is aware that if QL were accidentally released near a power plant burning high-sulphur coal, VX could form spontaneously.

Bigeye is just one part of a planned improvement in chemical weapons. By 1994, DoD plans to destroy all existing stocks of unitary weapons, switching over to binary weapons. Besides Bigeye, DoD plans to deploy 155-mm artillery shells carrying the non-persistent nerve agent GB, and a multiple-launch rocket system also carrying GB. But Congress has required that the North Atlantic Council, the political arm of the North Atlantic Treaty Organization (NATO), should approve the United States' "force goals" before production can proceed. Congress has also insisted that NATO's Supreme Allied Commander in Europe must establish plans for how chemical weapons will be used before production funds are released.

To gain European support, President Reagan is said to have struck a deal with West German Chancellor Helmut Kohl to remove existing stockpiles from West Germany in exchange for Kohl's support for binary weapons production. Last month, the NATO Defense Planning Committee endorsed the US plans for new chemical weapons production, a move the administration hopes will allow production to proceed. But congressional opponents argue that North Atlantic Council approval is still needed.

Even if the binary weapons plan is approved, critics worry that not having the weapons actually based in Europe will make them ineffective as a deterrent. DoD plans to airlift the bomb components separately to Europe in the event of an attack. The United States holds to the position that it will never be the first to use chemical weapons. But critics worry that a massive influx of such weapons to Europe at a time of crisis may make it appear that the United States is abandoning that policy, prompting a Soviet first strike.

A report by the specially empanelled Chemical Warfare Review Commission to President Reagan last year concluded that the long-range capability offered by the Bigeye bomb is urgently needed if the United States is to have a credible chemical weapons deterrent. But many in Congress believe the binary bomb is just an expensive mistake. The GAO reports should provide congressional opponents with ammunition when they attempt to shoot down Bigeye. **Joseph Palca**

Estonian protest

A GROUP of Estonian scientists, including members of the Estonian Academy of Sciences, has written an open letter to the West, calling for protests against Soviet plans to build a large oil terminal at Muuga near Tallinn. The terminal, which will be adjacent to the controversial grain harbour, will, the scientists say, be a major source of pollution to north Estonia and to the whole Baltic area. The oil terminal, although necessary to the All-Union plans, is not necessary to the economy of the Estonian republic. Since the plans for the terminal have not been officially announced (the scientists describe their source as a reliable leak from civil servants), they clearly hope that international criticism might induce the central planners to scrap the project quietly, and to deny the report as unfounded.

The area under threat by the proposed terminal includes lake Peipsi, the main water source for Tallinn. It is the only area of the country not already a victim of major pollution from oil-shale and phosphorite mining. (A recent study by the Estonian Academy's Institute of Economics found that the large phosphorite mine now being planned at Toolse will cause extensive seepage of pollution through the ground-water.) A particularly worrying aspect of the problem is that, since January 1986, censorship control has become so strict that it is now virtually impossible to inform the general public about environmental hazards.

The scientists, however, are not concerned only with the pollution threat posed by the oil-terminal, grave though that is. All major construction and engineering projects in Estonia are accompanied by a major influx of Russian labour, which, in its turn, means the gradual linguistic and cultural Russification of the area. If this policy continues, the scientists say, by the end of the century, a broad zone of north-eastern Estonia, comprising about 60 per cent of the population of the republic, will be effectively Russified. Vera Rich

Biotechnology

Insect virus as super-vector?

Washington

AN insect virus that could become a second-generation recombinant vector is gaining a quiet following in biotechnology. The baculovirus is easily engineered and achieves both high synthesis rates and complex processing of recombinant products. Cetus, Eli Lilly, Genentech and 15 other companies are investigating the system, but a three-year-old Connecticut company called MicroGeneSys claims it has already foiled the competition.

Although he heads only 25 employees, founder and president Frank Volvovitz believes MicroGeneSys has invested more time, money and expertise in the use of baculovirus than any other company. Volvovitz culled six virologists from laboratories at the National Institutes of Health, Baylor College of Medicine and Texas A&M for his research team. The company will not disclose the yields it has achieved, but published reports contain examples of recombinant protein production nearing 700 mg per litre of culture within a few days of infection. This rivals the rates of monoclonal antibody production by hybridomas, the most efficient recombinant machinery known.

The system is based on a cell line established in the late 1970s from the pupal ovarian cells of the moth *Spodoptera frugiperda*. When infected with baculovirus carrying a foreign gene, these cells can secrete recombinant products complete with post-translational modifications such as phosphorylation and glycosylation. The system may therefore dispense with costly downstream processing. Mammalian cell cultures offer the same processing advantages, but are not as prolific.

The productivity of the baculovirus derives from the efficiency of the viral promoter of the gene encoding the protein called polyhedron, the sole component of a crystalline matrix that acts as a protective shield for viral particles existing outside their insect host. Caterpillars eat the matrix and release the particles, which then temporarily suspend polyhedron synthesis. When the caterpillar is near death, the virus resumes matrix protein production until roughly 20 per cent of the larval host consists of polyhedron.

MicroGeneSys has already harnessed this productivity for a hepatitis-B vaccine which will enter clinical trials this fall. The company is also developing vaccines against acquired immune deficiency syndrome and malaria infections. Meanwhile, research in Texas A&M and the University of Idaho is generating a network of academic and corporate collaboration on baculovirus technology.

Eli Lilly has been working closely with Max Summers in Texas, who is generally recognized as the technology's pioneer. Summer's laboratory is also working on interleukin-2 with Hoffman–LaRoche. Cetus is building on its preliminary results with colony-stimulating factor, while Genentech assigned a handful of researchers to investigate the system and says merely that it is "very interesting". Genetics Institute (which has just raised $75 million in its first public offering of shares), had originally planned to use baculovirus for making pesticides, but changed the emphasis of its programme on learning more about the system.

There are some sceptics in the field as well. Chiron considers that the baculovirus has only "marginal utility" compared with its own yeast systems. Even the staunchest supporters of baculovirology admit that the analysis of the gene products so far has not been thorough enough to ensure smooth passage through the regulatory process. Little is known, for example, about the characteristics of the insect cell glycosylation, which could affect biological activity. **Karen Wright**

European research

Still hope for budget increase

Luxembourg

RESEARCH ministers of the twelve member states of the European Economic Community (EEC) meeting here last week refused to triple the research budget of EEC, demanding that the European Commission, which administers EEC affairs, be more "realistic" in its requests. The Commission, however, regards its proposal for an ECU (European Currency Unit) 10,350 million (£6,600 million) "framework programme" of international research for 1987–91 as eminently realistic, and indeed vital for the economic future of Europe — and has retired to prepare a new proposal to put before the ministers in October.

But this apparently eyeball-to-eyeball confrontation is not official. It occurred over lunch — when no official minutes are taken. But the British, French and German delegations did not aid Commission digestions with their insistence on only small increases in the ECU 3,750 million five-year research budget of the EEC.

The EEC spend is dwarfed by the ECU 150,000 million or so that the individual nation members of EEC spend on research each five years, and the Commission is arguing, in effect, that a great part of this national spending is wasted, either by duplication of effort or by a failure of research or technological enterprises to reach a critical mass of talent or investment. In its strategy to 1991, the Commission aims to expand existing successful coordination programmes in areas such as information technology and biotechnology, and to turn pilot programmes into fully-fledged actions.

EEC research ministers, particularly in the larger European nations, are apparently holding back this expansion, or — even if the research ministers are more willing to support the Commission — over-zealous finance ministers in the newly monetarist France, in West Germany and the United Kingdom are putting the brakes on. Research ministers at a political level now strongly back the objectives of "improving Europe's technological competitiveness" and of increasing the "cohesion" among individual national research and technology policies, two of the current "buzz phrases" in European science policy, but at an economic level the ministers seem unable or unwilling to back the principles with cash.

Meanwhile, Geoffrey Pattie, the British minister of technology, recommended that the Commission could save money on science, by cutting its energy research by 20 per cent (it is set to remain roughly constant in the new framework programme) or by offering only fractional subsidies (down to 25 per cent on a sliding scale from the current 50 per cent) to university, institutional and industrial projects granted EEC support, thus making a small sum go further. The Chernobyl reactor disaster may make the first unlikely, as projected decreases in nuclear fission safety research may have to be reversed; and according to Commission officials the second is already practised.

Pattie and other "purse-strings" ministers present, including Alain Devaquet from France and Heinz Reisenhuber from West Germany, made it plain that when the Commission returns with new proposals they must be realistic or further delays in agreeing the programme are inevitable. Everything rests on what "realistic" means, but estimates were ranging here from around ECU 4,300 million — the sum estimated to be necessary to keep going with the present programme, to "around half" the proposed programme (some ECU 5,500 million). With these sums it would be possible to go ahead with the planned programme, according to Commission officials, but the number of grants awarded would be nowhere near able to satisfy the demand, the disappointment of good applicants would cause disillusion, and the function of the programme as a real catalyst of European economic and technological transformation would prove more difficult to achieve.

Robert Walgate

Materials research

Europeans wake up

Luxembourg

EUROPE is to launch an ECU (European Currency Unit) 30 million (£20 million) three-year programme of research on new materials, it was agreed here last week, a year after the proposal was first tabled. The programme covers ceramics to the new neodymium-iron-boron high-field permanent magnets which are posted to replace electromagnets and reduce the volume of electric motors by half. The plan has been held up only because the European Parliament demanded more than either the European Commission had proposed or the Council of Ministers, which takes decisions, could accept.

EURAM, (European Research on Advanced Materials), is a belated response to the spending of some $1,000 million (£666 million) by the US Federal Government each year on materials science, to similar spending in Japan and to the relative weakness of European research and industry in new materials. In the new magnetic technologies alone, which were Japanese and American research discoveries just four years ago, General Motors has already begun pilot production of starter motors.

According to the Commission, "there are still excellent materials laboratories in Europe, but their innovative capacity is one the decline". EURAM aims to help reverse the decline, and also to strengthen perennially weak links between universities and industry. Its budget was less than the ECU 38 million the Commission had requested, but much more than what it had been spending in pilot programme.

In the ambitious "framework programme" also debated by ministers here (see p.718), support for materials research would leap to some ECU 200–300 million over five years. Although the ministers declined to back the whole budget, a further expansion of the new materials programme won political support.

With the framework programme to be debated again in October, the Commission can meanwhile get on with implementing EURAM, which already has a detailed list of projects to support in metallic materials, engineering ceramics and composites. The object will be to link existing laboratories in joint programmes of research, with, preferably, an industrial partner. The programme will not be exclusive to the European Economic Community; the Swedish car-makers Volvo and Saab have already shown interest. Officials claim that 90 per cent of the leading European laboratories in the field of magnetic materials are involved in a pilot programme. **Robert Walgate**

US research overheads

Government semi-retreat

Washington

THE Office of Management and Budget (OMB) bit the bullet last week and published, in the *Federal Register* for 9 June, its final revisions to Circular A-21, the document that determines how institutions are reimbursed for the indirect costs associated with research grants. OMB came under a storm of criticism from universities after publishing its initial proposals for revising Circular A-21 earlier this year.

Indirect costs now represent nearly a third of all payments for research grants, according to OMB figures. To control this steady increase, the new revisions set a fixed allowance of 3 per cent of total research costs for the salaries of department heads and faculty attributable to the administrative overhead costs of research. Institutions receiving federal funds will not have to fill in forms to receive the allowance, which will eliminate the need for the much-hated "effort reports" formerly required to justify payments for time spent on administrative activities.

According to Milton Goldberg of the Council on Governmental Relations, this will give a windfall to universities whose costs have been less than 3 per cent. OMB estimates these costs now run between 5.5 and 6 per cent nationwide (see table).

	Deans, chairs	department lab directors	Faculty
Yale University	0.88	5.55	
Boston University	5.74	4.82	
University of California, Berkeley	0.80	1.45	
Harvard University	1.77	2.30	

OMB's first shot at a revision of A-21, first published in the *Federal Register* on 12 February, brought a storm of disapproval from universities and their allies in Congress. The proposal would have capped reimbursements for all administrative costs at 26 per cent for the current fiscal year, a figure that was to drop to 20 per cent for 1987. OMB estimated the government would save $200 million if the original plans had been put into effect. The new plan will save the government only $100 million.

A principal complaint of universities at the time of the initial OMB proposal was that they had not been consulted. Although OMB held numerous meetings with interested parties in the months following publication of the proposal, Goldberg says its final proposal still came as a surprise. Carol Scheman of the American Association of Universities is encouraged that OMB is taking universities' concern seriously, but is unconvinced the new revisions will solve the problem of rising indirect costs. She maintains that such costs will continue to rise as more money is needed for facilities and equipment.

The new regulations must take effect by 1 July 1987, although individual agencies may implement the changes sooner if they wish. The changes will apply only to new federal grants, leaving existing commitments untouched. But a move by Congress may hold up the new rules until October, the beginning of the next fiscal year. Congressman Sidney Yates (Democrat, Illinois) has amended the House version of a supplemental appropriations bill in a manner forbidding government agencies from spending money to implement the new plan.

The original Senate version of the appropriations bill contained a similar form of words. A House/Senate conference will make a decision this week whether to include the provision in the final version of the bill. **Joseph Palca**

Test-tube babies

Tokyo

JAPAN may be on the edge of a test-tube baby boom, according to predictions made by Dr Bob Seamark, an Australian expert in *in vitro* fertilization (IVF), and Dr Masakuni Suzuki, Japan's pioneer of the test-tube baby. Suzuki is so confident of the future that he has built a private hospital near Sendai to deal primarily with infertility problems using IVF techniques. But there are many problems still holding back development of IVF in Japan.

In Japan and Australia the incidence of infertility is similar, with as many as 10–12 per cent of couples unable to produce children. But the number of test-tube babies in Japan stands at only 27 compared with over 1,300 in Australia. Why has Japan lagged so far behind?

The Japanese public and academics are often severe critics of major new medical procedures, as shown, for example, by the outcry against heart transplants and sex selection. But probably more important than this is the lack of government support for IVF research and the cost of IVF treatment. Unlike Australia, IVF is not covered under national health insurance in Japan.

Another major difference between Australia and Japan is the almost complete lack of communication between Japanese scientists involved in reproductive biology research and the clinicians in hospitals who apply IVF techniques. Co-operation between clinicians and scientists, particularly those involved in animal breeding, is, according to Seamark, one of the major driving forces behind the tremendous surge in IVF research in Australia. David Swinbanks

Japanese gynaecology

Gender selection sparks row

Tokyo

A GROUP at Keio University in Tokyo has caused a sensation by claiming a major medical scoop on national television last month, when it announced that six married woman had given birth to baby girls after artificial insemination with X-chromosome sperms separated by centrifugation. But the publicity has back-fired, and the Keio team has come under a barrage of criticism even from within their own university for failing to inform the public of the experiments, and for going ahead without first discussing the ethical questions raised by sex selection.

The ethical committee of Keio University met last week and decided that once the reliability of the method has been established, it should be used only to prevent hereditary diseases. In the meantime, practitioners around Japan have already started using the technique.

Soon after the Keio group made its announcement, a group promoting sex selection headed by Dr Shiro Sugiyama, owner of Sugiyama Gynecology Clinic in Tokyo, revealed that 40 girls had been born around the nation using the Keio technique, and out of 24 women who conceived, 22 gave birth to girls, a success rate of over 90 per cent.

The principle of the technique is simple enough and well known — X-chromosome sperms are marginally more dense than those with Y chromosomes because of the larger size of the former chromosome, and they can, in theory, be separated by centrifugation. Although many claims of successful sex selection based on this principle have been made, no reliable technique has yet emerged. The Keio team, headed by Professor Rihachi Iizuka of Keio University and Professor Hideo Mori of Tokyo University, described their method in 1984 (*Biomedical Research*, **5**, 187; 1984).

The secret lies in the fluid in which the sperm are suspended for centrifugation. A density gradient of Percoll, a modified silica gel, is used and the sperm are separated on the basis of differential velocity sedimentation. After a 20–30-minute spin in a centrifuge at 250*g*, 95–100 per cent of the sperm in the bottom layer carries the X chromosome, while the overlying layer has about 85 per cent sperm containing the Y chromosome. According to Sugiyama, it is then just a simple matter of pricking a hole in the bottom of the centrifuge tube and draining a few drops of the X-chromosome-rich sperm which are used for impregnation.

First treatment in the Sugiyama Clinic costs 50,000 yen (about £170) and, in the case of failure, each subsequent treatment is 20,000 yen. Four or five attempts are usually required for success.

Sugiyama heads the Sex Selection Research Group which was established 7 years ago and which has 770 practising gynaecologist members throughout the nation. In the past they used vinegar-rinsing of the vagina as a technique to promote the conception of girls. But success was "less than 80 per cent".

According to Sugiyama, the new method has been used in most cases to prevent hereditary diseases such as haemophilia which occur in men, but he admitted some parents wanted a girl for personal reasons, such a wanting to raise their child to be a ballerina. It is revelations like this that have raised a furore.

Iizuka also initially claimed that the technique had been applied to avoid hereditary diseases, but many Japanese colleagues questioned this and Professor Yasuo Uemura, head of Keio University ethics committee, criticized the Keio team for applying the technique to couples who simply wanted a girl because they already had boys.

Uemura also though it "regrettable" that Iizuka went ahead without consulting the ethics committee in advance and "imprudent" that some of the members of his team attended meetings of obstetrical practitioners to teach them the sex-selection method.

Immediately after the meeting of the Keio University ethics committee, Sugiyama said he would abide by the committee's decision and limit application of the technique to prevention of hereditary diseases.

But in a complete about-turn a few days later he declared that he would continue to help ordinary parents to select the sex of their babies until advised otherwise by nationwide medical organizations, such as the Japan Medical Association or the Japan Society of Obstetrics and Gynecology. His change of heart came because he was deluged with letters and telephone calls from people asking him to continue the technique, and he felt it was "his duty as medical practitioner" to respect the wishes of such people.

According to a report in *Shukan Bunshun*, a Japanese weekly publication, the Keio group started clinical trials of the technique in May last year, and for the past six months Japan's national broadcasting corporation, Nihon Hoso Kyokai (NHK), has been allowed to cover the research.

But a difference of opinion arose between the Keio group and NHK about when to release the news; NHK felt that the preliminary success of the technique raised important social issues which should be discussed in public while the Keio team wanted to test about 100 women to obtain statistically reliable results.

In the end, NHK was allowed to broadcast after the successful birth of six girls by the Keio technique. **David Swinbanks**

Brown eggs catch on in Japan

Tokyo

FIRST it was the Australian "superpig" and now comes Japan's "biochicken", the next contender in the farmyard biotech race. And what makes biochicken special? She lays brown eggs, lots of them.

That may not sound like much of a feat until one realizes that shiny reddish brown eggs (literally "red eggs" in Japanese) command twice the price of the paler white variety on the Japanese domestic market. The inflated price of brown eggs in Japan can be attributed to limited supply and a belief among the general public that brown eggs are more nutritious.

Quick to spot a potential money-maker, scientists at Nagoya University and the Agricultural Experiment Station of Aichi prefecture have created White Leghorn hens that lay brown eggs instead of their usual white ones. Ths is achieved by false fertilization.

Sperm of a Rhode Island Red rooster, which carries the gene for brown eggs, is first irradiated with gamma radiation to inactivate it. The sperm is then allowed to enter the egg of a White Leghorn, thereby introducing some Rhode Island Red genetic material into the egg which is then fertilized with normal White Leghorn sperm. About 7 per cent of the fertilized eggs result in chickens that lay brown eggs. This technique was developed in New Zealand in 1982 by Pandey, but it had no commercial applications there — in New Zealand brown eggs cost the same as white.

But why go to all this trouble when Rhode Island Reds already lay brown eggs? The answer lies in greater productivity — the White Leghorn is a profuse egg layer. No doubt also, the label "bioeggs" will have commercial appeal in this country where "biolipstick" has swamped the cosmetic market (see *Nature* 314, 395; 1985).

Biochicken, however, is not yet quite living up to expectations; her eggs are only pale brown and are more typical of a hybrid White Leghorn/Rhode Island Red than a true Rhode Island Red.

But by selective breeding the Japanese team is confident that by this autumn it can come up with a hen that lays pure brown eggs, and it has already named this chicken of the future the "Aichi Bio Red".

Colombian immunology

More plans for malaria vaccine

Bogotá

COLOMBIA, hitherto best known for its coffee, now seeks to cultivate a reputation in science. As his last act in support of science, outgoing President Belisario Betancur earlier this month announced a

scheme whereby six of Colombia's best science graduates at a time would be awarded fellowships to study at the Research Institute of Scripps Clinic in California.

As the students will be paid from Colombia, they will be obliged to return there after their three-year stints in Richard Lerner's department of molecular biology at Scripps.

The hope is to increase Colombia's abilities in modern biomedical research, now concentrated in Manuel Patarroyo's Institute of Immunology at the San Juan de Dios Hospital in Bogotá.

Patarroyo, with the aid of the presidency and particularly of one of its economic advisers, Diego Pizano, whose support of science stems from a friendship with French virologist Gerard Bricogne while both were studying at the University of Cambridge, together with a gift of several sequencing and synthesizing machines from Arnold Beckman, has set up what is probably the best-equipped biomedical laboratory in South America.

Patarroyo, together with approximately thirty enthusiastic young researchers, is beginning to pursue gene cloning and vaccine development for malaria, leprosy and tuberculosis. They do so against the odds. For example, customs and other delays tend to allow "hot" radioisotopes to become cold and heat-degradable enzymes to warm up before they reach the institute. And there is no adequate postgraduate research programme in Colombia.

On the other hand, Colombians do have the advantage over laboratories in North America and Europe of having easy access to malaria and leprosy patients and to the animal models for the diseases, the *Aotus* monkey and the armadillo, respectively.

The most important outcome of the institute's research so far is the development of a candidate malaria vaccine. Reporting the initial data on the vaccine at a conference entitled Perspectives for Chemistry in Medicine in Bogotá this month, Patarroyo described how the immunization of monkeys with a combination of three synthetic peptides, corresponding to partial sequences of one of the major proteins on the surface of malarial red blood cells, protects the animals against infection with the protozoan *Plasmodium falciparum*, which is the main malaria parasite of humans.

So far the tests have involved only a few monkeys, but up to 50 will be included in an extended trial.

About a thousand scientists and students attended the conference. According to the organizers, Patarroyo and Pizano, the main purpose was to provide a stimulus to Colombian science, which came in the form of 10 speakers from the United States and 4 from Europe.

Four of the speakers, Lerner plus Gobind Khorana of Massachusetts Institute of Technology, David Baltimore of the Whitehead Institute and Peter Perlmann of the University of Stockholm, were awarded the Order of San Carlos in the rank of knight by President Betancur during the conference.

Should an effective malaria vaccine emerge — and even with the first phase of clinical trials of some possible vaccine components about to begin in other countries, nobody doubts that there is a long way to go — Colombia should be well placed to carry out a mass vaccination campaign.

During 1985 and early 1986, several million young children were vaccinated against five common diseases by means of a campaign that involved the newspaper *El Tiempo*, the radio network *Caracol*, UNICEF, the Roman Catholic Church, the armed forces, various government agencies and a host of volunteers.

The only part of the country to be missed out, a strip of inaccessible Pacific coastland, is about to be tackled in a week of action involving 100 helicopters and hundreds of boats. **Peter Newmark**

Catch your monkey

AOTUS monkeys are collected by Indians in the Amazonian basin. With a group of monkeys inside the hollow tree trunks that they live in, the Indians first seal off all the exit holes. They then reopen one hole and as the enraged animals emerge, try to catch them by the tail.

It can take a week to catch a single animal. Captured monkeys are taken to Leticia at the southernmost tip of Columbia, where the malaria trials are carried out. Because the *Aotus* monkey is a protected species, those that succumb to malaria have to be cured with drugs. They are then passed on to a breeding colony elsewhere in Colombia and, sometimes, released back into the wild. □

Coffee benefaction

As coffee is far and away Colombia's main export, it is not surprising that the *Federación Nacional de Cafeteros de Colombia* maintains two laboratories, one that concentrates on the chemistry and the other on the biology of coffee.

The chemistry laboratory in Bogotá under Marco Quijano employs approximately twenty scientists and seventy students to study coffee composition and processing as well as tissue culture and the problems of coffee rust, a fungal disease that reached Colombia only in the past two or three years.

Copper-containing sprays are the main way to defeat the rust fungus but they are expensive to administer, not least because they have to be delivered by hand as aerial spraying would ruin the electricity cables. The chemistry laboratory is conducting a careful study of the effects of copper on the coffee plant, to establish whether it would be possible to treat the soil with copper to inhibit rust disease. In the end, however, Quijano believes that the fungus will develop resistance to copper.

Studies of coffee processing are a particular focus of the laboratory because of the growing demand for decaffeinated coffee in the developed nations. There has been talk of using biotechnology genetically to manipulate the coffee plant so that the beans are caffeine-free. But in economic terms, this makes little sense, because the process of decaffeination is paid for by the sale of the caffeine to the pharmaceutical industry. Cloning of coffee plants, on the other hand, is considered important and 250 plants derived by tissue culture are being studied.

Colombian coffee tends to be sold at a premium price because it is made from ripe beans only. That is possible because the beans are hand-picked rather than mechanically shaken from the plants. This fits with the fact that Colombian coffee is largely grown on small plots owned by a single family which receives a guaranteed price from the coffee growers' association to whom they have to sell their crop. This provides a buffer against bad years, but also means that the farmers are not benefiting from this year's high prices, occasioned by the failure of the Brazilian crop. □

The Paluxy River mystery

SIR—The article "On the Tracks of Men and Money" by Tony Thulborn (*Nature* **320,** 308; 1986) contains many inaccuracies on a subject that cries for clarity. The presumed occurrence of both human and dinosaur tracks in the Lower Cretaceous Glen Rose limestone in central Texas has for over a decade been the favourite illustration of the creation model, while being, as Thulborn personally admitted to me, "the evidence evolutionists feared the most".

It is true, as Thulborn stated, that, at a January 1986 lecture at the University of New South Wales, I called attention to recent changes in the nature of the tracks which bring into question the original interpretations by myself and others. Having been involved in this project for a decade and having written the definitive book on the subject, I did not find this comfortable, but as an empiricist and honest man, I dared not do less. Even though Thulborn calls the present nature of the tracks "embarrassingly obvious" and the process by which they changed "well known", the truth is, evidently, that an unprecedented geological phenomenon has taken place which is, as yet, only poorly studied and less well understood.

Somehow, since 1984, surface stains in the shape of tridactyl dinosaur prints have appeared, surrounding many of the eroded remnants of elongated tracks once interpreted as human-like. In almost all cases, these stains are not associated with any impression in the rock — they are a coloration phenomenon only. In some cases, the stain ingores the "mud up-push" surrounding the human-like impressions.

Neither my two field trips to the Paluxy in the fall of 1985, nor the analysis of samples taken, answer all the questions. There are only two possibilities: (1) an, as yet, undeciphered geological process partially obscured portions of the tracks of a previously unknown dinosaur which walked in an atypical plantigrade fashion, or (2) that someone has fraudulently altered the appearance of the tracks.

I emphasize that I have seen no direct evidence of fraud. I plan to continue my research once water levels are lower, to gain a more complete understanding, but meanwhile I have encouraged creationists to refrain from using the Paluxy as an anti-evolutionary argument.

Thulborn and other evolutionists are rushing to embrace this evidence, relishing the fact that the tracks, once thought to be human, now appear reptilian. But hitherto, the usual evolutionists' explanation has been that the markings were not tracks at all. The 1986 booklet *Creationism, an Australian Perspective* by the Australian Skeptic Society implied that I had carved some of them. Others have claimed they were scour marks, eroded potholes, worm burrows or creationist footprints in the river-bottom mud. After studying both the present nature of the prints and photographs of their nature when first discovered, I am convinced that the original interpretation was not only valid, but arguably the best.

Thulborn, president and founder of the Australian Association for the Protection of Evolution (APE), is also less than objective when he repeats the Skeptics' charge of financial impropriety on the part of the Creation Science Foundation (CSF) of Australia. He claims "CSF still declines to give a detailed explanation" of the whereabouts of $92,000. However, he should know (I was standing next to him when the president of CSF explained it to him) that an employee of the investment company in which the money had been placed had embezzled from many accounts, including that of CSF, and that the authorities had frozen the remaining assets. Court cases are now in progress. So far CSF has received only a portion of its money back.

Likewise, Thulborn repeats the charge that federal money had wrongly been given to CSF in the form of an "export market development grant". My understanding is that the Australian government financially encourages companies and organizations that export products to be sold overseas; CSF has recently begun to publish and print locally a magazine and other publications which are primarily sold in North America and Europe and, as such, is eligible for such an export development grant.

JOHN D. MORRIS
Institute for Creation Research,
10946 Woodside Avenue North,
Santee, California 92071, USA

SIR—Tony Thulborn reports (*Nature* **320;** 308; 1986) that Robert Morris now admits that the "human" footprints on those of big dinosaurs in Cretaceous limestones, Paluxy River, Texas, were those of small three-toed dinosaurs. Additional news is now available from San Diego, California, that the fake exhibit at the Institute for Creation Research, showing an 80-million-year-old human being beside a dinosaur[1], has been "closed for revision", and that the "casts" have been removed. Will there be a revision of *Dry Bones*[1]?

There is more joy, among evolutionists, over one sinner that repenteth than over ninety and nine that are too brazen to repent. Can we hope that other creationist intellectual atrocities may be abjured by their perpetrators? Examples are misrepresentations of the second law of thermodynamics and of isotopic dating, claims for variability of the speed of light, and engagement, by good and bad angels, in their own form of star wars[1].

Many evolutionists will be glad to help the creationists put their house in order, even at the expense of its disappearance into thin air.

Cometary first

SIR—The magnificent 15 May 1986 issue of *Nature* containing the first results from the spacecraft voyages to comet Halley was marred by an unfortunate lapse in the Editorial (p. 366) by John Maddox entitled "First journey to a comet". For the record, the first encounter took place on 11 September 1985 when the International Cometary Explorer passed 7,800 km tailward of the nucleus of comet Giacobini–Zinner. Of the missions to comet Halley, only Giotto came closer to the nucleus.

The field of cometary research has been advanced in 1985 and 1986 by a massive effort from a variety of disciplines. We applaud the work of the Giotto, Sakigake, Suisei and Vega projects for their pivotal contribution. However, appreciation of this achievement does not require a revision of history.

Safe nuclear energy

SIR—The important lesson from the Chernobyl disaster is that the best brains in the world are needed urgently to work on developing safe nuclear energy, and that the warnings of these scientists must be heeded even when they say things that their governments and the nuclear power industry do not like. Unfortunately, one of the best brains in the nuclear safety business has been out of the action for several years. Andrei Sakharov has been isolated, harassed and prevented from contributing to this important effort because he says things that his government does not like.

If General Secretary Gorbachev is really serious about the need for a collective world effort to make nuclear energy safe, he should bring this great pioneer of nuclear safety back into the mainstream of nuclear research.

High Energy Physics Division,
Argonne National Laboratory,
9700 South Cass Avenue,
Argonne, Illinois 60439, USA

When reference means deference

Hoyle and Wickramasinghe protest that none of the contributors to recent accounts of the encounters with Halley's comet have referred to them. But they have only themselves to blame.

WHAT follows is a sad but disturbing tale, which is told not for the sake of making further trouble but in the hope of stilling what there is already. It centres on the recent encounters of the two Soviet Vega spacecraft and the European Giotto spacecraft with Halley's comet in March, the publication of preliminary accounts of the encounters in *Nature* on 15 May, the publication in the succeeding issue (**321**, 385; 1986) of a "prediction" (published after the event) by Professor J.M. Greenburg at the University of Leiden that the surface of the nucleus of Halley's comet would appear black and the complaints of two British scientists, Sir Fred Hoyle and Professor Chandra Wickramasinghe, that their own earlier predictions to the same effect have wilfully and even maliciously been overlooked.

Most readers will not have ready access to the documents in which the complaints surface, which consist chiefly of "preprints" circulated from the Department of Astronomy at University College, Cardiff. The description of this now considerable volume of largely unpublished literature is a misnomer, because much of it is plainly not written with the intention that it should go through the processes that ordinarily precede publication, scrutiny by referees, for example. This is certainly the case with "Cardiff Astrophysics and Relativity preprint No. 125", dated 1 June 1986, under the title *On deliberate misreferencing as a tool of science policy*, which has been artfully contrived to appear as if it were the galley proof of a letter due to appear in *Nature*. (For future reference, the authors of this little joke should know that our type size is known in the trade as "9 on 10", not "9 on 11", and that our wide columns are 20.6, not 20.0 "ems" wide.)

Readers will also know that Sir Fred Hoyle is one of the most talented and ingenious theoretical scientists since the Second World War. With Bondi and Gold, he launched the steady-state theory of cosmology, with a variety of collaborators (W.H. Fowler and the two Burbidges) he laid down the outlines of the theory of nucleogenesis and, almost as if in passing, showed how to calculate the evolution of stars. Latterly, Hoyle has been exploring a question originally posed in urgent form by Wickramasinghe, that of the constitution of interstellar dust. Many readers will know the eccentric direction this work has taken. Hoyle and Wickramasinghe have remarked that carbon is a common constituent of interstellar dust (as it is of gas), that much of this carbon is in the form of sedimentary organic molecules and have then gone on, in a series of mostly *samizdat* publications, to argue that the prevalence of interstellar carbon only goes to support one of the other theories to which they are attached. They say that life as it is known on the surface of the Earth is genetically far too complicated to have arisen by means of darwinian evolution from primordial chemicals, that at least the first steps in the evolution of life are likely to have taken place "out there" and that, as it happens, comets are likely to have been among the means by which the surface of the Earth is from time to time repopulated by external organisms.

Those writing off for a copy of preprint 125 should be sure also to ask for preprint 121, dated 1 March, which put forward a particular model of the constitution of the periodic comets (of which Halley is one). Most of the objects, the argument goes, will have lost volatile material from the outer surface, which will therefore be a loose uncompacted "protective" skin of material with low refractive index and, therefore, low reflectivity for sunlight. The authors are partly concerned to explain the discrepancy between the calculated and observed (only a tenth as many) number of periodic comets; their solution is to suggest that most periodic comets slip by unobserved, but that those with more than one nucleus become visible because the nuclei rub against each other, exposing parts of the volatile interior to solar radiation. Hoyle and Wickramasinghe did not on 1 March say so explicitly, but it may be inferred from their general discussion that the surface of Halley's comet was predicted to appear mostly black.

The complaints in preprint 125 are more entertaining. First, they marvel at Greenberg's "sibylline achievements" in predicting what Halley's comet would seem like after the event, overlooking that Greenberg's model is radically different from their own; in fact the reason for its publication was not that it made a "prediction" but that it is a model of which many readers of *Nature* would not previously have heard. Second, they remark, in sorrow rather than anger, that none of the Halley authors in the issue of 15 May refers to them. They go on to note that, in its time, *Nature* has been guilty of removing a reference to their work from an article written by a third party. Finally, they darkly speculate on the possibility that this neglect may simply have been a consequence of this journal's malign attitude both towards themselves and as a willing "vehicle of propaganda for Darwin's theory". They suspect that it may be a "management condition" that "persons judged to be a threat to Darwinism are to be blotted out from the scientific world".

This lengthy reply to what Hoyle and Wickramasinghe allege stems not so much from the circumstance, attested by preprint 125, that the authors and the present editor of *Nature* are old friends but from a wish that these two talented people should come to see the error of their ways. But in passing, it should be known that the sinister deleted reference was a reference to their panspermiology in D.A. Allen and D.T. Wickramasinghe (*Nature* **294**, 239; 1981), an otherwise helpful measurement of infrared absorption in interstellar space.

Moreover, they may be right about comets. Much of what they have written over the years deserves to be widely read, for example the argument that comets contain polyformaldehyde (Vanysek, V. and Wickramsinghe, N.C. *Astr. Space Sci.* **33**, 19; 1975) or the demonstration (with W.K. Wallis) that comets Cernis and Bowell probably contain organic molecules rather than water-ice (*Earth, Moon and Planets* **33**, 179; 1985). What these authors seem incapable of understanding is that their panspermian convictions sully even their sober contributions to the literature. People who might (and even should) read their articles on comets do not do so for the simple reason that they half expect to find there a rehearsal of the now familiar and widely popularized view that life began in space.

Not that even that is necessarily wrong. Time may yet show that Hoyle and Wickramasinghe have been true prophets crying in the wilderness of disbelief. Yet as things are, there is no evidence but conjecture on their side. Their flimsy account of the origin of life has as its sole foundation their scepticism of the efficacy of natural selection among primordial molecules. It is as if a particle theorist chose to say that, while the Higgs boson remains undiscovered, the only partly successful theory so far must be discarded and all others, however flimsy, must be given more than equal time. They ask a lot, too much for most.

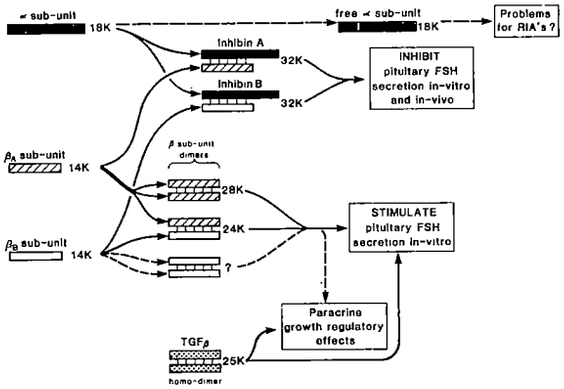
Endocrinology



Dual gonadal control of follicle-stimulating hormone

from Con G. Tsonis and Richard M. Sharpe

OF all the reproductive hormones, none has had a more chequered history than inhibin, a glycoprotein produced by the gonads that feeds back to the anterior pituitary gland to decrease specifically the secretion of follicle-stimulating hormone (FSH)[1]. Attempts at the purification of inhibin proved far from straightforward. Reports of molecules with inhibin-like activity ranging in relative molecular mass (M_r) from 10,000 to 100,000, (10K–100K) raised doubts about the authenticity of inhibin. These have recently been resolved by demonstration that is composed of an interlinked α- and β-subunit. Now comes a major surprise. Two reports on page 776 and 779 of this issue[2,3] show that dimers of the β-subunits of inhibin are potent stimulators of FSH synthesis and secretion, raising the possibility of dual control of FSH from within the gonads.

Clarification of the nature of inhibin occurred in two phases. In 1984 a low M_r (14K) form of inhibin, present in human seminal plasma, was purified and sequenced[4], but was later shown to originate from the prostate and not the gonads[5]. It is now known to be structurally unrelated to gonadal inhibin. This probably excludes it as a physiological regulator of pituitary FSH secretion. More importantly, in December 1985 the full sequence of two 32K forms of porcine follicular fluid (pFF) inhibin (inhibin$_A$ and inhibin $_B$) were published[6], and have since been confirmed for bovine inhibin[7]. Each form is composed of two crosslinked subunits (see figure), a larger common α-subunit of M_r 18K and a smaller, distinctive β-subunit of M_r 14K, designated as β_A or β_B according to differences in the amino terminus. As these were the predominant forms of inhibin present in pFF and, as higher molecular mass forms of FF inhibin (for example, 58–108K) can probably be explained by extensions of the α- or β-subunits[7,8], it appeared that inhibin had finally yielded its main secrets.

Two independent laboratories now report the isolation and purification of two inhibin-related factors from pFF which are potent and selective stimulators of pituitary FSH release *in vitro*. These factors are referred to as FRP (ref.2) and activin[3], respectively, by the authors. FRP is a 28K polypeptide composed of two β_A subunits of inhibin and activin is a polypeptide composed of one β_A and one β_B subunit of inhibin held together by disulphide bond(s) (see figure). Although only two β dimers were isolated this does not exclude the possibility of a third factor, a homodimer composed of two β_B subunits. For the β dimers to have biological activity both subunits must be joined together because reduction of the disulphide bonds destroys their bioactivity, as is also the case for inhibin. The β dimers are highly potent stimulators of both the biosynthesis and secretion of FSH but have no effect on luteinizing hormone (LH) or prolactin. The β_A homodimer is reported also to reduce the secretion of growth hormone and adrenocorticotrophic hormone[2].

Diagrammatic representation of how the α- and β-subunits of porcine follicular fluid inhibin can be combined to yield molecules with either FSH-inhibiting of FSH-stimulating activity. ——→ Proven pathways; - - - → possible pathways. Reported relative molecular masses are shown.

The action of the β dimers can be distinguished from those of luteinizing hormone-releasing hormone (LHRH) in several ways. Compared with LHRH, β dimers have no effect on LH secretion, act much more slowly (greater than 4 hours rather than minutes for LHRH) and have greater stimulatory effects on the biosynthesis of FSH. Also, LHRH antagonists, which completely block the LHRH-stimulated release of both FSH and LH *in vitro*, have no effect on the secretion of FSH mediated by the β dimers. These data suggest that the β dimers act through receptors separate from those for LHRH and probably via a different mechanism.

An additional finding of great interest is the striking homology between the β dimers and transforming growth factor-β (TGF-β)[6]; the homology is such that they are considered to be products of the same gene family. TGF-β exists as two 12.5K sub-units linked by disulphide bond(s) to yield a 25K homodimer (see figure) which is also a potent stimulator of FSH release at low concentrations (10^{-10} M)[9].

The discovery that the β dimers are present in follicular fluid together with inhibin suggests that there is a 'push-pull' system operating from within the gonad to control production of FSH. When both inhibin and the β dimers are added to pituitary cells, the effect of inhibin predominates and FSH secretion is decreased. As inhibin is present in follicular fluid in higher amounts than the β dimers this implies that negative control of FSH by the gonad is the principal feedback message, though this does not exclude the possibility that secretion of the β dimers may predominate under different physiological states.

However, before critical evaluation of the role(s) of the β dimers is possible it will be necessary to establish first, whether they are secreted from the gonads into the peripheral circulation; and, second, whether they have local growth effects within the gonads analogous to the effects of TGF-β reported in other tissues[10]. If the β dimers are secreted systemically then problems would arise if they also had TGF-β-like activity because the latter has widespread local effects in various tissues and the β dimers might activate these sites. The structural differences between the β dimers and TGF-β may prevent this.

Alternatively, the β dimers may not be released systemically but the ability of the β dimers (or TGF-β) to increase pituitary FSH release at picomolar concentrations or less *in vitro* suggests strongly that this effect is of some physiological importance. Indeed, if the β dimers are not secreted from the gonads into the blood, then perhaps a molecule resembling the β dimers or TGF-β is secreted by the hypothalamus to modulate pituitary FSH. There are several reports of the existence of a hypothalamic FSH-releasing hormone[11], but these have never been widely accepted and appear to describe a smaller molecule than the β dimers. With respect to the possible local effects of the β dimers, it has been shown recently that TGF-β can enhance FSH-stimulated secretion of oestradiol by rat granulosa cells *in vitro*[12]. This suggests that the β dimers may normally exert a comparable effect within the ovarian follicle. In the same study, 32K inhibin was shown to antagonize FSH-stimulated secretion of oestradiol, raising the possibility of dual local modulation of FSH action within the gonad.

These recent developments have important implications with regard to the measurement of inhibin by radioimmunoassay[13] and bioassay[1]. The relative abun-

dance in the ovary of the messenger RNAs for the α-subunit precursor of inhibin is estimated from Northern blots to be at least 10-fold greater than that for the β_A precursor, and about 20-fold greater than for the β_B precursor[6]. This suggests that there may be secretion of free α-subunit or its precursor. As free α- or β-subunits are devoid of FSH-releasing or inhibiting activity, antibodies directed towards the α-subunit of inhibin may cross-react with the free α-subunit, therefore overestimating the amount of inhibin in a sample. In a preliminary report[8], however, free α-subunit of the hormone could not be detected in bovine follicular fluid.

Antibodies raised against the β-subunits of inhibin (β_A or β_B) may prove even more troublesome in that they may well cross-react with the β dimers as well as with inhibin. This again would lead to an overestimation of the levels of inhibin. Similar problems can be expected with antibodies raised against the β dimers, as these may show major cross-reaction with inhibin. Furthermore, bioassays of inhibin may underestimate the actual level of the hormone in a sample if the β dimers are also present and countering the effects of inhibin.

Until now it has been an accepted principle of endocrinology that gonadal feedback control of FSH secretion is under the dual control of steroids and inhibin. Introduction of β dimers or an equivalent as a third candidate would neccessitate a major rethink about control of the hypothalamic-pituitary-gonadal axis. Finding out how the function of this third factor interacts at the pituitary level with the actions of LHRH and with those of the recently described LHRH-associated peptide (GAP)[14,15] and elucidating the local roles of inhibin and the β dimers undoubtedly presents reproductive endocrinologists with a considerable task but it also promises more surprises. □

Precambrian geology

The most ancient rocks revisited

from Stephen Moorbath

THREE years ago, a group of workers from the Australian National University surprised the geological world by reporting[1] uranium–lead (U–Pb) dates of between 4,100 and 4,200 million years (Myr) for 4 detrital zircons out of 102 analysed from the Mount Narryer quartzite in Western Australia, which was probably deposited and metamorphosed about 3,600–3,350 Myr ago. On page 766 of this issue[2], W. Compston and R.T. Pidgeon report a further occurrence of such old detrital zircons, identified once again with the ion-microprobe SHRIMP, in a conglomerate from the Jack Hills metasedimentary belt at a site about 60 km north-east of Mount Narryer.

In Compston and Pidgeon's study, 17 zircon grains out of 140 analysed yield U–Pb dates greater than 4,000 Myr. Indeed, one zircon grain registers the exceptionally old date of 4,276±6 Myr, which may still be a minimum value for its original age. The authors regard the 'old' zircon population as either having a single original age close to 4,300 Myr with subsequent early as well as recent Pb loss, or as a mixed-age population that formed during discrete events over an extended time period between 4,100 and 4,300 Myr ago. The age of these ancient minerals constrains the time of the earliest preservation of Earth's solid crust.

As at Mount Narryer, the majority of zircons at Jack Hills register very much younger dates than 4,000 Myr, probably related to igneous and/or metamorphic thermal events 3,100–3,500 Myr ago. In principle, early gain of Pb (or loss of U) followed by recent Pb loss could produce anomalously old apparent U–Pb zircon dates, but although this process has been demonstrated in a zircon from Mount Sones, Antarctica[3], it is not regarded by the Australian workers as a plausible model for Mount Narryer and Jack Hills.

What clearly needs to be done next is to subject the Jack Hills zircon population to conventional solid-source mass spectrometry and isotope dilution analysis of single grains and individual fragments of single grains. Schärer and Allègre[4] performed this type of analysis on 32 single zircon grains from Mount Narryer; they obtained no 4,100–4,200 Myr dates and interpreted the results solely in terms of zircon crystallization 3,800–3,300 Myr ago. From simple statistics, Compston *et al.*[5] countered by postulating that Schärer and Allègre had simply been unlucky in failing to find any zircons more than 4,100 Myr old at Mount Narryer. (The chance of selecting 32 'young' grains in succession was shown to be 27 per cent.) Because the proportion of 'old' zircon grains at Jack Hills is about five times that at Mount Narryer, the conventional analytical approach will be greatly facilitated.

The morphology as well as the U and Th contents of the Jack Hills zircons suggest to Compston and Pidgeon that their source consists of a mafic rock which has undergone granulite-facies metamorphism. In contrast, the source rock at Mount Narryer may have been a felsic igneous rock not recrystallized by granulite-facies metamorphism. Thus, the ancient source terrain of the detrital zircons, not yet found *in situ*, may have had considerable geological complexity although, as I pointed out in a previous *News and Views* article[6], one should be cautious in attributing a truly continental character to the source-region crust. Perhaps the ancient source terrain was more like an early non-continental volcano-sedimentary assemblage of greenstone belt facies, such as the now well-known Isua Belt of West Greenland which, with a well-established age of ~3,800 Myr, is the oldest *in situ* terrestrial rock assemblage known[7,8] and has survived in a relatively pristine condition until the present day. It is highly significant for any model of early crustal evolution that a 4,100–4,300-Myr-old source region should have remained exposed for at least 600–800 Myr at such a very early period of the Earth's history and preserved from recirculation into the mantle by plate tectonics or by any other process.

It may be too much to hope that the source rocks of the oldest Mount Narryer and Jack Hills zircons will actually be found *in situ* and thus become amenable to dating by other isotope methods. In the meantime, I shall try to repress a recurring nightmare that SHRIMP will one of these days come up with zircon U–Pb ages significantly greater than 4,600 Myr, the widely accepted age of the Earth. It would not be the first dating method to have undergone this embarrassing trial, and yet emerged triumphantly. □

Archaeology

Finding the earliest Americans

from Warwick Bray

THE problem of the age and nature of the first human colonization of the New World has divided the archaeological profession for more than a century. Even now, there is general agreement on only two points: that the source of the colonizing population was north-east Asia; and that man was around by 11,500 years before present (BP), when fluted stone spear heads (Clovis points) are documented at several localities in North America. The Chilean site of Monte Verde[1] (13,000 yr BP), and perhaps the Alice Boer locality in Brazil[2] (14,200 ± 1,150 yr BP), push back the threshold by a few millennia, but no material older than 15,000 yr BP has gained universal acceptance. The strong evidence for stone tools dated at 32,000 yr BP at a site in Brazil, reported by Guidon and Delibrias on page 769 of this issue[3], is therefore important to archaeologists and to palaeontologists. The controversial belief that human predation caused the extinction of many large mammals at the end of the Pleistocene (that is, the Clovis point period)[4] is much weakened if large populations of hunters were already present in the Americas some twenty thousand years earlier.

Recently, the proponents of very early dates have suffered two setbacks. Using a corrected calibration, the apsartic acid racemization ages of the California 'Palaeoindian' skeletons have been drastically revised, and all these specimens turn out to be Holocene[5]. Still worse is the revised date for the only undisputed bone tools from the Old Crow Basin in the Yukon. In the 1970s, carbon extracted from the inorganic apatite fraction of a fleshing tool made of caribou rib gave a radiocarbon age of about 27,000 yr BP, but a re-dating of organic proteinaceous material (by the accelerator mass spectrometry method) has reduced this age to 1,350 ± 150 yr BP, though the dates for the redeposited (and possibly flaked) mammoth bones from these gravels remain more or less the same as the original date[6].

In essence, however, the basic dispute is not about individual sites or artefacts, but about what constitutes archaeological proof. It is true, of course, that piling up dubious cases proves absolutely nothing, and that a single unassailable find is enough. In theory, the criteria for acceptability are simple: there must be man-made artefacts (or other signs of human presence, such as hearths or structures) datable either directly or by their occurrence in deposits of known age. The ideal site would have a long stratigraphy, plentiful tools, multiple radiocarbon dates and evidence for evolution within the stone industries. This is exactly what Guidon and Delibrias provide in the work on the Brazilian site of Boqueirao of Pedra Furada[3]. Their oldest carbon-14 date, 32,160 ± 160 yr BP, comes from a fire hearth in a stratum with flaked tools and with spalls of painted rock from the walls of the shelter. Another sixteen radiocarbon dates are scattered at intervals through 3.5 metres of sediments. The validity of their evidence seems beyond doubt, and the excavation also suggests that cave art in the New World began at much the same time as in Eurasia and Africa.

It is to be hoped that Pedra Furada does not suffer the neglect given to Tlapacoya, in the Basin of Mexico, where good artefacts were discovered more than 20 years ago in a long sequence of lacustrine sediments and volcanic ashes dated at about 24,000 yr BP[7]. And there are other reports which, if eventually confirmed, will strengthen the argument for early colonization. At El Cedral, Mexico, stone tools and extinct fauna are provisionally dated at more than 30,000 yr BP[8] and in the deepest strata at Monte Verde, Tom Dillehay (personal communication) has found a split basalt pebble, wood fragments, two modified stones and charcoal dated at about 33,000 yr BP.

Evidence supporting an early colonization is also emerging from other disciplines. A study by Richard Rogers[9] of linguistic diversification in North America suggests that man must have been present south of the ice sheets before the Wisconsin maximum of about 18,000 yr BP, and long before the (post-glacial) incursions of the Na-Dene and Eskimo-Aleut language families.

A parallel study of the dental evidence by Christy Turner II[10] also indicates three separate colonizations, equating with the three major language introductions. He proposes that colonists initially spread outwards from North China around 20,000 yr BP and moved, via the Lena Basin of Siberia, into Beringia and Alaska. By the end of the Pleistocene this same, early Amerindian population had got as far as Tierra del Fuego. The descendants of Turner's proposed original group of immigrants could have filled up the Americas and must have been responsible for all stone industries older than 10,000 yr BP, when microblade tools and Na-Dene languages came to Alaska. In the light of the evidence from Pedra Furada we may now have to push Turner's starting date back by more than ten thousand years. □

Caldesmon

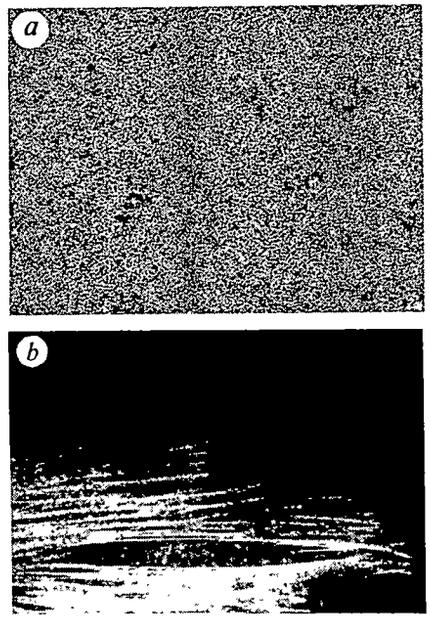
Thin filament regulatory proteins of smooth- and non-muscle cells

from Anthony Bretscher

THE mechanism by which changes in the concentration of cytosolic calcium regulate the contractile machinery of smooth muscle has been a controversial problem. But the situation has now changed dramatically with the emergence of evidence in favour of a Ca^{2+}-calmodulin-mediated filament regulatory system.

The now well-established discovery[1,2] that the interaction of myosin light-chain kinase and Ca^{2+}-calmodulin leads to the phosphorylation of myosin and thereby enhances the actin-activated ATPase of myosin was a major step forward. It led to the common belief that smooth muscle contraction is controlled by the regulation of thick filaments. This mechanism contrasts with that in striated muscle, which is regulated by the classic tropomyosin–troponin thin filament system.

The smooth muscle thick filament regulatory model was extended to non-muscle cells when regulation of some non-muscle myosins via light-chain phosphorylation and dephosphorylation was found[3]. Overwhelmed by the simple elegance of the phosphorylation mechanism of smooth muscle thick filament regulation, scant attention was paid to suggestions of thin filament regulation — that is, thin filaments that activate myosin in the presence, but not in the absence, of Ca^{2+}.



During this period, Ebashi and colleagues[3] suggested that a protein called leiotonin might impart some regulation, although this has not been independently substantiated.

The first evidence that suggested thin filament regulation of smooth muscle contraction was in systems containing activated myosin, but gave no clear indication of the regulatory molecules involved. As these experiments were refined, interest focused on the major components of partially purified thin filaments that retained Ca^{2+} regulation, namely actin, tropomyosin and a polypeptide of high relative molecular mass (M_r) $\simeq$ 120,000 (120 K)[4]. The second line of evidence was the identification in chicken gizzard smooth muscle of a protein that binds both actin filaments (F-actin) and Ca^{2+}-calmodulin[5]. This protein, with an apparent polypeptide $M_r \simeq$ 140 K, was named caldesmon (from a combination of calmodulin and $\delta\varepsilon\sigma\mu o\varsigma$ — bond) because its binding to F-actin can be inhibited in the presence of calmodulin in a Ca^{2+}-dependent manner. Further characterization in a reconstituted contractile system (consisting of desensitized actomyosin, myosin light-chain kinase, tropomyosin and limiting calmodulin) revealed that caldesmon inhibits the phosphorylated actin-activated ATPase of myosin[6]. This system can be regulated by the addition of excess Ca^{2+}-calmodulin which relieves the inhibition imposed by caldesmon (refs 4,6, but see ref. 7 for an alternative view). The two lines of evidence merged when it was found that the 120 K thin filament protein is caldesmon[4]. The inhibitory activity of caldesmon can be inactivated by phosphorylation of the protein by a specific protein kinase, which suggests another level of regulation. This caldesmon kinase activity is activated, like myosin light-chain kinase, by Ca^{2+}-calmodulin[7].

Taken together, these data indicate that smooth muscle is regulated at several levels by Ca^{2+}-calmodulin: first, regulation of myosin by reversible phosphorylation; second, Ca^{2+}-calmodulin binding to caldesmon which relieves the inhibitory effects of caldesmon on the actomyosin interaction; and third, regulation of caldesmon by reversible phosphorylation via the Ca^{2+}-calmodulin-regulated specific kinase and a phosphatase.

So what is known about the molecular properties of caldesmon? The protein appears to be structurally very stable, as it can be boiled in high salt or precipitated with organic solvents, yet retains its characteristic properties. It is a mildly acidic protein that, at least in chicken gizzard, exists as two polypeptide chains of slightly different apparent M_rs that can each be resolved into several isoelectric variants[8]. Hydrodynamic data indicate that caldesmon is highly asymmetrical[8]; low-angle rotary shadow electron micrographs confirm this and reveal that it is a long, flexible molecule (*a* in the figure)[9].

Caldesmon seems to be widely distributed as immunologically related proteins have been found in all smooth and non-muscle cells so far examined (*b* in the figure)[10,11]. Here the story becomes perplexing. There is a great deal of heterogeneity in caldesmon species in different cells: the apparent M_rs of caldesmons from different smooth muscles varies although they are in the region of 140 K (ref. 9). In various non-muscle tissues and cultured cell lines the apparent heterogeneity becomes even more noticeable. Some tissues and all the cell lines so far examined contain two classes of immunoreactive polypeptides: those in the M_r range 120–150 K and those in the range 71–77 K[11]. Because these species all remain soluble after heat treatment and bind F-actin in a Ca^{2+}-calmodulin inhibitable manner[11,12], they are functionally related to smooth muscle caldesmon, but nothing is known about how they are related to one another. Caldesmon is present along stress fibres of cultured fibroblasts in a periodic pattern apparently coincident with the localization of myosin, myosin light-chain kinase and tropomyosin, and complementary to the distribution of α-actinin[11]. In smooth muscle, caldesmon is localized in the actomyosin domain rather than in the apparently non-contractile filamin domain[9]. Thus it is not only capable of regulating the actomyosin interaction *in vitro*, but is also localized in the correct region of the contractile apparatus of smooth and non-muscle cells to perform this function *in vivo*.

a, Low-angle rotary shadow electron micrograph of smooth muscle caldesmon (× 43,000). *b*, Indirect immunofluorescence micrograph of part of a cultured A7r5 smooth muscle cell showing localization of caldesmon (× 530).

How does caldesmon regulate the actomyosin interaction? Is it, together with tropomyosin, a primitive form of the tropomyosin–troponin regulatory system of striated muscle? We do not yet have enough information to answer either of these questions. But any model must take into account the following observations. First, the apparent regulatory properties of caldesmon seem to require the presence of tropomyosin[4,6]. The co-localization of caldesmon and tropomyosin along stress fibres of cultured cells may also indicate a regulatory role for tropomyosin. Tropomyosin has been suggested to stabilize selectively certain classes of microfilaments. In the light of the results I have described here, it seems more likely that caldesmon and tropomyosin are part of a contractile unit that regulates actomyosin interaction.

Second, the molar ratio of caldesmon to actin is surprisingly low for a putative regulatory protein, far below the level of tropomyosin. How can a protein with low stoichiometry to F-actin regulate the actomyosin interaction? Could caldesmon alter the interaction between tropomyosin and F-actin over considerable distances and thereby regulate the interaction? Or is caldesmon perhaps selectively associated with restricted domains of F-actin–tropomyosin filaments involved in contraction? Finally, the ability of Ca^{2+}-calmodulin to inhibit the binding of caldesmon to F-actin requires a large molar excess of calmodulin over caldesmon[12], a level in excess of that reported for chicken gizzard. Perhaps that's just life in a test-tube under the wrong conditions, or missing another component. An alternative explanation may be that caldesmon release from F-actin is not required for relief of the actomyosin inhibition[2]. To explore these questions further, we need to know more about the interaction of caldesmon with calmodulin, F-actin and other (identified or yet to be identified) components. In addition to these questions, the possibility that caldesmon is a 'latch' between the thick and thin filaments needs to be examined.

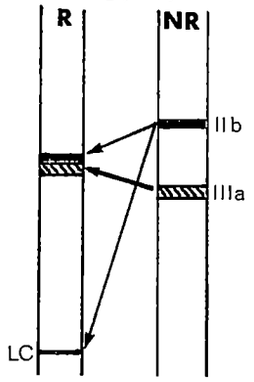
Cell biology

The fibronectin receptor family



from Maria Leptin

In a developing embryo cells and tissues are constantly on the move. Individual cells migrate over long distances and sheets of cells rearrange during processes such as gastrulation and neural tube formation. During wound healing and metastasis in cancer similar situations are recreated in adult organisms. The extracellular matrix (ECM) provides a guiding substrate for cell movement, and, *in vitro*, its components can serve as an attachment substrate for cells to spread and migrate on plastic surfaces. How do cells bind to the ECM and what is the link between the ECM and the cytoskeletal motor? Do different cells use the ECM to migrate to different places and, if so, how? The properties of a family of recently isolated receptors for fibronectin and other ECM components suggest that a complex system of receptor–ligand interactions governs cell movements.

Two paths led to the identification of fibronectin receptors. One used the cell binding domain of fibronectin to purify proteins from cell lysates by affinity purification. The success of this approach depends on a specific elution of material bound to the column. An obvious candidate for an eluant is the hexapeptide Gly-Arg-Gly-Asp-Ser-Pro (GRGDSP) containing the recognition sequence RGD of the fibronectin cell-recognition domain, especially as the peptide inhibits the binding of cells to fibronectin substrates, and of soluble fibronectin to cells. The second approach was to immunoprecipitate cell surface proteins with antibodies that inhibit cells from binding to fibronectin.

With these two methods similar cell surface proteins, each consisting of at least two subunits, were purified from a diversity of cell types[1-7] including epithelial, erythroid and myogenic cells and thrombin-activated platelets. The subunits of the platelet proteins are the previously identified glycoproteins IIb and IIIa. The RGD-containing domain of fibronectin binds to the IIIa subunit. All these cell surface complexes have the same general rather unusual structure (see figure). On reducing SDS gels the two (or more) subunits run as one band or as a doublet at a relative molecular mass of about 140,000. On non-reducing gels they appear as well-separated bands. This is because the lower band runs more slowly under reducing conditions (typical of proteins containing intramolecular disulphide bonds), while the upper bands (which I shall call IIb-like) run faster under reducing conditions. For the platelet IIb band this behaviour is caused by the release of a small component on reduction[8]; it is likely that all IIb-like components will have such a light chain attached.

What do all these receptors have to do with each other? Their fibronectin-binding activity (shown directly for some and inferred from the adhesion-blocking activities of the antibodies for the others) and their common structure suggest that they are all the same type of receptor. However, the differences between them indicate that there does not seem to be such a thing as *the* fibronectin receptor, but rather a whole family of related but subtly different receptors. They differ in molecular mass, glycosylation and number of components. Until direct comparisons of the proteins are made it is futile to speculate whether the differences in mass simply result from variations in gel conditions, but some are so great, that they probably reflect real differences between receptors from different cells.

Migration of the platelet fibronectin receptor IIb/IIIa on reducing (R) and non-reducing (NR) polyacrylamide gels. LC, light chain. (After ref. 8.)

A family of cell surface glycoproteins in which such cell-specific differences do occur are the PS antigens in the fruitfly *Drosophila*, which have the same unusual structure as the fibronectin receptors[9]. Found in most tissues of the body, these complexes each consist of one IIa-like component and one or more IIb-like components. The IIIa-like component is present in every complex whereas the IIb-like components attached to it vary between tissues[9]. PS antigens are thought to be involved in the segregation of cell populations during development, so it will be interesting to see if they are functionally similar to vertebrate fibronectin receptors.

Most importantly, fibronectin receptors differ in their affinities and fine specificities. In fact, these receptors are only a subset of a larger family of receptors for proteins containing the RGD recognition sequence (for example, vitronectin, laminin and fibrinogen). Cells can carry two separate receptors with different specificities, or they can use one receptor to bind to more than one ligand. The first case is exemplified by osteosarcoma cells[10], which have two different receptors for fibronectin and vitronectin, neither of which binds laminin. The binding of both receptors to their ligands is inhibited by peptides containing the RGD sequence. On the other hand, the receptor on fibroblasts can bind to both fibronectin and laminin[3]. Platelets appear to use a single receptor to bind fibronectin and fibrinogen, because fibrinogen inhibits binding of fibronectin to platelets. Finally, receptors for the same ligand on different cells can differ in their affinities. In contrast to the molecules isolated by affinity purification, the receptor isolated by one of the antibodies is not retained on fibronectin columns, but only retarded (compared with its elution from bovine serum albumin columns)[6]. Such weak binding is not unexpected, as receptors which cells use for migration should bind and be readily detachable from the substrate.

The RGD receptors may use the same trick that is developed to perfection by the immune system and that might be used by olfactory neurones[11], namely to use receptors with constant structure but variable specificities to handle diverse ligands in the environment. If all these receptors bind to the RGD sequence, how is their fine specificity determined? They all consist of more than one component, only one of which seems to bind to the RGD-containing domain, if the finding for the platelet IIIa band can be generalized. Perhaps this subunit mediates the binding to the recognition sequence RGD, while the other associated components determine the fine specifity of the receptor. These components might affect the conformation of IIIa and thereby modulate the binding site, so that RGD is recognized only in some contexts but not in others; they might combine to form different binding sites; or they might themselves carry a second binding site specific for another epitope on the target molecule. Such variation of receptor specificity could provide a guiding and sorting mechanism for cells during morphogenesis. □

Stratospheric chemistry

Depletion of Antarctic ozone

from A. F. Tuck

THE total amount of ozone overhead in late winter and early spring at Antarctica has decreased by about 40 per cent during the past decade[1]. Recent analysis of satellite data[2] shows that the phenomenon affects much of the cold, cyclonic vortex found there, and that column abundances are among the lowest recorded anywhere on the globe. A time series of ozonesonde profiles[3] taken in 1982, when compared with data taken in the late 1960s and early 1970s, suggests that much of the decrease occurs in the lower stratosphere, at and below the altitudes where maximum number densities of ozone occur (Fig.1). These experimental findings are a major surprise, and are taxing the theoretical ingenuity of stratospheric researchers. The first calculations of these late winter and spring antarctic ozone reductions appear on pages 755 and 759 of this issue[4,5]. Until an experimentally validated mechanism for these reductions is available, the implications for the global ozone layer are not clear.
